This volume contains the papers presented at , 6th International Conference on Electrical, Electronic and Computing , (Ic)ETRAN 2019 in conjunction of ETRAN 63rd National Conference on Electrical, Electronic and Computing Engineering held on June 3-6, 2019 in Veliko Gradište.

There were 247 submissions. Each submission was reviewed by at least 1, and on the average 2, reviewers. The committee decided to accept papers as follows. Invited papers are included and presented as papers in Sessions.

During the Conferences were held three Special Sessions:

- **Special Session dedicated to academician Rajko Tomović**

Moderators:
Academician SASA Dejan Popović, Professor Emeritus Srđan Stanković and Prof. Srbijanka Turajlić

- **Special Session: New Materials**

Moderators:
Corresponding member SASA Velimir Radmilović: **Decoupling of Electrical and Thermal Properties in Nanostructured Materials;**

Prof. Vladimir Srdić: **Ultrafast Spin Dynamics in Multiferroic Oxides;**

Prof. Petar Uskoković: **Synthesis and Supercapacitive performances of Electrospun Carbon Nanofibers Decorated with Spinel $Co_{1.5}Mn_{1.5}O_4$ Nanocrystals**

- **Special Session: Centers of Excellence**

Moderators:
Corresponding Member SASA Branislav Jelenković, **Center of Excellence: Photonics Center at the Institute of Physics**

Prof. Đorđe Janaćković, **Centre of Research Excellence: Nanotechnology and Functional Materials Centre**

Dr Branko Matović, **Center of Excellence: Multifunctional Materials Centre at the "Vinča" Institute for Nuclear Sciences**

SOUND EVENT DETECTION FROM PARTIALLY ANNOTATED DATA: TRENDS AND CHALLENGES

Romain Serizel, Nicolas Turpault

Université de Lorraine, CNRS, Inria, LORIA, F-54000 Nancy, France

ABSTRACT

This paper proposes an overview of the latest advances and challenges in sound event detection and classification with systems trained on partially annotated data. The paper focuses on the scientific aspects highlighted by the task 4 of DCASE 2018 challenge: large-scale weakly labeled semi-supervised sound event detection in domestic environments. Given a small training set composed of weakly labeled audio clips (without timestamps) and a larger training set composed of unlabeled audio clips, the target of the task is to provide not only the event class but also the event time boundaries given that multiple events can be present in an audio clip. This paper proposes a detailed analysis of the impact of the time segmentation, the event classification and the methods used to exploit unlabeled data on the final performance of sound event detection systems.

Index Terms— Sound event detection, Weakly labeled data, Semi-supervised learning, Audio segmentation, DCASE 2018

1. INTRODUCTION

We are constantly surrounded by sounds and we rely heavily on these sounds to obtain important information about what is happening around us. Ambient sound analysis aims at automatically extracting information from these sounds. It encompasses disciplines such as sound scene classification (in which context does this happen?) or sound event detection and classification (SED) (what happens during this recording?) [1]. This area of research has been attracting a continuously growing attention during the past years as it can have a great impact in many applications including smart cities, autonomous cars or ambient assisted living.

DCASE 2018 task 4 (large-scale weakly labeled semi-supervised sound event detection in domestic environments) focused on SED with time boundaries in domestic applications [2]. The systems submitted had to detect when an sound event occurred in an audio clip and what was the class of the event (as opposed to audio tagging where only the presence of a sound event is important regardless of when it happened). We proposed to investigate the scenario where a large scale corpus is available but only a small amount of the data is labeled. Task 4 corpus was derived from the Audioset corpus [3] targeting classes of sound events related to domestic applications. The labels are provided at clip level (an event is present or not within a sound clip) but without the time boundaries (weak labels, that can also be referred to as tags) in order to decrease the annotation time. These constraints indeed correspond to constraints faced in many real applications where the budget allocated to annotating is limited.

In order to fully exploit this dataset, the submitted systems had to tackle two different problems. The first problem is related to the exploitation of the unlabeled part of the dataset either in unsupervised approaches [4, 5] or together with the labeled subset in semi-supervised approaches [6, 7, 8]. The second problem was related to the detection of the time boundaries and how to train a system that can detect these boundaries from weakly labeled data [9, 10]. The evaluation metric chosen was selected because it was penalizing these boundary estimation errors heavily. The goal was to encourage participants to focus on the time localization aspect.

Through a detailed overview of the systems submitted to DCASE 2018 task 4 we propose an overview of some recent advances in SED with partially annotated data[1]. We will first briefly describe task 4 and the related audio corpus in Section 2. Systems performance over all classes will be presented and analyzed in Section 3. We will present a class-wise analyze in Section 4 and discuss the impact of the metric chosen in Section 5. Section 6 will draw the conclusions of the paper and present some perspectives for SED.

This work was made with the support of the French National Research Agency, in the framework of the project LEAUDS Learning to understand audio scenes (ANR-18-CE23-0020) and the French region Grand-Est.Experiments presented in this paper were carried out using the Grid5000 testbed, supported by a scientific interest group hosted by Inria and including CNRS, RENATER and several Universities as well as other organizations (see https://www.grid5000)

2. DCASE 2018 TASK 4

2.1. Audio dataset

The task focuses on a subset of Audioset that focuses on 10 classes of sound events [2]. Audioset consists in 10-second audio clips extracted from youtube videos[3]. The development set provided for task 4 is split into a training set and a test set.

2.1.1. Training set

In order to reflect what could possibly happen in a real-world scenario, we provide three different splits of training data in task 4 training set: a labeled training set, an unlabeled in domain training set and an unlabeled out of domain training set (clips that do not contain any of the target classes):

Labeled training set: contains 1,578 audio clips (2,244 class occurrences) for which weak labels provided in Audioset have been verified and corrected by human annotators. One-third of the audio clips in this set contain at least two different classes of sound events.

Unlabeled in domain training set: contains 14,412 audio clips. The audio clips are selected such that the distribution per class of sound event (based on Audioset labels) is close to the distribution in the labeled set.

Unlabeled out of domain training set: is composed of 39,999 audio clips extracted from classes of sound events that are not considered in the task (according to unverified Audioset labels).

2.2. Test set

The test set is designed such that the distribution in term of clips per class of sound event is similar to that of the weakly labeled training set. The test set contains 288 audio clips (906 events). The test set is annotated with strong labels, with time boundaries (obtained by human annotators).

2.3. Evaluation set

The evaluation set contains 880 audio clips (3,187 events). The process to select the audio clips was similar to the process applied to select audio clips in the training set and the test set, in order to obtain a set with comparable classes distribution (See also Table 1). Labels with time boundaries are obtained by human annotators.

The duration distribution for each sound event class is presented on Figure 1. One of the focus of this task is the development of approaches that can provide fine time-level segmentation while learning on weakly labeled data. The observation of the event duration distribution confirms that in order to perform well it is essential to design approaches that are efficient at detecting both short events and events that have a longer duration.

Class	Test	Eval
Alarm/bell/ringing	112	306
Blender	40	56
Cat	97	243
Dishes	122	370
Dog	127	450
Electric shaver/toothbrush	28	37
Frying	24	67
Running water	76	154
Speech	261	1401
Vacuum cleaner	36	56
Total	906	3187

Table 1: Number of sound events per class in the test set and the evaluation set.

2.4. Task description

The task consists of detecting sound events within web videos using weakly labeled training data. The detection within a 10-seconds clip should be performed with start and end timestamps.

2.4.1. Task evaluation

Submissions were evaluated with event-based measures for which the system output is compared to the reference labels event by event [11] (see also Figure 2). The correspondence between sound event boundaries are estimated with a 200 ms tolerance collar on onsets and a tolerance collar on offsets that is the maximum of 200 ms and 20 % of the duration of the sound event.

- True positives are the occurrences when a sound event present in the system output corresponds to a sound event in the reference annotations.
- False positives are obtained when a sound event is present in the system output but not in the reference annotations (or not within the tolerance collars on the onset or the offset).
- False negatives are obtained when a sound event is present in the reference annotations but not in the system output (or not within the tolerance collars).

Submissions were ranked according to the event-based F1-score. The F1-score was first computed class-wise over the whole evaluation set:

$$F1_c = \frac{2TP_c}{2TP_c + FP_c + FN_c}, \quad (1)$$

where TP_c, FP_c and FN_c are the number of true positives, false positives and false negative for sound event class c over the whole evaluation set, respectively.

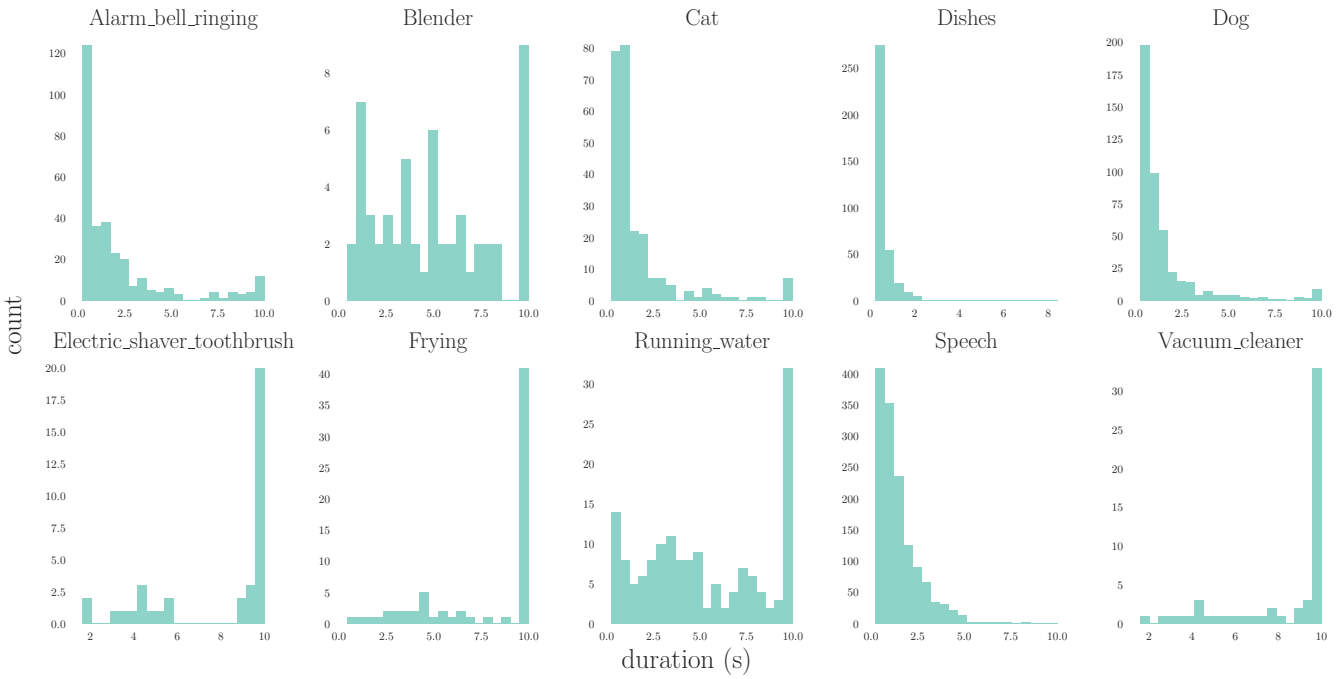

Fig. 1: Duration distribution by class of sound events on the evaluation set.

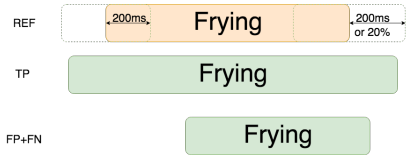

Fig. 2: Event-based F1-score.

The final score is the F1-score average over sound event classes regardless of the number of sound events per class (macro-average):

$$F1_{\text{macro}} = \frac{\sum_{c \in \mathcal{C}} F1_c}{n_{\mathcal{C}}}, \tag{2}$$

where $\mathcal{C}$ is the sound event classes ensemble and $n_{\mathcal{C}}$ the number of sound event classes.

3. ANALYSIS OF THE PERFORMANCE OVER ALL SOUND EVENT CLASSES

In this section we present and analyze submissions performance regardless of the sound event classes.

3.1. Task submissions and results overview

DCASE 2018 task 4 gathered 50 submissions from 16 different research teams involving 57 researchers overall. The official team ranking and some characteristics of the submitted systems are presented in Table 2. The best two submissions quite clearly stand out from other submissions. They also go beyond the rather standard approaches based convolutional neural networks (CNN) or stacked CNN and recurrent neural networks (RNN) also denoted as CRNN. The best system, submitted by JiaKai (**jiakai_psh**) [12], relies on a mean-teacher model that exploits unlabeled data to regularize the classifier learned on the weakly labeled data [28]. The system submitted by Liu et al. (**liu_ustc**) [13] that ranked second relies on an energy based sound event detection as a pre-processing to a capsule network [29]. The output of the network is then post processed to ensure that silence between events and events themselves are longer than a minimum duration.

Other notable submissions include the system from Kothinti et al. (**kothinti_jhu**) [15] that relies on a sound event detection based on restricted Boltzmann machines (RBM) as a pre-processing. This solution performs well at detecting onsets but not so much for offset detection (see also Section 4.1). Dinkel et al. proposed a system (**dinkel_sjtu**) that uses Gaussian mixture models (GMM) and hidden Markov models (HMM) to perform sound event alignment [25]. Gaussian filtering is then used as post-processing. Pellegrini et al. proposed a system (**pellegrini_irit**) that relies on multiple instance learning (MIL) to exploit weakly labeled data [23]. Both these systems perform pretty decently on segmentation (see also Section 3.2) but they suffer from pretty poor sound event classification performance (see also Figure 8).

Rank	System	Features	Classifier	Parameters	F1 (%)

Table 2: Team ranking and submitted systems characteristics.

3.2. Segmentation

In this section, we focus on the segmentation performance. That is, the ability of the submitted systems to localize sound events in time without having to predict the class. Figures 3, 4 and 5 present the event-based F1-score computed without taking the sound event class labels into account and for a tolerance collar of 200 ms, 1 s and 5 s, respectively. The fact that there is only little performance difference between the sound event detection performance (Table 2) and the segmentation performance tends to indicates that segmentation is possibly the main limiting factor in overall performance. This is actually confirmed by the rather high tagging performance of most systems presented on Figure 8.

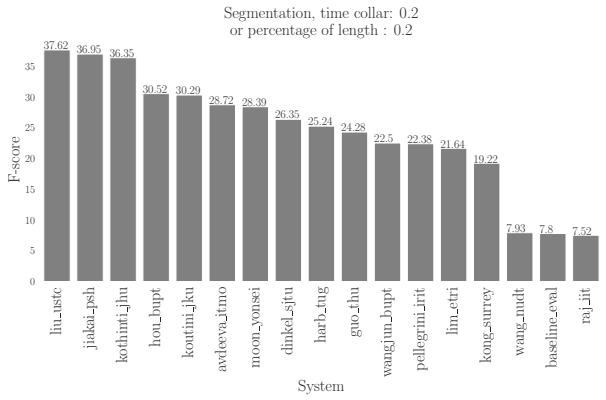

Fig. 3: Segmentation performance (tolerance collar on onsets is 200 ms and tolerance collar on offsets is the maximum of 200 ms and 20 % of the event length).

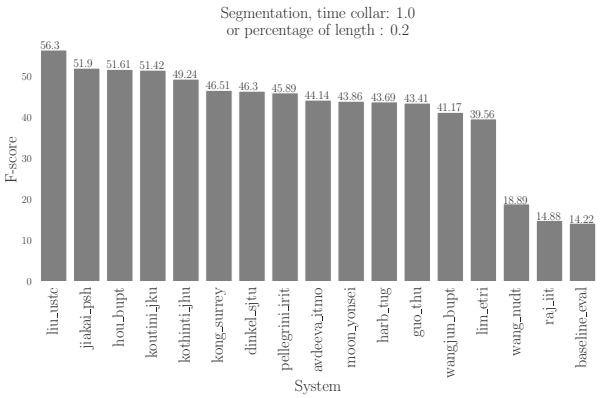

Fig. 4: Segmentation performance (tolerance collar on onsets is 1 s and tolerance collar on offsets is the maximum of 1 s and 20 % of the event length).

Currently, most of the systems are able to detect if an event occurred within a rather crude time area (see also Figure 5 but are not able to properly segment the audio clips in terms of sound events (see also Figure 3). The systems that performed best in terms of segmentation are the systems that actually implemented some sort of segmentation among which **liu_ustc** [13] and **kothinti_jhu** [15]. The winning system is ranked second in term of segmentation and owe its first overall rank to a much better classification than competing systems (see also Figure 8).

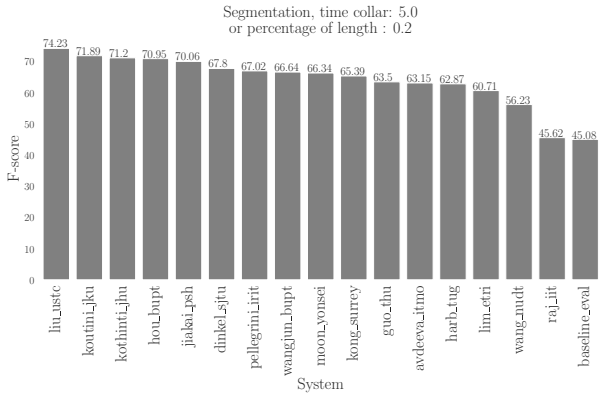

Fig. 5: Segmentation performance (tolerance collar on onsets is 5 s and tolerance collar on offsets is the maximum of 5 s and 20 % of the event length).

3.3. Use of unlabeled data

One of the challenges proposed by DCASE 2018 task 4 was to exploit a large amount of unlabeled data. In the section we analyze the approaches proposed by participants. Most of the systems submitted used a pseudo-labeling approach where a first system trained on the labeled data is used to obtain labels for the unlabeled set (**liu_ustc**) [13], **hou_bupt** [19]). Variations on this included setting a confidence threshold to decide to keep the label or not (**koutini_jku** [17], **wang_nudt** [26], **pellegrini_irit** [23], **harb_tug** [16], **moon_yonsei** [24]) and gradually introducing new audio clips with these pseudo labels (**wangjun_bupt** [22]).

The winning system (**jiakai_psh** [12]) used the unlabeled data within a mean-teacher scheme [28]. It is composed of two models: a student model and a mean-teacher model whose weights are the exponential average of the student's weights. On labeled data, the student model weights are updated to optimize a classification cost on the sound event classes. Additionally, consistency costs are computed to compare the output of the student model and the mean-teacher model on both the labeled and the unlabeled data. Kothinti et al. (**kothinti_jhu** [15]) proposed to use both the weakly labeled and unlabeled in-domain data to train several RBM that are used to detect sound event boundaries.

3.4. Complexity

The complexity of the submitted systems (in terms of number of parameters) is presented in Table 2. The only system that used raw waveforms as input (**moon_yonsei** [24]) is among the most complex systems yet it is not even among the top 10 systems. This tends to indicate that the dataset proposed for task 4 is too small to train SED systems using raw waveforms that are usually known to require a lot of training data. The most complex system (**wang_nudt** [26]) is about 200 times more complex than the baseline in particular because it combines several complex models. However it performs only slightly better than the baseline. The winning system (**jiakai_psh** [12]) is about 10 times more complex than the baseline and the best performing system that has a number of parameters similar to that of the baseline (**koutini_jku** [17]) improves the baseline F1-score performance by more than 10 % absolute.

3.5. Duration of events

It has been shown above that the systems performance largely depends on the systems ability to properly segment the audio clips in terms of sound events. Figure 1 presents the duration distribution for each class of sound events on the evaluation set. From this distribution we can separate the sound events into two categories of events: short sound events ('Alarm/bell/ringing', 'Cat', 'Dishes', 'Dog' and 'Speech") and long sound events ('Blender', 'Electric shaver/toothbrush', 'Frying', 'Running water' and 'Vacuum cleaner').

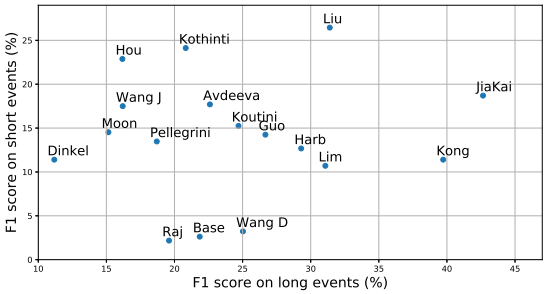

Fig. 6: Systems performance on short sound events depending on their performance on long sound events.

System	Short	Long	All	Rank
liu_ustc [13]	**26.4**	31.4	29.9	2
kothinti_jhu [15]	**24.1**	20.8	22.4	4
hou_bupt [19]	**22.9**	16.2	21.1	8
jiakai_psh [12]	**18.7**	42.6	32.4	1
avdeeva_itmo [21]	**17.7**	22.6	20.1	10
baseline [2]	**2.6**	21.8	10.8	16

Table 3: Top 5 systems on short events ('Alarm/bell/ringing', 'Cat', 'Dishes', 'Dog' and 'Speech").

Figure 6 presents the performance of the submitted systems on short sound events depending on their performance on long sound events. No system is clearly outperforming the others on both short and long sound events. This is confirmed when looking at the top performing systems on short sound events (Table 3) and on long sound events (Table 4). These rankings tend to show that the approaches proposed

System	Long	Short	All	Rank
jiakai_psh [12]	**42.6**	18.7	32.4	1
kong_surrey [14]	**39.7**	11.4	24	3
liu_ustc [13]	**31.4**	26.4	29.9	2
lim_etri [20]	**31.1**	10.7	20.4	9
harb_tug [16]	**29.3**	12.7	21.6	5
baseline [2]	21.8	**2.6**	10.8	16

Table 4: Top 5 systems on long events ('Blender', 'Electric shaver/toothbrush', 'Frying', 'Running water' and 'Vacuum cleaner').

were either tailored to perform well on short sound events (top systems are also the systems that performed best in terms of segmentation, see also Figure 3) or on long sound events (top systems are also among the best systems in terms of tagging, see also Figure 8). However, in order to perform well on the SED task systems had to perform reasonably well on both short and long sound events. This is the case for the top two systems (**jiakai_psh** [12] and **liu_ustc**) [13]) that are in the top five both short and long sound events.

4. ANALYSIS OF THE CLASS-WISE PERFORMANCE

It have been shown above that systems performance can vary to a great extent depending on the sound events duration that is tightly related to the sound event class itself. Therefore, in this section we focus on the performance of the submitted systems depending on the sound event classes. Table 5 presents the class-wise event-based F1-score for the 10 best performing submitted systems. The best system (**jiakai_psh** [12]) outperforms other systems on five sound event classes upon ten (mainly long sound events). However, it performs rather poorly on some of the remaining sound event classes (mainly short sound events). On the other hand, the second best system (**liu_ustc** [13]) outperforms other systems on a single sound event class ('Dog') but is generally not too far from the best performance on several other sound event class. This explains why it can still compare with the winning system in terms of overall performance.

In general 'Speech' and 'Alarm bell ringing' seem to be the easiest sound event classes to detect and classify. This could be explained by the fact that sound events from these classes are not too short (with a median duration of 1.17 s and 0.57 s, respectively), occurs many times in the training set (in 550 clips and 205 clips, respectively) and generally have rather clear onsets and offsets (see also Section 4.1). There is a clear separation between 'Cat', 'Dishes' and 'Dog' and other sound event classes. The former seems more difficult to detect and classify than the latter. This can be due to the fact that sound events in these classes are short and present a large acoustic variability. Interestingly, the submitted systems that perform best on these sound event classes are not necessarily among the top three systems. For example **hou_bupt** [19] obtains the best performance on 'Dishes' and clearly outperforms other submissions with 23.5 % F1-score. However, it ranked eighth overall (but was among the top five systems on short sound events, see also Table 3). The best system on 'Cat' (by a rather large margin) with 25.3 % F1-score is **pellegrini_irit** [23] that relies on MIL and that is not even in the top 10 in terms of overall performance.

4.1. Performance on onset and offset detection

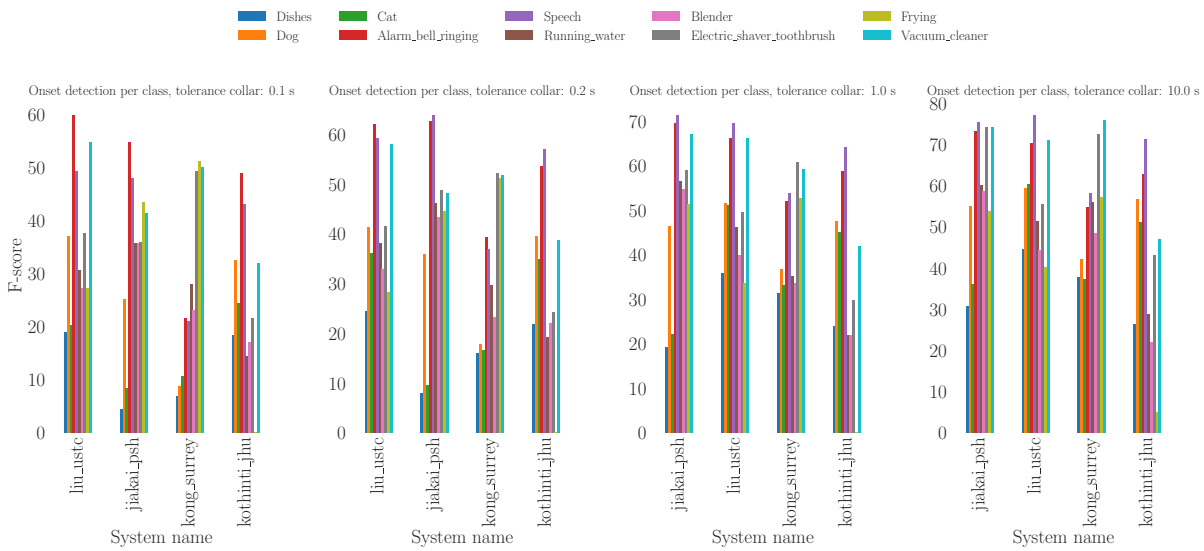
For some sound event classes that slowly decay the time location of offsets can be difficult to locate (and the concept of offset itself can even become ambiguous in reverberant scenarios). Therefore, we now focus on the detection of onsets and offsets separately. In the plots presented in this section (see also Figure 7), sound events are classified from the shortest (on the left) to the longest (on the right) according to their median duration. Additionally, for the sake of clarity, only the systems among the top four in overall performance are presented here. Systems are presented in decaying overall onset or offset detection performance (the best system is on the left side).

4.1.1. Onset

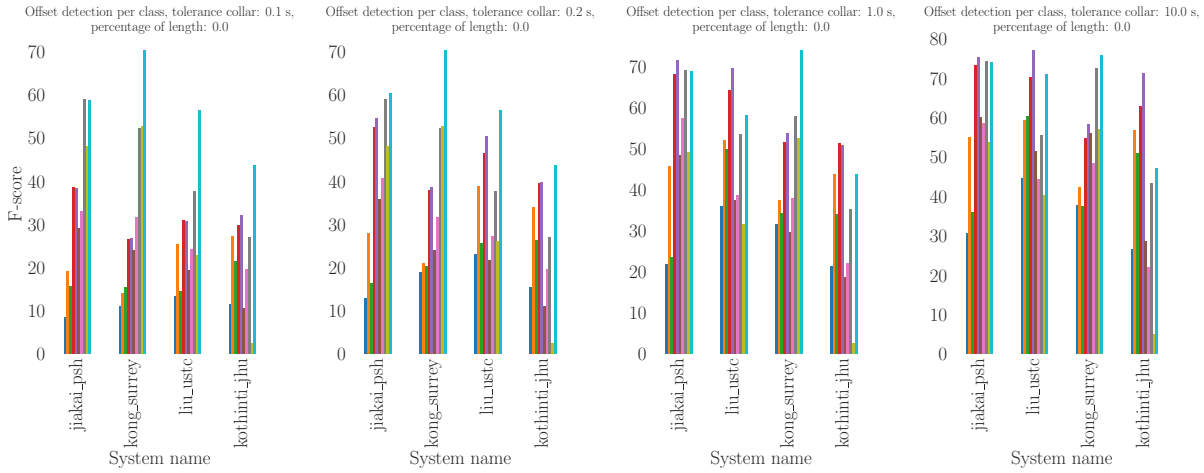
Figure 7a presents F1-score for onset detection for varying tolerance collars (in seconds). Performance generally increases when the tolerance collar is increased. For small tolerance collars, **liu_ustc** [13] performs best which confirms previous analysis about the relatively good segmentation of their system. When the tolerance collar is larger than 0.5 s **jiakai_psh** [12] outperforms other system which also confirm that the proposed segmentation is a bit too coarse.

The remaining errors for a 10 sec tolerance collar indicate that the systems were not able to predict how many onsets for the specific sound event class occurred within the audio clip. In most cases this could also corresponds to the case where the sound event was not detected at all (see also Figure 7b).

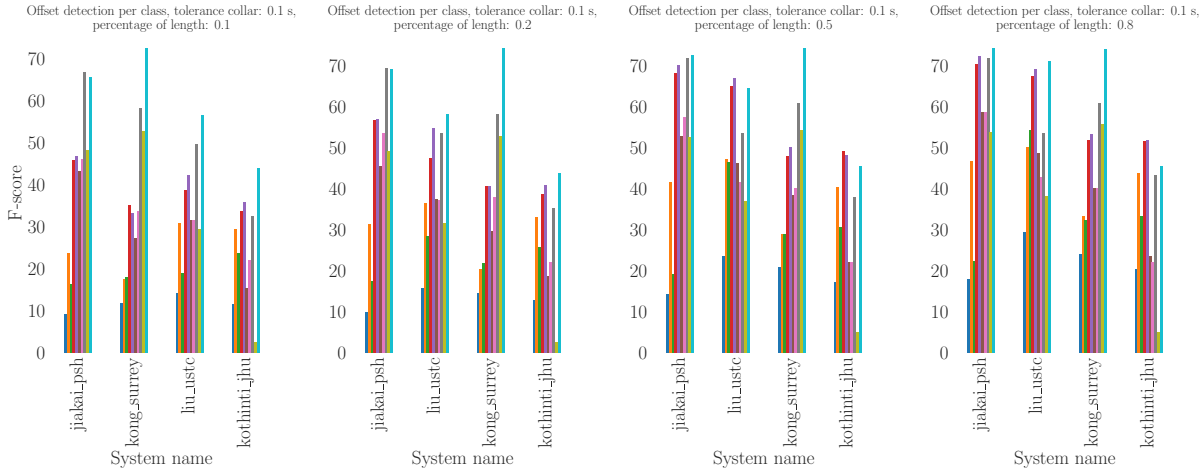
When looking at particular sound event classes, in general systems exhibit good onset detection performance for 'Speech' and 'Alarm bell ringing'. As mentioned above, this can be due to the fact that these sound events occur frequently in the training set but it can also be related to the fact that the sound events from these classes indeed have rather clear onsets that appear to be easier to detect. On the other hand, sound event classes as 'Cat' and 'Dishes' seem to be difficult to detect. For the former it is probably due to the fact that the onsets are not always clear as for the latter it is most generally related to sound events that are simply missed by the systems because they are too short. For the remaining sound event classes, the performance varies a lot from one system to another and seems to be affected by the segmentation strategy implemented.



(a) F1-score for onset detection with absolute tolerance collars.



(b) F1-score for offset detection with absolute tolerance collars.



(c) F1-score for offset detection with tolerance collars relative to event duration.

Fig. 7: Event-based F1-score for onset and offset detection with varying tolerance.

System	Alarm	Blender	Cat	Dishes	Dog	Electric	Frying	Water	Speech	Vacuum

Table 5: Class-wise event-based F1-score for the top 10 submitted systems.

4.1.2. Offset

Figure 7b presents F1-score for offset detection for varying tolerance collars (in seconds). When comparing with Figure 7a it appears that offsets are indeed more difficult to detect. The high F1-score for some sound event classes such as ('Electric shaver toothbrush', 'Frying' or 'Vacuum cleaner') is mainly due to the fact that many of the sound events in these classes do not have an offset within the audio clips and therefore the offset to be detected is simply the final boundary of the audio clip.

It is generally admitted that penalizing offset detection based on an absolute time tolerance collar is not a reasonable choice specially for long sound events. In particular because this type of tolerance collar might be affecting long sound events (with longer decay) much more than short (possibly percussive) sound events. Therefore, the metric retained for DCASE 2018 task 4 include both an absolute time tolerance collar and a tolerance collar that was computed as a percentage of the sound event duration (the maximum of these two values was retained). With this approach, the absolute time tolerance collar usually applies to short sound events while the tolerance collar relative to event length applies to longer sound events.

Figure 7c presents F1-score for offset detection for varying tolerance collars (in percent of the sound event duration). Note that the absolute time tolerance collar is kept to 0.1 s here in order to avoid unreasonably small tolerance collars for short sound events. As expected, this kind of tolerance collar has less effect than absolute time tolerance collar on offset detection of short sound events such as 'Cat', 'Dishes' or 'Dog' but can affect greatly the offset detection performance on long sound events such as 'Running water' or 'Blender'.

Quite surprisingly, **jiakai_psh** [12] outperforms the other submitted systems (even those which had demonstrated a better segmentation performance until now) including with low tolerance collars. When looking at particular sound event classes, in general the submitted systems exhibit good offset detection performance for 'Speech' and 'Alarm bell ringing' even if in this case offsets are usually not as well defined as onsets were.

5. IMPACT OF THE METRIC

For DCASE 2018, the F1-score was computed in an event-based fashion in order to put on strong focus on the sound event segmentation. Class-wise performance was averaged in order to discard the effects of the sound event classes imbalance (2). In this section, we study the impact of these choices on the performance evaluation of the submitted systems.

5.1. F1-score computation relatively to events or segments

As opposed to event-based metrics, segmented-based metrics are computed by comparing the system outputs and the reference on short segments. The sound event classes are then considered to be active or not on the full segment. The final metric is computed on all the segments [11]. This approach reports if a system is able to detect if a sound event class is active with a specific time resolution (the segment length) and can prove more robust than event-based metrics to phenomena such as short pauses between consecutive sound events. Figure 8 presents a comparison between the event-based F1-scores (on the left) and the segment-based F1-scores (on the right) for varying tolerance collars and time resolutions, respectively.

As expected, segmented-based metrics are more permissive to errors in the detection of the sound event boundaries. Indeed the reported segment-based F1-scores (from 40 % to 70 % depending on the time resolution) are much higher than their event-based counterpart (from 5 % to 60 % depending on the tolerance collar). Additionally, the segment-based F1-score seems to be favoring systems that are good at tagging while event-based F1-score favors systems that have good segmentation performance. This is particularly clear for sys-

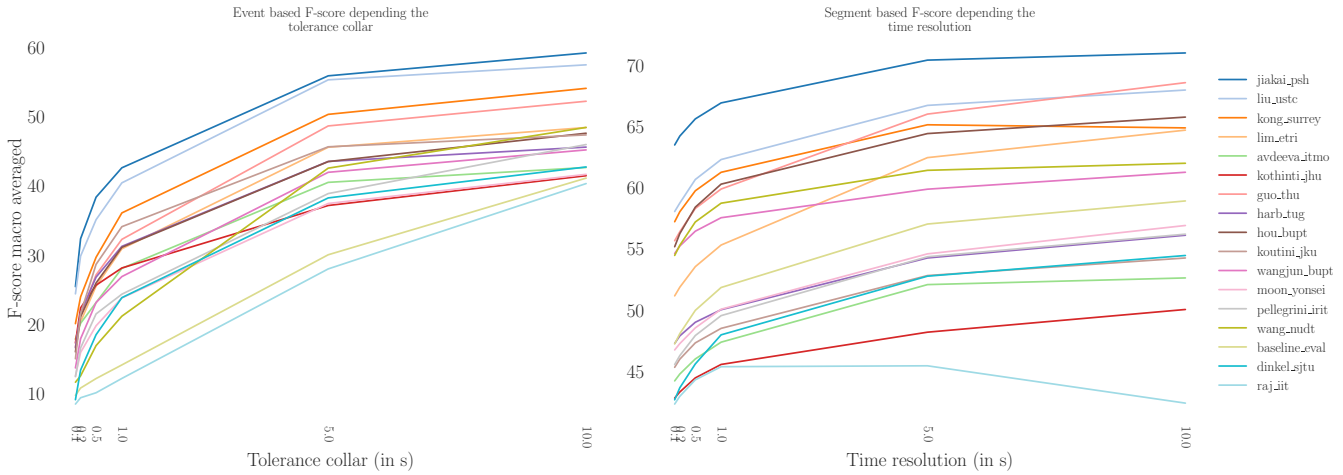

Fig. 8: Comparison between event-based and segmented-based F1-scores depending on the tolerance collar and time resolution, respectively.

tems like **hou_bupt** [19], **guo_thu** [18] and the task baseline [2] which perform much better in terms of segment-based F1-score and for **kothinti_jhu** [15] that performs much better in terms of event-based F1-score.

When the time resolution for the segment-based F1-scores is 10 s the reported performance is actually that of a tagging task. The tagging ranking is then rather different than the general ranking (see also Table 2) and the ranking for segmentation (see also Figure 3). This emphasizes once again that none of the submitted systems is actually outperforming others in both segmentation and tagging but that in order to perform well on the task, systems had to perform at least decently on both. This is the case for **jiakai_psh** [12] and **liu_ustc** [13] that clearly stand out in the final ranking.

As the choice of the metric is tightly related to the targeted application, some approaches can be better suited when you need to know exactly when a sound event from a specific class did occur (in which case you might select a system that performs well in terms event-based F1-score) some other approaches can be suited to monitor the activity within a time period (approximately when was each sound event class active, depending on the time resolution, in which case we might select systems that perform well in terms segment-based F1-score)

5.2. Micro average

While macro-averaging (used in task 4) computes the final F1-score as the average across sound event classes (regardless of the number of events for each class), micro-averaging computes the final F1-score as the average of each single decision. It therefore gives more importance to sound event classes that occur more frequently (see also Table 1 for the distribution). For example, 'Speech' events will account for almost half of the performance when using micro-averaged F1-score.

Figure 9 presents event-based F1-score depending on the averaging method. We can observe a clear performance improvement between macro-averaged and micro-average F1-score for the systems that performed well the most frequent sound event classes ('Alarm bell ringing', 'Dishes', 'Dog' or 'Speech') such as **lim_etri** [20]. One the other hand the systems that were able to perform well on less frequent sound event classes ('Electric shaver/toothbrush', 'Frying'...) but not on frequent sound event classes can see their performance decreased between macro-averaged and micro-averaged F1-score as this is the case for **kong_surrey** [14]. The top two systems (**jiakai_psh** [12] and **liu_ustc**) [13]) were performing reasonably well on the most frequent sound event classes and therefore still outperform other systems in terms of micro-averaged F1-score.

Once again, the choice of the metric is related to the targeted application. If you want to detect mainly the sound event classes that occur the most frequently and that missing rare sound event classes is not really a problem then you should select approaches that perform well in terms of micro-averaged F1-score. On the contrary if detecting rare sound event classes is important then approaches that perform well in terms of macro-averaged F1-score seem better suited.

6. CONCLUSION

In this paper we proposed an overview of some of the latest advances and challenges in sound event detection with systems trained on partially annotated data through the analysis of the results of DCASE 2018 challenge task 4. The paper focused on the scientific aspects highlighted by the task: exploiting both unlabeled and weakly labeled data to train a system that provides not only the event class but also the event time boundaries. It has been shown that both the segmen-

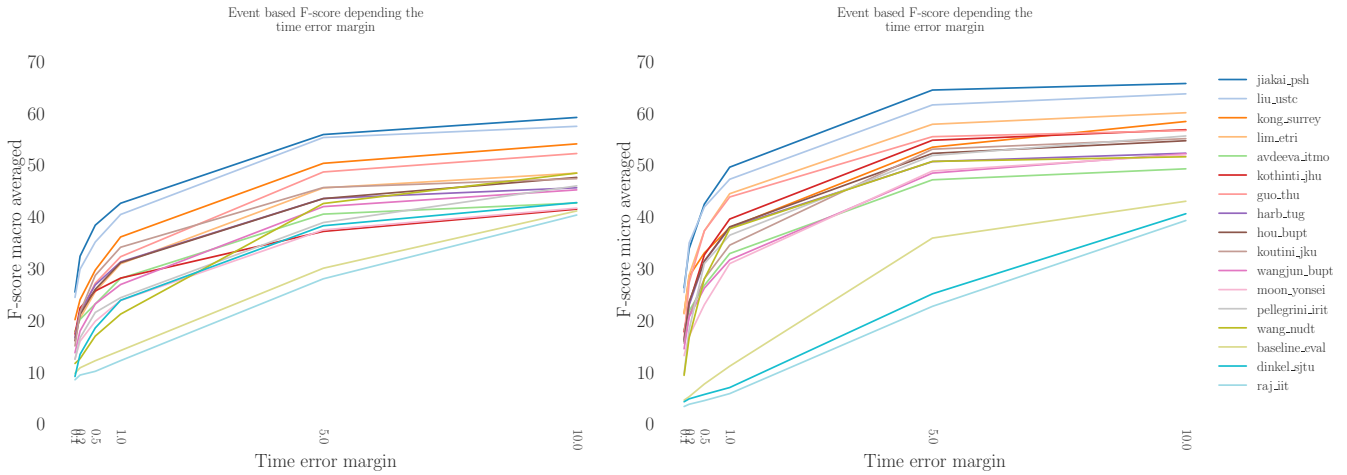

Fig. 9: Event-based F1-score depending on the class averaging method.

tation and the classification ability play an important role in the final performance. However whereas the tagging performance (related to the classification ability) is generally rather good for many systems, only few systems did implement an explicit segmentation strategy. This aspect actually remains quite challenging as training a system to detect sound events and predict their time localization from weakly labeled data is far from trivial. Therefore, one question for future works is to investigate if strongly labeled data that is generated synthetically can help solving this issue. This is one of the challenges investigated in the task 4 of DCASE 2019 challenge.

7. ACKNOWLEDGMENT

The authors would like to thank the other organizers of DCASE 2018 task 4 (Hamid Eghbal-zadeh from Johannes Kepler University – Austria and Ankit Parag Shah from Carnegie Mellon University –United States) as well as all participants to the task. They also would like to thank the DCASE 2018 challenge organization team (Toni Heittola, Annamaria Mesaros and Tuomas Virtanen from Tampere University of Technology – Finland) for they support while organizing the task.

Visualization and optimization of features in classification of motor sound

Ana Đorđević, Dejan Ćirić and Marko Ličanin

Abstract— Sound waves conduct a lot of important information about sound sources and environment, from individual physical events to sound scenes as a whole. Hitherto, in sound analysis and processing, two or three dimensional plots have been sufficient to correctly represent needed information, e.g. frequency response plot or spectrogram plot. With emerging machine and deep learning technologies, choosing the right technique for visualization of multidimensional matrices is of great significance for abstracting out the right information, understanding and interpreting the results clearly and easily. In this paper, various options for representation of acoustic features are analyzed in order to improve machine learning model for classification. This analysis is based on audio signals (sounds) of DC motors. Various types of visualizations have been used in order to optimize feature vector for classification.

Index Terms—acoustic features, features visualization and optimization, machine learning, DC motor sounds.

I. Introduction

A sound event is a segment of audio that a listener can consistently label and distinguish in an acoustic environment [1]. Analysis of a large variety of sounds requires calculation of a larger number of parameters from sound signals, and usage of automatic methods like machine learning [2] to differentiate between various types of audio signals. The applications of such automatic sound event detection are various. Any embedded system with capability to record sound signals can become more aware of sound in its environment [3]. In industrial and environmental surveillance systems, smart homes and cities, devices can automatically detect and/or classify sound events of interest.

Automatic annotation of sound can significantly improve for example, quality control and predictive maintenance in various industries. Here, break down or faulty product (part) can be detected in an automated way. By analyzing a large variety of sounds of a particular industrial product in good and bad conditions, a model for supervised learning can be made. Based on this model, bad or faulty products (parts) can be detected and eliminated early in production.

Ana Đorđević is with the Faculty of Electronic Engineering, University of Niš, Aleksandra Medvedeva 14, 18000 Niš, Serbia (e-mail: ana.djordjevic@elfak.rs); Ana Đorđević is also with the innSonoFaculty of Electronic Engineering, University of Niš, Aleksandra Medvedeva 14, 18000 Niš, Serbia (e-mail: ana.djordjevic@elfak.rs).

Dejan Ćirić is with the Faculty of Electronic Engineering, University of Niš, Aleksandra Medvedeva 14, 18000 Niš, Serbia (e-mail: dejan.ciric@elfak.ni.ac.rs).

Marko Ličanin is with the Faculty of Occupational Safety, University of Niš, Čarnojevićeva 14, 18000 Niš, Serbia (e-mail: marko.licanin@znrfak.ni.ac.rs).

There are several challenges in computational sound analysis needed for the mentioned purpose. First, acoustic characteristics of even a single class of sounds can be highly diverse. For example, in the case of “bed DC motor” (faulty motor), the acoustics can vary enormously depending on the type of error in the motor. Second, in industrial environments, there are almost always multiple sources producing sound (noise) simultaneously. In such environments, many different types of sounds and unwanted noise can be present. Acoustic characteristics of some of them may be very close to the target sounds. Generally speaking, the captured audio is a superposition of contributions of all the sources present, which again distorts the signal. Third, an audio signal captured by a microphone is affected by impulse response between the source and microphone, which may alter the signal sufficiently to prevent matching of models developed to recognize the sound.

To overcome the present situation, spatial attention must be paid to choose the right sound signal features. [1] In this way, the aim is to generate a reliable and large enough data base that should be used for building the correct model.

Fig.1 presents the block diagram of a typical audio classification system based on supervised machine learning. The input of this system is an audio signal, either recorded in real-time or loaded from an audio recording file from storage. The audio processing block consists of different processing stages such as filtering, noise reduction or similar.

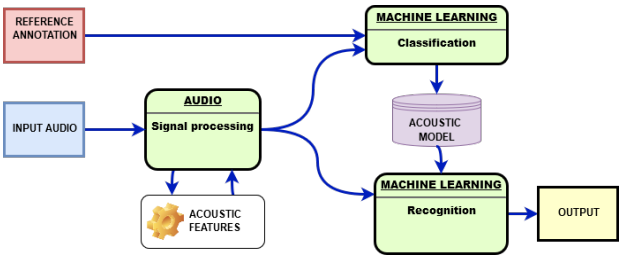

Fig. 1. Block diagram of a typical audio classification system.

The purpose of the feature extraction block is to obtain information sufficient for classifying the target sounds. This also includes making the subsequent modeling stage more computationally efficient and also easier to be realized with limited amount of development material. In other words, by feature extraction, the signal is transformed into a representation (feature matrix) that maximizes the sound recognition performance of the analysis system [4]. The acoustic features provide a numerical representation of the audio content relevant for machine learning. They characterize the signal containing information about its

physical properties, i.e., signal energy, distribution in frequency, and change over time. Acoustic features can be categorized in five main groups: temporal features, spectral shape features, cepstral features, perceptually motivated features and spectrogram image based features [1].

II. Acoustic Features

Temporal features are computed directly from the temporal waveform. Mostly used temporal features are temporal envelope, zero crossing rate, temporal waveform moments, and autocorrelation coefficients. Human perception of sound widely relies on its frequency content. Consequently, it is a natural choice to derive acoustic features from frequency representation of the signal. Among others, spectral features include energy, entropy of energy, spectral envelope, central frequency and spectral irregularity features. In audio analytics, temporal and spectral features are rarely used separately. Those are the simplest features extracted to model specific aspects of the signal, usually considered and evaluated together as one set of features sometimes referred as low-level features.

On the other hand, the cepstral features are powerful enough to be used on their own as input for classification or machine learning problem. Mel frequency cepstral coefficients (MFCC) are the most common cepstral coefficients [5]. They are obtained as the inverse discrete cosine transform of the log energy in mel frequency bands. Besides MFFC, linear prediction cepstral coefficients (LPCC) based on LPC coefficients, the gammatone feature cepstral coefficients (GFCC) or constant-Q cepstral coefficients (CQCC) are also very popular.

Good representatives of perceptually motivated features are loudness as the subjective impression of the intensity of a sound, then sharpness and perceptual spread as a measure of the timbral width of a given sound.

Acoustic features can also be extracted from the time-frequency representation of a sound signal. Spectrogram image-based features are inspired by computer vision to characterize the shape, texture and evolution of the time-frequency content in a sound scene. Such features have proven to be competitive with more traditional above mentioned acoustic features on classification tasks [6].

The obtained acoustic features together with labels of the training examples are used to learn models for the sound classes of interest. The labels contain information about the presence of target sound classes in the training data. They are used as a reference information to automatically learn a difference between acoustic features of different classes. At the final step, the learned acoustic model is made.

Analysis of various acoustic features, feature selection and process of optimization of the acoustic model for classification of DC motors has been presented in this paper. DC motors are divided (labeled) in two classes - non-faulty motors and faulty motors, depending on their working conditions. Labeling is based on subjective opinion of expert listeners working for the DC motor manufacturer. Data base is made of sound samples of a number of DC motors. Recording has been made in the semi anechoic chamber, where only the floor is reflective. Processes of collecting audio data is aspired to obtain sufficient amount of representative examples of both sound classes necessary for as accurate as possible classification. After recording and signal processing, feature extraction and visualization has been performed. All of the extracted features has been analyzed from various aspects in order to optimize the final feature vector, which will be used for classification. Furthermore, results from this analysis has been used to determine cause of error in classification.

III. Data Processing and Feature Extraction

A. Data acquisition and pre-processing of audio signals

In the process of designing and building machine learning system, data acquisition plays an important role since the performance of the final application highly depends on the data used to develop it. Audio signals that make the data base for this research are recorded in the semi anechoic chamber. The measurement microphone and tested DC motor samples are held on exactly the same positions throughout the measurement sessions. The microphone faces the center of tested DC motor with the distance of 42 cm. To cover intra-class variability, nearly 200 samples of both non-faulty and faulty DC motors are recorded.

After recording, pre-processing is applied to the audio signals as a step before the acoustic feature extraction. The main aim of this stage is to reduce the effects of disturbances and potentially enhance certain characteristics of the audio signal in order to maximize performance of learning algorithm. When DC motors are tested in industrial environment, low frequency noise can significantly affect the recordings. To address this issue, some noise suppression techniques can be used to reduce interference of ambient noise [1]. In this study, only high-pass filtering of the signal with cutoff frequency of 300 Hz is applied.

B. Acoustic feature extraction

Feature extraction can also be considered as a procedure of data rate reduction. Features extracted must contain relevant information with respect to the desired properties of the analyzed sound. Analysis algorithms should be based on a relatively small number of features. An audio signal is voluminous, and as such, it is hard to be processed directly in any analysis task. Therefore, it is needed to transform the initial data representation to a more suitable one. Properties of original signal can be typified by acoustic features which will result in the reduction of data volume. Good knowledge of the application domain is necessary in order to choose the best features.

In Fig. 2, the block diagram of acoustic feature extraction is shown. For that purpose, *short term* processing technique is applied. Thus, an audio signal is divided into overlapping short-term windows (frames) and the analysis is carried out on a frame basis. Length of frame used here is 50 ms, which can be often met in audio analytic applications. Naturally audio signals are non-stationary, their properties vary over time. But in a short time frame, sound from the DC motor can be considered to be stationary. This type of processing generates a sequence, one feature vector per audio signal. The dimensionality of feature vector depends on nature of the adopted features. It is not uncommon to use one-dimensional

features, like the energy of a signal. However, in most sophisticated audio analysis applications several features are extracted and combined to form feature vectors of increased dimensionality. The extracted sequence(s) of feature vectors can then be used for subsequent processing/analysis of the audio data.

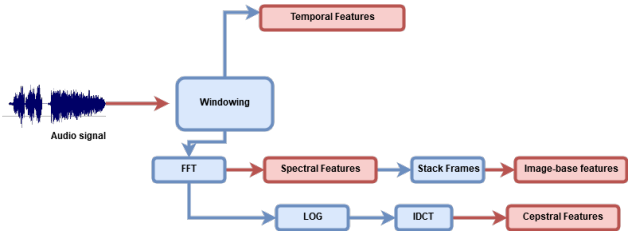

Fig. 2. Block diagram of extraction of a DC motor acoustic features.

For this research, a large set of 212 acoustic features is generated from each short term frame. In the first step, matrix of dimensions 46×212, where 46 represents the number of short term overlapping frames, and 212 is the number of features. This situation is not preferable, since the number of features is rather large. This can lead to a learning model that tends to be over–fitted. As a result, their performance degenerates.

IV. Feature Vector Visualization and Optimization

As it is previously mentioned, DC motor sound signal can be considered to be stationary. This can be observed in Fig.3, where energy in time as an audio feature is presented. The value of this feature fluctuates to a certain extent over the time (over the frames). These fluctuations are larger for some sound samples, while they are smaller for some others.

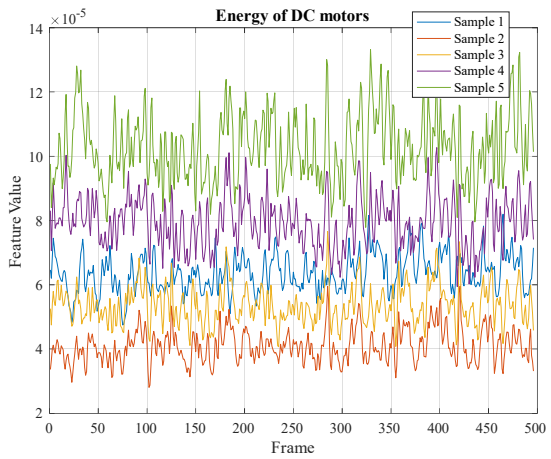

Fig. 3. Energy of five different samples of DC motors over the time (frames).

Stationary behavior of a signal is used as the first step to reduce dimensionality of the feature vector. For each feature, its mean value is calculated from all short term frames. By this procedure, each signal in the data base is represented by a single value for each feature. Also, values in the feature vector are normalized in order to overcome the differences in ranges of values of the features of different nature.

The total number of 212 extracted features is rather large and computationally demanding. This is why the next logical step is to optimize the feature vector by reducing the number of features needed for correct classification. In order to optimize the data set and to reduce complexity of feature matrix, few different visualization and feature selection techniques are used.

First, a 1D representation of normalized feature vector is made (the 1D is related to mean feature value). This representation for three different samples of non-faulty and faulty motors is given in Fig 4. The difference between classes is observable from the 20th to 40th feature, and from 140th to 180th feature. The rest of the features does not show significant variation between classes, which means that they do not contribute to a significant extent to the classification process. A very basic optimization of feature vector can be done by using this kind of plot for data analysis. A drawback of this kind of plot is that the only the small number of audio signals (samples) can be observed at once.

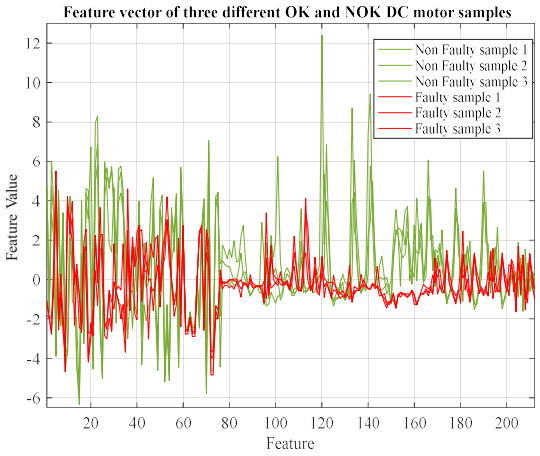

Fig. 4 1D representation of feature vector of three different samples of non-faulty and faulty DC motors.

Another option for visualization is to divide features into groups of two. The next step is to make graph where values of feature 1 (F1) are given in the *x*-axis, while values of feature 2 (F2) are given in the *y*-axis. In this way, a 2D graph of features is generated, that is, a field of features in two-feature domain. Representative examples of two such graphs are presented in Fig. 5. On the first pair of features represented on Fig 5 subplot a) the distinction between Non Faulty and Faulty motors is greater than in the second pair. A similar conclusion can be made for lot of other combinations. Even though this process has been slow, unnecessary features can be detected and removed from further classification process.

In the same way as previously done, the features can be divided into groups of three features. Then, 3D graphical representations of these groups of features are generated. Here, the values of feature 1 (F1) are shown in *x*-axis, the values of feature 2 (F2) are shown in *y*-axis, and the values of feature 3 (F3) are shown in *z*-axis. The effects of features are more prominent in spaces of three different features than in

1D or 2D spaces.

Besides, increase of graph dimensionality provides some new insights in the analysis of differences between classes. This kind of graph is presented in the figures below.

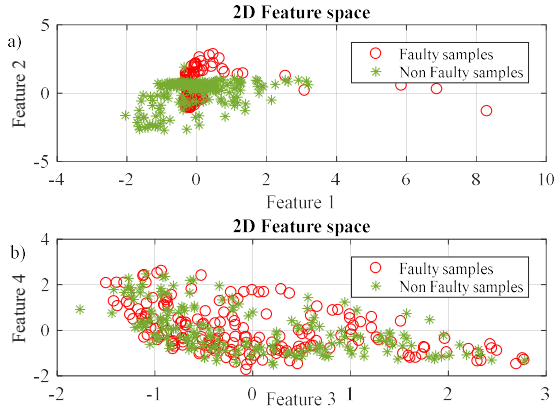

Fig. 5 2D representation of features in two-feature domain a) 2D space made of Feature 1 and 2 as representation of good distinction between classes b) 2D space made of Feature 1 and 2 as representation of bed distinction between classes

In Fig. 6, the values of the 22nd, 23rd and 24th features differ significantly between the classes, so it is easy to make distinction between them. These three features carry important information beneficial to the classifier.

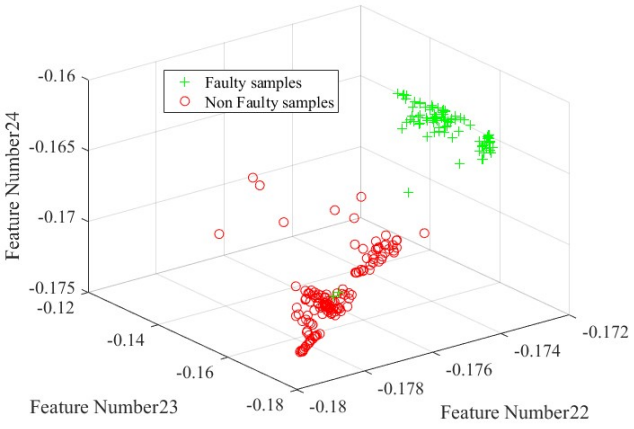

Fig. 6 3D visualization of class difference between non-faulty (OK) and faulty (NOK) DC motors using features 22, 23 and 24.

Opposite to the situation presented in Fig 6, the features given in Fig 7 do not show significant difference between the classes, so they do not contribute to classification process. This kind of visualization has proved to be a useful tool in optimization process where features relevant for classification are selected. Unfortunately, this visualization is slow for analysis, since there are a number of combinations of features to go through.

Another approach to cope with the large dimensionality of the feature space is to use transformation techniques such as Principle Component Analysis (PCA). This is low-dimensional linear approximation of the original data, which can be viewed as a projection of data on the new coordinate axes. In this procedure, the variances on the axes are maximized. In Fig.8, the results of the PCA for non-faulty and faulty motors are shown.

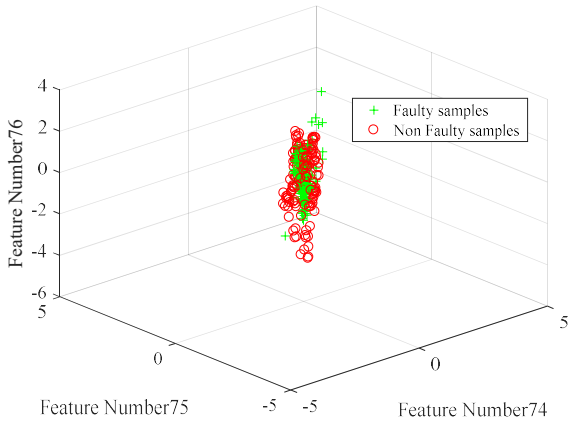

Fig. 7 3D visualization of features using features 74, 75 and 76, where the class difference between non-faulty (OK) and faulty (NOK) DC motors is hardly visible.

As it can be observed, there are some differences between the classes but not that prominent to improve the classification process. The PCA is shown to be good for visualizing the classes. However, in this particular case, especially for optimization of used features, it does not seem to be promising - better results are obtained by simple visualization of samples in three features space. By employing the PCA, there is no guarantee that unwanted or unneeded features will be eliminated, since the features may exhibit high variance. The transformed features could not be easily interpreted, which is one of major drawbacks in a process of understanding the quantities that best describe the classes of DC motors.

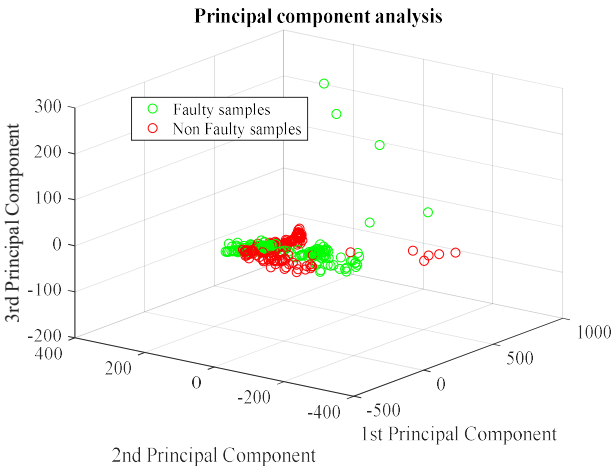

Fig. 8 Principle component analysis (PCA) of feature matrix of non-faulty (OK) DC motors and faulty (NOK) DC motors.

An alternative to feature transformation technique is feature selection approach for feature vector optimization. This technique is based on search through the subsets of extracted features with a goal to find the best ones based on evaluation function among the competing candidate subsets. For this purpose, several different algorithms for selection are tested. [7

] Based on rank in the selection, the extracted features are graded, only the k best ones are used in the machine learning process.

One of the tested methods for feature selection is Infinite Latent Feature Selection, ILFS, the algorithm that allows the investigation of importance of a feature when injected into an arbitrary set of cues. The results from this algorithm are tested in the liner Support Vector Machine (SVM) for classification of DC motors. When only two best ranked features are employed, accuracy of the used algorithm is 95.97%. This is plotted in 2D space of those two features and shown in Fig. 9.

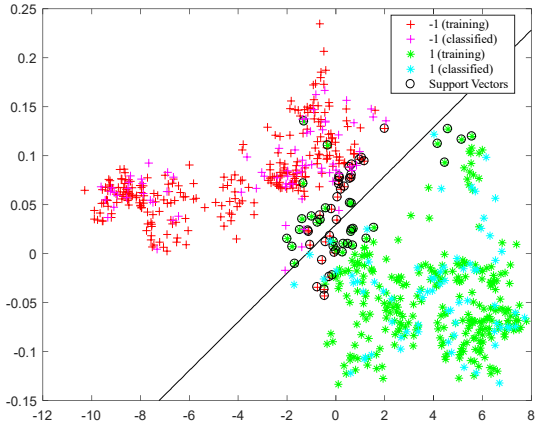

Fig. 9 Visualization of results of SVM trained with 2 best features based on infinite latent feature selection algorithm.

The Laplacian sore algorithm for feature selection is also studied. In this algorithm, for each feature, its Laplacian score is computed to reflect its locality preserving power. The Laplacian score is based on the observation that two data points are probably related to the same topic if they are close to each other.

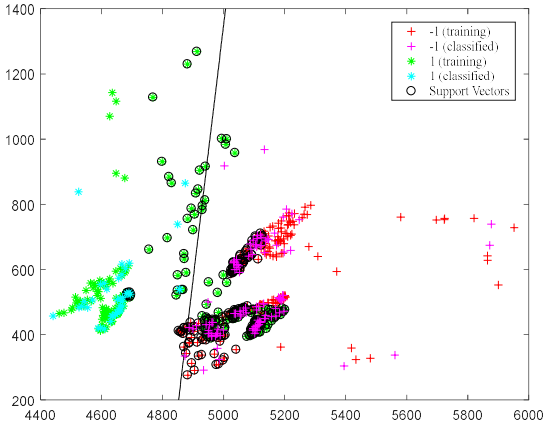

Fig. 10 Visualization of Support Vector Machine trained with 2 best features based on Laplacian score

The machine trained with two best ranked features from this algorithm is less accurate than the previous mentioned one. Here, the accuracy is only 75.84 %, and visualization of the results are shown in the Figure 10. More accurate machine can be obtained by using more than two features in the learning process. In the case of features ranked with the Laplacian score, 15 best features are needed to obtain the same accuracy as in the case of infinitive latent feature selection.

Some other feature selection algorithms are studied, too, and the results are similar to the previously mentioned two. Decision which features will be used for the final classification algorithm is based on the presented visualization and optimization techniques. In the end, in the tested example of DC motors, dimension of the feature vector is reduced from 212 to 35 features. Thus, the computational demand for the machine learning process is significantly reduced and optimized.

V. Conclusion

A large number of potentially useful features can be considered in the design of sound classification systems. Though in some cases it is practicable to use all those features for the classification, it may not be optimal to do so. Beside good audio data base preparation, feature visualization and selection are two very important steps in designing an optimal machine learning algorithm for classification. Visualization and optimization techniques presented in this paper can significantly improve the efficiency of the classification problem. Also, they play a decisive role in the process of designing and building the machine learning algorithm for automatic classification.

Analysis of DC Motor Sounds Using Wavelet-Based Features

Đorđe Damnjanović, Dejan Ćirić and Zoran Perić

***Abstract*—Widespread usage of wavelets in signal processing nowadays confirms effectiveness of this method for different applications such as de-noising of audio signals. The wavelet method can be considered to be either the Fourier transform replacement or its complement and it is able to overcome some important disadvantages of Fourier transform. The wavelet transform typically provides the detail and approximation coefficients as results. They can be used for further processing, as it is the case in de-noising, but these coefficients can be used for some other applications, too. This paper presents the application of wavelet decomposition into detail and approximation coefficients as features of audio signals for their classification. Sounds of direct current (DC) motors with and without fault in both directions of rotation are recorded and used as test audio signals. The effects of wavelet parameters such as wavelet function and decomposition level on the features distinction is investigated. Time and frequency analysis is also done for the tested DC motors.**

***Index Terms*—Wavelets; Detail coefficients; Approximation coefficients; Audio features; DC motors.**

I. Introduction

Wavelets were primarily introduced to solve problems of the Fourier transform [1]. The first official term wavelet dated back to 1909 when Alfred Haar mentioned wavelet in his research [2]. Looking from the historical point of view, the roots of wavelet transform appeared in the Fourier's papers [2]. During the decades, group of scientists developed different types of wavelet families and explained wavelet as a small wave [2,3]. More correct definition states that wavelet is a waveform of effectively limited duration that has an average value of zero [2,3]. The most of the families are named by these scientists: Gabor, Morlet, Daubechies, Haar, etc. Majority of newer wavelet families are upgraded and improved version of the old ones.

Nowadays, the wavelets are widespread. They have found their place in many applications including signal and image de-noising. When special acoustical signals are in focus (for example room impulse responses), wavelets can be applied for their processing (de-noising), too [4]. In this way, it is possible to significantly increase the dynamic range of room impulse responses [4]. Besides image and audio signal de-noising, wavelets can also be used for de-noising of other signals including biomedical signals (electromyogram, electrocardiograph and electroencephalogram) [5] and for remote sensing of very low frequency signals [6]. Another wavelet usage, which is quite new in research, is estimation of truncation time of an RIR [7].

Recently, an increased interest of both academia and industry is shown for audio signal classification and auditory scene recognition. This kind of audio signal processing plays an important role in various areas: biomedical engineering, mechanical engineering, telecommunications, acoustics, etc. In that regards, different features of audio signals are extracted and used for classification and recognition purpose [8,9]. Some of those features are based on wavelets [10,11].

One real problem that occurs in industry is how to assess the quality of produced motors or how to detect a faulty motor and recognize the failure type. A number of different approaches are already presented [12]. Unfortunately, it seems that there is no established unique - "the best" approach. Instead, since in most of situations there are some specific characteristics of the classification or recognition problem, a logical solution would be to apply a customized set of features and appropriate classification algorithm.

One of results of symbiosis of knowledge from signal processing, audio and acoustics is usage of wavelet transform as a tool for extrication of audio features. More specifically, audio features can be generated by signal decomposition into detail and approximation coefficients by applying wavelets [8]. This possibility is explored and analyzed here. The examples of audio signals of recorded DC motors both faulty and non-faulty are used as test samples. Since there are several parameters of wavelets, these parameters are changed and their effects on set of audio features consisting of detail and approximation coefficients are investigated. The focus is on possibility to differentiate faulty from non-faulty motors using sound that they generate. The processing is done in Matlab software package. The results for a few representative examples are presented here, although the research included more than 40 DC motors.

II. Related Work

There are different types of fault detection in motors that include vibration monitoring, motor current signature analysis (MCSA), electromagnetic field monitoring, chemical analysis, temperature measurement, infrared measurement, acoustic

Zoran Perić is with the Faculty of Electronic Engineering, University of Niš, Aleksandra Medvedeva 14, 18000 Niš, Serbia (e-mail: zoran.peric@elfak.ni.ac.rs).

noise analysis, and partial discharge measurement [13]. Current signature, vibration signature and sound signature analysis are the most common in use because of certain advantages in relation to these methods [14]. MCSA is a rather popular and reliable technique providing good results, but in some cases it is not sensitive enough, it has low-frequency resolution and installation can be more complicated [14]. Vibration analysis requires appropriate sensors (accelerometers), which can be an additional expense, and sometimes it is not easy to correctly place the sensor in a right place [13,14]. Sound analysis is contactless, low-cost and easy installation approach, where problem typically comes from disturbances of industrial environment (e.g., noise). MCSA is often used in combination with sound signature analysis [14,15].

Rotor faults, bearing faults and unbalanced faults in wings are the most common mechanical faults that can be detected and analyzed with sound signature analysis [13]. There are different methods for extracting relevant sound based features for classification purpose. The authors of Ref. 9 proposed extraction of the following audio features: the average zero-crossing rate, the fundamental frequency and spectral peaks. There are some recent studies where wavelet based features are applied for motor faults detection and motor classification [10,11,15,16]. An example is Ref. 16 where experimental results prove that wavelets can be used for this purpose as simple, easy and fast method.

Decomposition of audio signals with wavelet transform into approximation and detail coefficients represents one of possibilities for feature extraction. Typically, pre-processing stage precedes the wavelet transform. In this stage, audio signals are segmented in smaller frames, although in literature it can be found that wavelet transform is implemented either on longer frames or whole signals [10,15,16]. Since audio signals usually contain noise, de-noising in pre-processing can often be beneficial De-noising can be done by applying wavelets, Notch filtering, moving average filtering, etc [10,15].

For fault analysis in different types of motors, the most common wavelets are Haar and Daubechies, although Coiflets, Symlet and Mayer wavelets are also proposed for that purpose [10,15]. Selection of wavelet type can be very tricky, especially in some cases. For example, certain wavelet families, like Daubechies, have a large number of different types (there are up to 45 Daubechies wavelets when Matlab is used). In Ref. 11, a complete research about the choice of right wavelet in classification of percussive sounds is done. Fig. 1 presents the classification success rate depending on the chosen wavelet from this reference.

Regarding detection of faulty motors, besides selection of appropriate audio features, it is also important to choose right classifier. Similar to the situation with features, different classifiers have been proposed and used in studies [13-15].

For majority of authors, level of decomposition in wavelet transform is one of the most important parameters whose effects need to be investigated. Some authors use decomposition up to the level 8 or 9 [10-12], while some other authors can provide suitable results with much smaller level, for example 3, 4 or 5 [13,17].

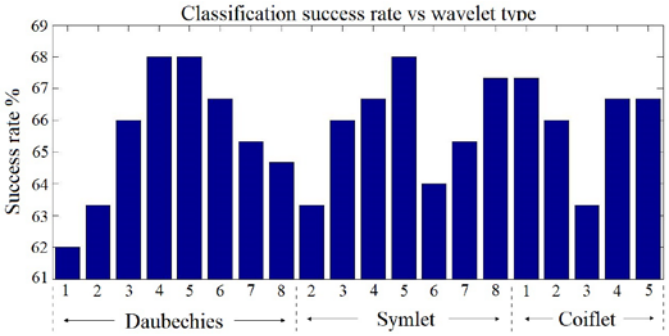

Fig. 1. Classification success vs. wavelet type from Ref. 11.

III. METHODS OF ANALYSIS

More than 40 different DC motors are used in the analysis. All motors are divided in two groups: motors with certain faults (faulty motors) and motors with good characteristics (non-faulty motors). Sound of each motor was recorded in semi-anechoic conditions (only the floor was reflective). The motors were placed on a test bench provided by the motor manufacturer. This test bench is able to drive the motors with adequate force and to apply an adequate load simulating real conditions. The motors were driven in two directions of rotation, where operation in each direction lasted approximately 8 s. The measuring microphone was placed about 40 cm from the tested motor.

In order not to use the transition regions in the beginning and at the end of the recorded signals, the medium parts of duration of 5 s of signals are extracted and further processed.

Wavelet-based feature extraction starts with decomposition of audio signal. The decomposition is usually done using discrete wavelet transform (DWT) rather than continuous wavelet transform (CWT) because of its easier implementation in multilevel signal decomposition [2]. Signal is decomposed into approximation and detail coefficients (high and low frequency components) at each level. This is why the DWT is equivalent to low and high pass filtering [3]. The described procedure is presented in Fig. 2 (down to level 3 of decomposition), where LP is a low-pass filter, HP is a high-pass filter, A stands for approximation coefficients, D stands for detailed coefficients, and 2↓ is down-sampling.

Different wavelets are applied on recorded signals with the main purpose to provide an adequate set of wavelet-based features being able to make difference between faulty and non-faulty motors. Generally speaking, the most common wavelet used in audio signal processing is Haar wavelet. This wavelet is proved to be the most stable in signal de-noising, although Daubechies wavelets provide somewhat better results than Haar in this particular application [4]. Other wavelets families used here are: Coiflets, Symlet, biorthogonal, reverse biorthogonal and Mayer.

The level of decomposition is an important part of analysis too, especially because many authors use different values for the level. Here, the levels of decomposition from 2 to 8 are

used.

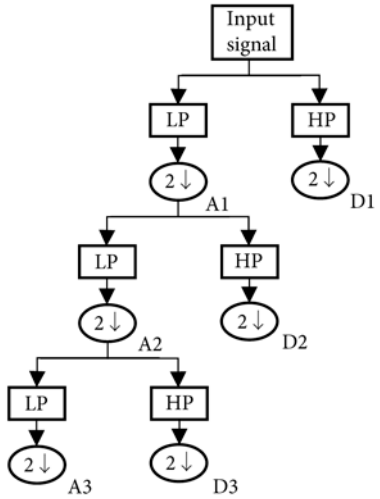

Fig. 2. Block diagram of wavelet transform decomposition into detail and approximation coefficients.

The described processing is done in Matlab software package using the corresponding toolkits. The application is fully automated. The selected wavelet and its level of decomposition is applied on the defined signal for decomposition process by the command *wavedec*. Approximation and detail coefficients are obtained with two commands - *appcoef* and *detcoef*, respectively according to the level of decomposition.

Regarding the analysis, the recorded signals are first observed in time and frequency domain separately, but also their spectrograms are investigated. Then, the wavelet-based features obtained by different combination of wavelet parameters are analyzed in detail. Special attention is paid to differences between faulty and non-faulty motors present in the time and frequency domains (if any), but also in the domain of wavelet-based features.

IV. Results

In this section, the illustrative results for some characteristic samples of tested motors are presented. Thus, Fig. 3 presents the recorded sounds of both faulty and non-faulty DC motors in both directions of rotation. As can be seen from these figures, there are certain fluctuations of amplitude (levels) in time. In some cases (signals), the amplitude fluctuations in time are more prominent. The fluctuations can have shape similar to low frequency pattern or some sudden onset of high amplitude can appear in certain time moments. Regarding faulty motors detection, considering only the time domain presentation, it is rather difficult to make a distinction between faulty and non-faulty motors.

Spectra of signals shown in Fig. 3 are presented in Fig. 4. There are some prominent low frequency components (below 100 Hz), that are mainly consequence of ambient noise. In rest of the frequency range, some peaks and dips appear. Distinction between directions of rotation can be made in an easier way in the spectral domain instead in the time domain. However, even in the spectral domain, it is not an easy task to differentiate the faulty motors from the non-faulty motors.

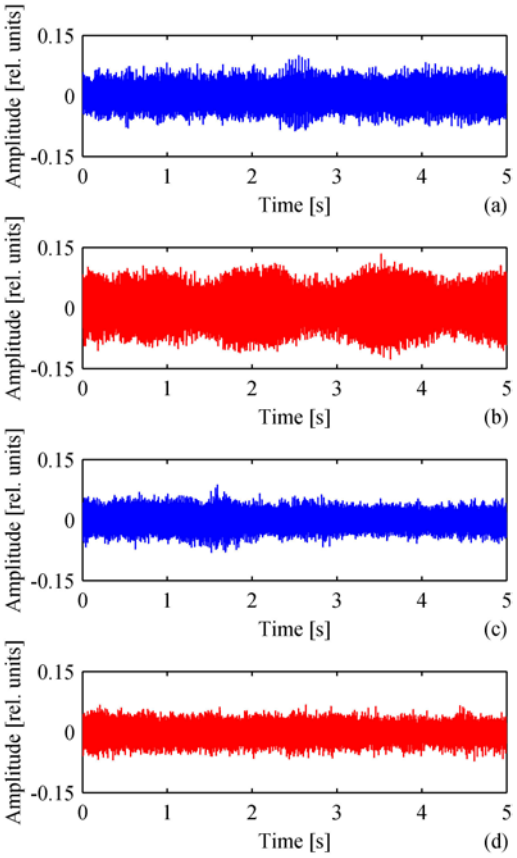

Fig. 3. Audio signals (sounds) of DC motors in time domain: a) non-faulty motor (direction of rotation 1) b) faulty motor (direction 1) c) non-faulty motor (direction 2) d) faulty motor (direction 2).

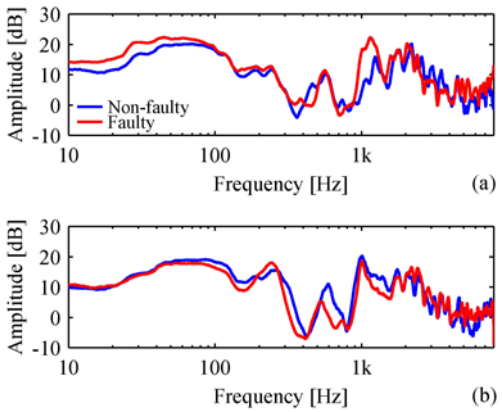

Fig. 4. Spectra of sounds of faulty and non-faulty DC motors: a) non-faulty motor (blue) and faulty motor (red), direction of rotation 1; b) non-faulty (blue) and faulty motor (red), direction of rotation 2.

Spectrograms of motor sounds in direction 1, whose time domain amplitudes are given in Fig. 3(a) are shown in Fig. 5. The peaks of spectra are visible as prominent horizontal lines in the spectrograms. These lines (spectral components) can be considered to be sound harmonics. In the shown case, higher sound levels are present for non-faulty motor, Fig. 6(a). These higher levels for non-faulty motor represent the main difference in the spectrograms for non-faulty and faulty

motors. Unfortunately, this situation is not the general one. Amplitude values (overall levels) changes from motor to motor independently whether the motor is faulty or non-faulty. The amplitude value could not reflect faults in motor.

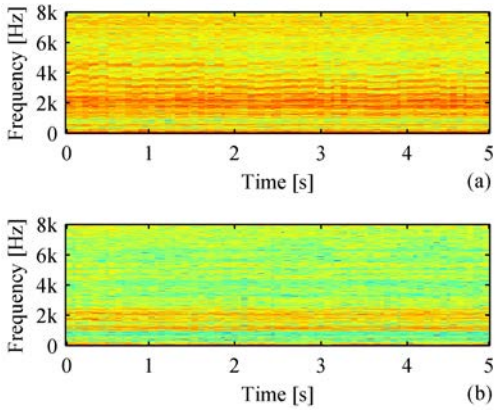

Fig. 5. Spectra of sounds of motors: a) non-faulty b) faulty in direction 1.

The presented characteristics of audio signals in time domain, spectral domain as well as in combined time-frequency domain show that it is rather difficult to make difference between faulty and non-faulty motors. In that regards, it sounds very logical to try to find an alternative approach able to make a clearer distinction between these motors.

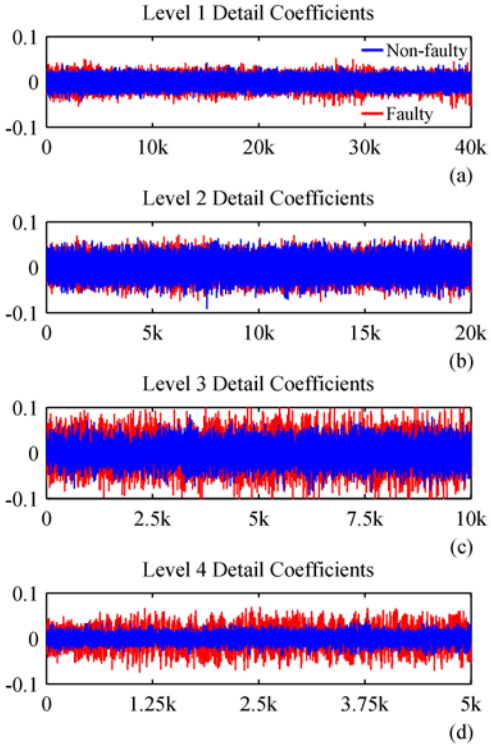

Fig. 6. Detail wavelet coefficients after applying Daubechies 2 wavelet for faulty (red) and non-faulty motors (blue) in direction 1 of rotation: a) level 1, b) level 2, c) level 3 and d) level 4.

The next step in finding adequate set of audio features is the wavelet transform, where Daubechies 2 wavelet (db2 in Matlab) is applied with different decomposition levels on the whole signal. The detail coefficients up to the level 4 for direction of rotation 1 are presented in Fig. 6. In this case, the detail coefficients for faulty and non-faulty motors for level of decomposition of 1, 2 and 3 seem to be rather similar to each other. This is not the case for the level of decomposition of 4 where the values of detail coefficients for the faulty motor are greater than those for the non-faulty motor.

For the levels of decomposition between 5 and 8, the values of detail coefficients for faulty and non-faulty motors are rather similar, see Fig. 7. Looking at both Figs. 6 and 7, it can be seen that the length of detail coefficient array becomes shorter with increase of the level of decomposition.The detail coefficients for the same motors (one faulty and one non-faulty), but for opposite direction of rotation (direction 2) are presented in Figs. 8 and 9. Comparing the results for faulty and non-faulty motors here, the situation is a bit different. The patterns of detail coefficients for these motors are rather similar except for the level 1 and partly for the level 7.

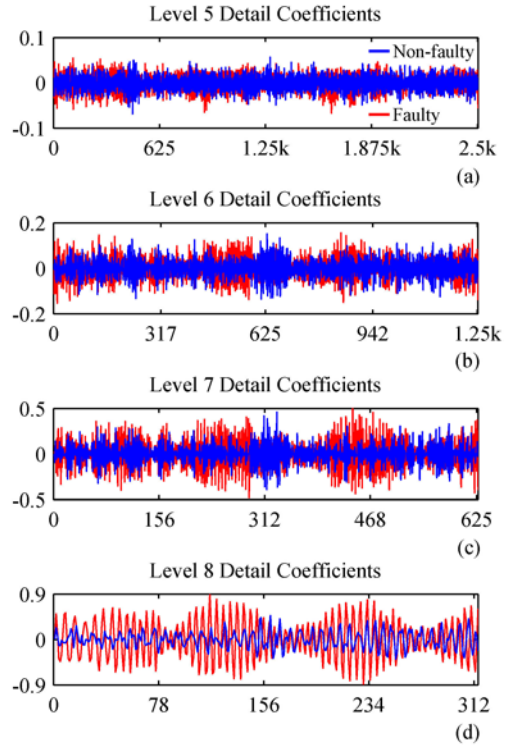

Fig. 7. Detail wavelet coefficients after applying Daubechies 2 wavelet for faulty (red) and non-faulty motors (blue) in direction 1 of rotation: a) level 5, b) level 6, c) level 7 and d) level 8.

Different situation appears when the approximation coefficients are observed. Wherever the approximation coefficients are considered in research, these coefficients from the highest level of decomposition are used. This is one of main differences between analysis of detail and approximation coefficients.

For the tested faulty and non-faulty motors from previous figures, the approximation coefficients for the level of decomposition 8 are presented in Fig. 10. Generally speaking, in some cases, the approximation coefficients can provide difference between faulty and non-faulty motors, as is shown in Fig. 10(a), but there are also examples where these coefficients are similar for faulty and non-faulty motors, as it

is the case given in Fig. 10(b).

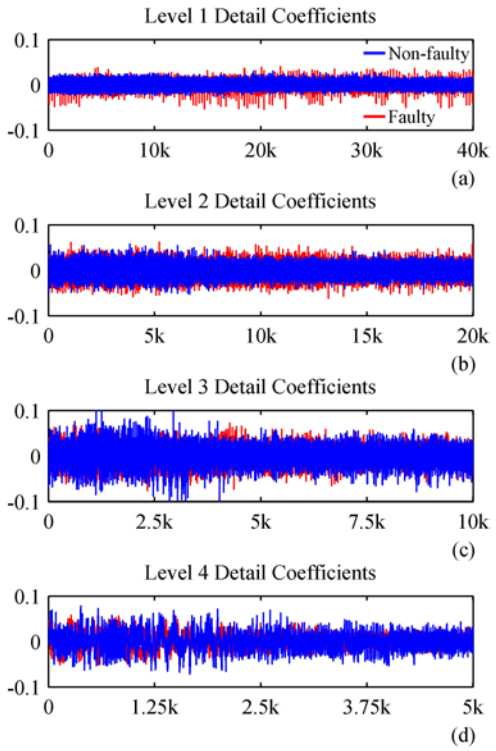

Fig. 8. Detail wavelet coefficients after applying Daubechies 2 wavelet for faulty (red) and non-faulty motors (blue) in direction 2 of rotation: a) level 1, b) level 2, c) level 3 and d) level 4.

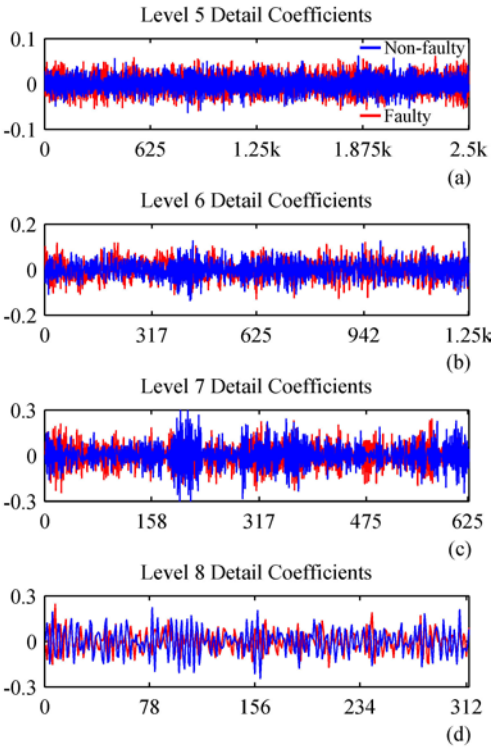

Fig. 9. Detail wavelet coefficients after applying Daubechies 2 wavelet for faulty (red) and non-faulty motors (blue) in direction 2 of rotation: a) level 5, b) level 6, c) level 7 and d) level 8

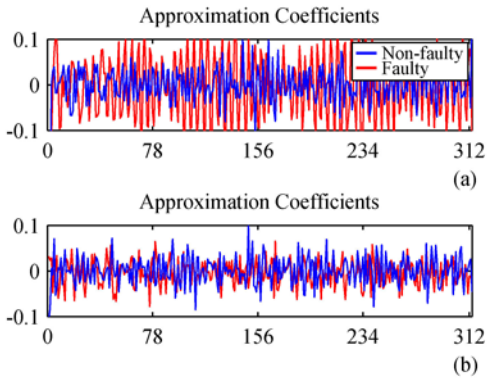

Fig. 10. Approximation wavelet coefficients after applying Daubechies 2 wavelet for faulty (red) and non-faulty motors (blue) a) in direction 1 of rotation, and b) in direction 2 of rotation.

When the wavelet function is changed from Daubechies 2 to other functions (Haar, Symlet, Coiflet, biorthogonal, reverse biorthogonal, Mayer), the patterns of detail and approximation coefficients are also changed to a certain extent. Figure 11 presents 4 cases of 4 different wavelet functions (Haar, Simlet 8, Coiflet 5 and Meyer) applied to the faulty and non-faulty DC motor in direction 1 of rotation. Detail coefficients of the level 4 are presented. Situation is rather similar to the case of Daubechies 2 wavelet. Mayer wavelet leads to slightly poorer result.

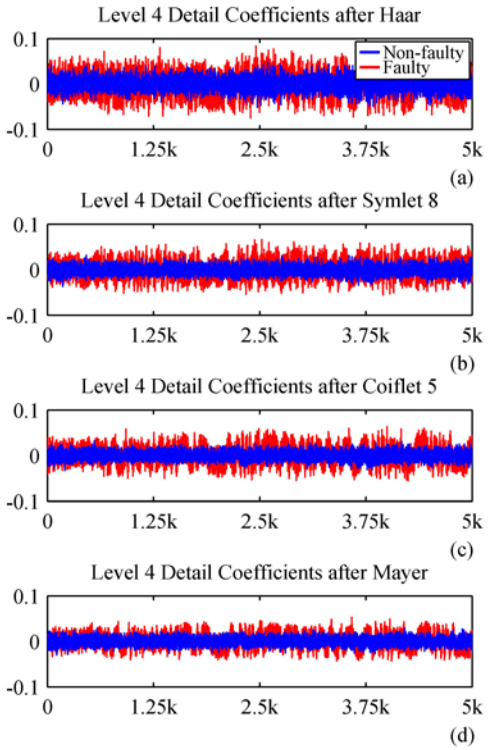

Fig. 11. Detail coefficients of the level 4 for faulty (red) and non-faulty motors (blue) in direction 1 of rotation after applying wavelets: a) Haar b) Symlet 8 c) Coiflet 5 and d) Meyer.

When the effects of decomposition level are observed, it can be concluded that the patterns for detail and approximation coefficients are changed by changing the level of decomposition. In some cases, the best results (the best distinction between faulty and non-faulty motors) are obtained

applying the level 4 (see Fig. 6), but in some other cases (other motors), some other levels would be preferable. Fig. 12 presents cases where differences between faulty and non-faulty motors are larger for some other levels.

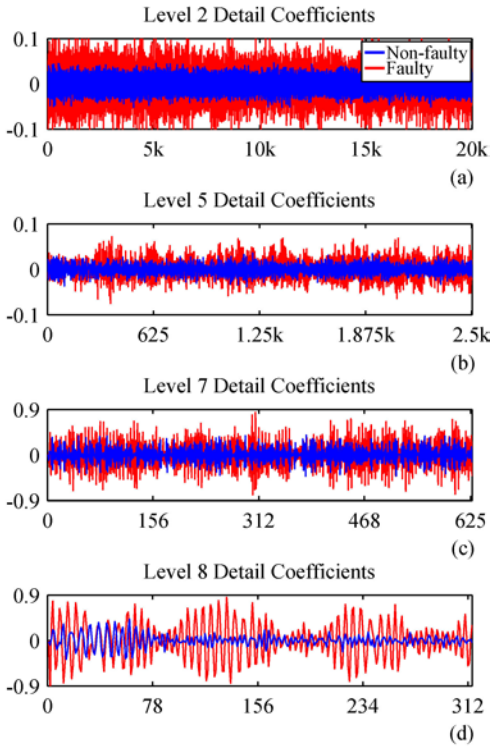

Fig. 12. Detail wavelet coefficients after applying Daubechies 2 wavelet for faulty (red) and non-faulty motors (blue): a) level 2, b) level 5, c) level 7 and d) level 8, where the results for different motors are given in figures from (a) to (d)

V. Conclusion

Depending on the motor fault, sound generated by the motor can be significantly changed from the sound generated by a non-faulty motor. However, in many cases, especially where the fault is considered to be a minor one, the sounds of faulty and non-faulty motors are perceptually rather similar to each other. For naive listeners, it is not easy to make a distinction between these two types of motors.

Wavelet technique is one of options to extract usable features when sound signature analysis is applied for motor estimation. Decomposition of an audio signal into detail and approximation coefficients is the main task in this type of wavelet analysis. With the right choice of wavelet function and level of decomposition, differences in wavelet coefficients for faulty and non-faulty motors can become prominent.

Regarding the wavelet parameters, different wavelets provide rather similar results, although there are cases that are slightly different. One of the main observations of this research is that there is no unique decomposition level leading to the largest differences between faulty and non-faulty motors. If the most preferable level has to be chosen, than this level is either 4 or 8. In the continuation of the research, other options will be explored, such as first to segment the tested audio signal in frames, and then to apply wavelet decomposition.

The Numerical Study of Atmospheric Attenuation of Outdoor Sound Propagation

Milan Mišković, Miomir Mijić and Miljko Erić

***Abstract* — It is well known that atmospheric attenuation of outdoor sound propagation dominantly depends on meteorological conditions - ambient atmospheric parameters such as temperature, pressure, humidity, etc. The atmospheric attenuation is a function of frequency and propagation distance. In engineering practice as well as in theoretical and applied researches, numerical modeling of atmospheric attenuation of outdoor sound propagation is needed. So, such numerical study is a subject of this paper. Some results of numerical modeling of atmospheric attenuation are presented which quantitatively illustrate the influence of different meteorological parameters on atmospheric attenuation. In order to share their effort with readers, the authors attached MATLAB code for numerical modeling of atmospheric attenuation of sound during propagation outdoors in appendix.**

***Index Terms* — Outdoor sound propagation, attenuation of sound, atmospheric sound attenuation, geometrical divergence attenuation.**

I. Introduction

Motivation of authors for numerical study of atmospheric attenuation is twofold:

- Although qualitative influence of meteorological factors on atmospheric attenuation in outdoor sound propagation is theoretically known and standardized [1], in engineering practice, such as planning of measurement campaign of acoustical events or deployment elements of distributed system for acoustical monitoring, a quick tool for numerical modeling and prediction of acoustical attenuation is needed.
- A key research focus of authors is to find the answer to the question if it is possible to extract signal features needed for automatic classification/identification of acoustic sources (signals), especially sources of impulse acoustic signals which are independent on distance or if such signal features need to be dependent on distance. For such study numerical modeling of atmospheric attenuation is needed.

Different phenomena occur in outdoor sound propagation. In the past, it was a subject of many published papers [1-9]. Phenomena such as attenuation, refraction, diffraction, reflection, etc. are the consequence of the air properties of physical sound propagation media and obstacles that are found on the propagation path. Sound energy is dissipated in air by two major mechanisms. The first is viscous loss due to friction between air molecules which results in heat generation "classical absorption". The second is relaxation process – sound energy is momentarily absorbed in the air molecules and causes the molecules to vibrate and rotate. These molecules can then re-radiate sound at a later instant, like small echo chambers, which can partially interfere with the incoming sound [1].

Outdoor sound propagation is affected by three basic factors: meteorological conditions, ground characteristics and the presence of obstacles [2,3,4].

Meteorological conditions in which sound propagation occurs, such as temperature changes, atmospheric turbulence, precipitation, air humidity, lead to an increase or decrease in sound attenuation during propagation. Changing meteorological conditions can easily cause fluctuations in sound levels by 10-20 dB over time periods of minutes. The longer is the transmission path, the larger are the fluctuations in levels [6]. With sound attenuation, gradients of wind or temperature refract waves either upwards or downwards. Upwards, if sound propagation takes places along upwind or in temperature lapse. Downwards, if sound propagation takes places along downwind or in temperature inversion.

Propagation reality is more complicate then geometrical spreading above flat ground. Some grounds are acoustically hard like concrete, and others soft as snow. The surface over which sound propagates can seldom be considered perfectly rigid or totally reflective with possible exceptions of open water, ice, or concrete. Typical soil surfaces with or without vegetation tend to absorb energy from incident acoustic waves. Accurate prediction of ground effects requires knowledge of the absorptive and reflective properties of the surface respectively the acoustic impedance [7].

Starting from theoretical foundation of atmospheric attenuation given in standard and published papers, a numerical study of outdoor sound attenuation is done in this paper. Some results of numerical modeling are presented which quantitatively illustrate influence of different meteorological parameters on atmospheric attenuation. The authors attached MATLAB code for numerical modeling of atmospheric attenuation in appendix. The authors believe that this code could be useful in readers engineering and research activities.

II. Modeling of Attenuation of Outdoor Sound Propagation

The total attenuation A [dB] of outdoor sound

Milan Mišković – Military Technical Institute, 1 Ratka Resanovića, 11030 Belgrade, Serbia and School of Electrical Engineering, University of Belgrade, 73 Bulevar kralja Aleksandra, 11020 Belgrade, Serbia (e-mail: milan.miskovic@mod.gov.rs and miskomsm@gmail.com).

Miomir Mijić and Miljko Erić – School of Electrical Engineering, University of Belgrade, 73 Bulevar kralja Aleksandra, 11020 Belgrade, Serbia (e-mail: emijic@etf.rs, miljko.eric@etf.rs).

propagation, without wind, can be defined by the equation [8]:

$$A = A_{div} + A_{atm} + A_{gr} + A_{bar} + A_{misc} \quad (1)$$

where:

A_{div} – denotes the attenuation due to geometrical divergence,

A_{atm} – denotes the attenuation due to atmospheric absorption,

A_{gr} – denotes the attenuation due to the ground effect,

A_{bar} – denotes the attenuation due to a barrier,

A_{misc} – denotes the attenuation due to miscellaneous other effects.

If sound propagates on flat terrain without obstacles on the propagation path (barriers, trees, settlements, industrial zones, etc.) and the influence of the soil is neglected, the equation (1) can be written in the following form:

$$A = A_{div} + A_{atm} \quad (2)$$

The geometrical divergence accounts for spherical spreading in the free field from a point sound source, making the attenuation A_{div} [dB], equal to:

$$A_{div} = 20\log_{10}(d/d_0) + 11 \quad (3)$$

where:

d [m] – denotes the distance from the source to receiver,

d_0 = 1 m – denotes the reference distance.

The attenuation due to atmospheric absorption A_{atm} [dB] at distance d, is given by equation:

$$A_{atm} = \alpha d \quad (4)$$

where α [dB/m] is the atmospheric attenuation coefficient for each octave band at the mid band frequency. The atmospheric attenuation coefficient may be defined [1] with equations (5), (6), (7) and (8):

$$\alpha = 8.686 f^2 \left(\left[1.84\times10^{-11} (p_a/p_r)^{-1} (T/T_r)^{\frac{1}{2}} \right] + x \right) \quad (5)$$

$$x = (T/T_r)^{-\frac{5}{2}} (y + z) \quad (6)$$

$$y = 0.01275 e^{-\frac{2239.1}{T}} \left[f_{ro} / (f_{rO}^2 + f^2) \right] \quad (7)$$

$$z = 0.1068 e^{-\frac{3352}{T}} \left[f_{rN} / (f_{rN}^2 + f^2) \right] \quad (8)$$

where:

f [Hz] – denotes the frequency of the sound,

p_a [kPa] – denotes the ambient atmospheric pressure,

T [K] – denotes the ambient atmospheric temperature,

f_{rO} [Hz] – denotes the relaxation frequency of oxygen,

f_{rN} [Hz] – denotes the relaxation frequency of nitrogen,

p_r = *101.325* kPa – denotes the reference ambient atmospheric pressure,

T_r = 293.15 K – denotes the reference air temperature.

The relaxation frequency of oxygen and nitrogen are defined with equations (9) and (10), respectively.

$$f_{rO} = \frac{p_a}{p_r} \left\{ 24 + \left[\frac{(4.04\cdot10^4 h)(0.02 + h)}{0.391 + h} \right] \right\} \quad (9)$$

$$f_{rN} = \frac{p_a}{p_r} \left(\frac{T}{T_r} \right)^{-\frac{1}{2}} \left(9 + 280 h e^{-4.17\times\left[\left(\frac{T}{T_r} \right)^{-\frac{1}{3}} - 1 \right]} \right) \quad (10)$$

In equations (9) and (10), h [%] is the molar concentration of water vapor. The molar concentration of water vapor is defined with equations (11), (12) and (13):

$$h = h_r (p_{sat}/p_a) \quad (11)$$

$$p_{sat} = p_r 10^C \quad (12)$$

$$C = -6.8346 (T_{01}/T)^{1.261} + 4.6151 \quad (13)$$

where:

h_r [%] – denotes relative humidity,

p_{sat} – denotes saturation vapor pressure,

T_{01} = 273.16 K – denotes triple point isotherm temperature.

The sound attenuation due to geometric divergence is a consequence of the nature of the sound propagation i.e. the spherical spreading of the sound wave from the point source. When it is necessary to do the exact calculation of the absolute sound level at the distance d from the source, the attenuation A_{div} has to be taken into account.

The attenuation due to atmospheric absorption is the consequence of environment in which the sound propagates. It is linearly dependent on the distance from the sound source and the atmospheric attenuation coefficient. The atmospheric attenuation coefficient depends on: the frequency of the sound, the ambient atmospheric temperature, the relative humidity and the ambient atmospheric pressure.

III. RESULTS OF NUMERICAL MODELING

The mathematical model was used to show the dependence of the attenuation coefficient on the meteorological parameters and the frequency of sound. Numerical results, obtained using the presented mathematical model, confirm the well-known theoretical results on sound attenuation. Additionally, the significance of the simulation results is to show the effect of the change of individual meteorological parameters on the attenuation coefficient.

The results presented in Fig.1. show how the attenuation coefficient depend on relative humidity and frequency of the sound. Ambient pressure and reference ambient atmospheric are equal. The ambient temperature is constant and it is 20 °C.

As it can be seen in Fig. 1, the value of attenuation coefficient increases with the increase of frequency.

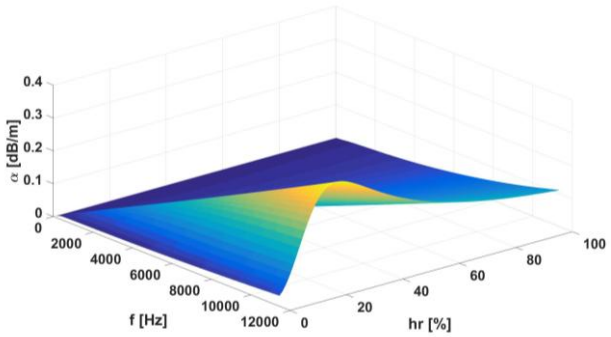

Fig. 1. The atmospheric attenuation coefficient depending of frequency, relative humidity and ambient temperature of 20 °C. The ambient pressure and the reference ambient atmospheric pressure are equal.

The results presented in Fig. 2. show the attenuation coefficient for different ambient temperatures. The ambient pressure and the reference ambient pressure are equal all the time.

It can be seen in Fig. 2. that there is the increase in the attenuation coefficient as the ambient temperature rise. In the numerical modeling, four values of ambient temperature were taken. The highest value of the attenuation coefficient of sound is at the highest frequency and the lowest values of relative humidity.

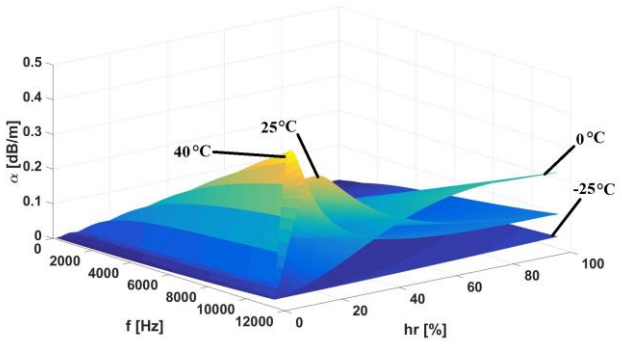

Fig. 2. The atmospheric attenuation coefficient for different ambient temperatures. The ambient pressure and reference ambient pressure are equal.

It cannot be clearly seen in Fig. 2. whether the attenuation coefficient changes with frequency and relative humidity at ambient temperature of -25 °C. In order to eliminate the confusion, the Fig. 3. shows the dependence of the attenuation coefficient on frequency and relative humidity at ambient temperature of -25 °C.

As it can be seen in Fig. 3. the level of the attenuation coefficient is about 10 times lower than the level of the attenuation coefficient when the ambient temperature is +40 °C. Additionally, the attenuation coefficient is the highest at the highest frequencies and relative humidity values. So, the attenuation coefficient also changes at low temperatures but that is much less pronounced than at higher temperatures.

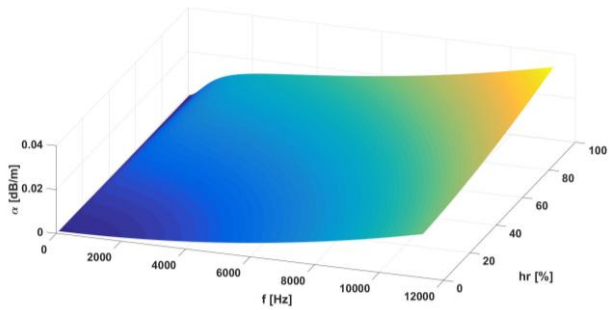

Fig. 3. The atmospheric attenuation coefficient of sound for ambient temperature of –25 °C. The ambient pressure and the reference ambient pressure are equal

The results presented in Fig. 4. show that the attenuation coefficient when ambient pressure is 913.25 mbar and 1213.25 mbar. The ambient temperature of 25 °C remain unchanged.

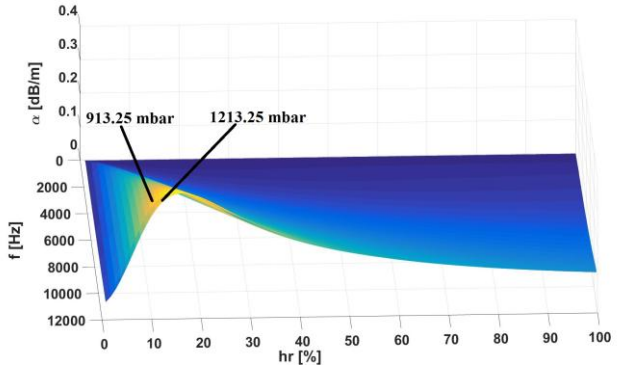

Fig. 4. The atmospheric attenuation coefficient for different ambient pressure. The ambient temperature is constant 25 °C.

The change in the attenuation coefficient is low when ambient pressure varies. Compared to the changes that occur when ambient temperature and relative humidity vary, this change in attenuation coefficient can be neglected. In order to achieve a greater change in the attenuation coefficient, the ambient pressure has to drastically deviate from the reference value of ambient pressure of 1013.25 mbar.

The results presented in Fig. 5. show the attenuation coefficient for the ambient pressure values of 413.25 mbar, 1013.25 mbar and 2413.25 mbar at constant ambient temperature of 25 °C. In the Fig. 5. it can be seen that a drastic deviation of ambient pressure from the reference value is required in order to achieve a greater change in the attenuation coefficient.

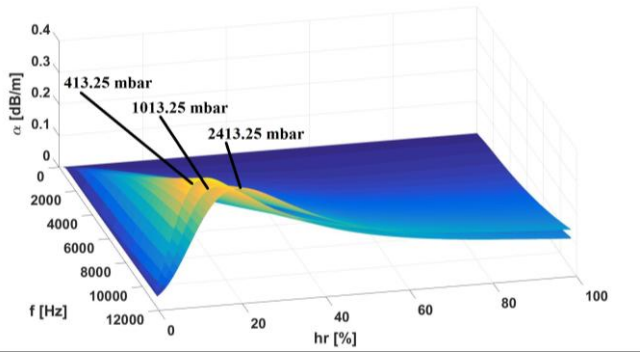

Fig. 5. The atmospheric attenuation coefficient for different ambient pressure of 413.25 mbar, 1013.25 mbar and 2413.25 mbar. The ambient temperature is constant 25 °C.

IV. Conclusion

The numerical study of atmospheric attenuation of sound during propagation outdoors is done in this paper. The described mathematical model indicates the clear dependence of sound attenuation on the meteorological conditions, metrological parameters (ambient atmospheric temperature, ambient atmospheric pressure, relative humidity) and the sound frequency. Several conclusions can be made from the simulation results which fully match the well-known theory.

During the outdoor sound propagation not all the spectral components are equally weakened in the sound wave. It can be concluded from the simulation results that the attenuation coefficient increases with the increase in frequency, i.e. the sound attenuation is highest at the highest frequencies. In this way, the higher spectral components are lost from the sound wave with the increase in distance from the source, and the air acts as a low-pass filter.

The increase in temperature increases the attenuation coefficient of sound in the air. If the ambient atmospheric temperature is -20 ° C and then increases on +40 ° C, the attenuation coefficient rises approximately 10 times.

In normal ambient conditions, the effect of ambient pressure fluctuations on the attenuation coefficient can be ignored in comparison with the effect of fluctuations in temperature and relative humidity.

In order to achieve a significant change in attenuation coefficient due to pressure change a major disturbance is required in the propagation channel or in the air, which in normal conditions cannot occur.

In the case that it is not necessary to carry out calculation of the absolute sound level at a specific point in space, the attenuation of the sound due to geometrical divergence can be neglected.

Usage of Averaging in Generation of Room Energy Decay Curve

Miljan Miletić, Dejan Ćirić and Marko Janković

***Abstract*—Acoustical quality of rooms is typically estimated by measuring a set of room impulse responses (RIRs) and extracting acoustical parameters from them including reverberation time and early decay time. These parameters are commonly determined by the backward integration of a squared RIR also known as Schroeder integration. In this way, a curve called backward integrated impulse response or energy decay curve (EDC) is obtained. After introduction of the Schroeder integration several decades ago, it has become a predominant method for EDC generation. One of the main reasons lies in the fact that the Schroeder integration considerably reduces the curve fluctuations providing smooth EDC. However, a weak point of this integration is cumulative summing of background noise. As a consequence, the late part of noisy EDC is bent upward. In this paper, an alternative method for generating smooth room EDC based on averaging is analysed. The averaging is also able to reduce the curve fluctuations. Besides, the cumulative summing is not a problem in this case. The target is to generate the EDC that deviates from the reference one (noiseless EDC) as little as possible. The effects of changing the number of points used for averaging are investigated.**

***Index Terms*—Energy decay curve; room impulse response; Schroeder's backward integration; averaging; reverberation time.**

I. Introduction

IN room acoustics, the generated sound is a combination of the direct sound coming from the source and indirect sound consisting of reflections coming from surfaces and objects in the room. This combination of direct and indirect sound, which is affected by the volume, shape and surfaces of the room, plays a key role in forming the room acoustic quality [1]. It is worth mentioning that every surface and object reacts to sound in a different way - some of them transmit or absorb sound while the others reflect or diffuse sound.

Evaluation of the acoustic quality of a room is done by analyzing relevant acoustical parameters. They are commonly calculated from measured room impulse responses (RIRs). A RIR can be measured using various techniques including the swept sine technique [2]. An important part of processing in parameter calculation is generation of the energy decay curve (EDC). More than five decades ago, Schroeder proposed procedure for obtaining the EDC based on the backward integration of a squared RIR [3]. It is also known as backward integrated impulse response or Schroeder's curve [4]. The Schroeder's backward integration has become more and more popular, and nowadays it is a preferable method for the EDC generation. Some international standards like ISO 3382 [5] and ISO 18233 [6] deal with the EDC and the way how it should be generated.

The two main problems of the Schroeder's integration come from background noise and finite upper limit of integration [7,8]. When a noisy RIR is backward integrated, which is always the case in reality (in measured RIRs), the noise energy is cumulatively added causing the EDC to bend upward. Over the last several decades, various noise compensation methods have been proposed, like RIR truncation, subtraction of mean square value of noise and correction for truncation [8].

Here, the results of study dealing with an alternative method for generating the EDC are presented. This method applies averaging of a squared RIR given in decibels in order to provide a smooth EDC that deviates from the reference EDC obtained from the noiseless RIR as little as possible. The required processing (including the averaging) is applied in the software package Matlab. The effects of length of averaging interval (window), that is, number of points used for the averaging are investigated. The goal is to find an optimal interval for averaging. The analysis is done on both broadband synthesized RIRs and RIRs filtered in third-octave bands.

After the introductory part, theoretical basis of the EDC is given. It is followed by the method section where the EDC generation and error calculation is explained. The next section contains the main results of the above mentioned analysis, which is followed by the discussion and conclusions as well as several guidelines for the future work.

II. Energy Decay Curve (EDC)

Since reverberation time is one of important acoustical parameters of a room, it should be estimated as precisely as possible. The usual method for this estimation is based on the linear regression of the EDC, although an approach based on nonlinear regression is also presented [9]. Besides reverberation time, one more parameter (early decay time - EDT) is also estimated from the EDC. In that regards, the EDC should be generated in such a way to reduce the effects of all disturbances as much as possible. There are two regular options used for EDC generation. The first one is related to

Marko Janković is with the Faculty of Electronic Engineering, University of Niš, 14 Aleksandra Medvedeva, 18106 Niš, Serbia (e-mail: marestudio2004@gmail.com).

logarithm of squared decay obtained by the interrupted noise method where white or pink noise is applied for excitation. The second one is the previously mentioned Schroeder's backward integration of a squared RIR. This integration in the discrete domain can be represented by the following equation:

$$d(t_k) = \sum_{r=t_k}^{t_\infty} h_n(r)^2 = \sum_{r=t_k}^{t_\infty} \left(h(r)+n(r)\right)^2 \qquad (1)$$

where $d(t_k)$ is the discrete time decay function, k and r are integers, t_k is a discrete time equal to $t_k = k\,\Delta t$, and $k = 0, 1, 2, \ldots$, while $\Delta t = 1/f_s$ and f_s is the sampling frequency. Noisy RIR h_n is given as a sum of noiseless RIR h and noise n. As a result of (1), the backward integrated impulse response or EDC is generated, which describes the decay of acoustic energy in the room.

Measured RIRs always contain certain background noise consisting of ambient noise and measurement equipment noise. Presence of noise seriously affects the generated EDC. Thus, the Schroeder's integration of noiseless (exponentially decaying) RIR is a straight line on the decibel scale. On the other hand, the integration of a noisy RIR leads to the EDC consisting of three parts: the main (reverberation) decay, the second decay with smaller slope caused by the cumulative summing of noise and the steep roll off caused by the finite upper limit of integration, see Fig. 1.

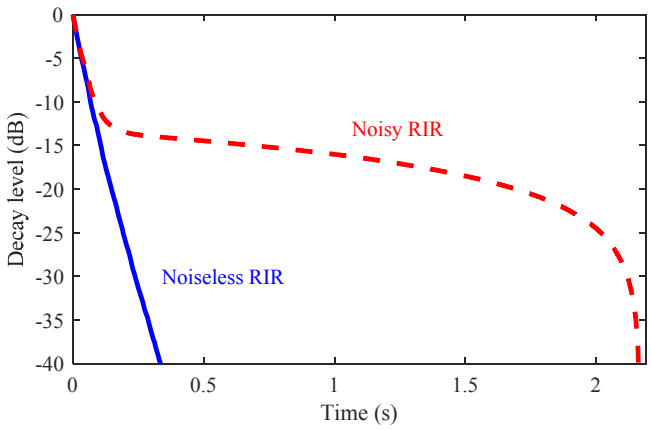

Fig. 1. EDCs of synthesized RIR with (noisy RIR) and without noise (noiseless RIR) obtained by Schroeder's backward integration.

III. EDC OBTAINED BY AVERAGING

The EDC can also be generated by logarithm of a squared RIR. Such an EDC (logarithmic squared RIR – LS RIR) has strong fluctuations in both parts – reverberation decay and noise, as presented in Fig. 2. Since data processing nowadays is much more powerful than it used to be, the linear regression can directly be applied even to this fluctuating EDC. However, the EDC fluctuations can lead to a larger deviation of the straight line approximation of the reverberation decay from true (target or reference) decay.

The fluctuations of LS RIR can be reduced by averaging. In this procedure, data points of the LS RIR within a current window are averaged to give a mean value. The current window is moved throughout the LS RIR from the starting point to the end point. The original LS RIR is then replaced by the mean values of the windows. Such a decay curve is called here averaged logarithmic squared RIR (ALS RIR).

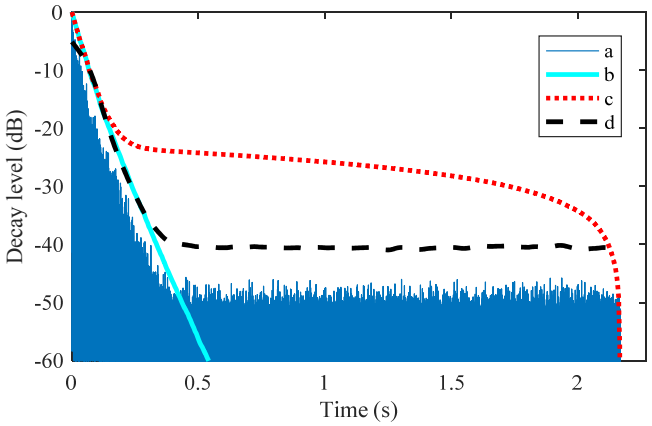

Fig. 2. Decay curves of synthesized noisy and noiseless RIR: (a) noisy LS RIR, (b) noiseless EDC obtained by Schroeder's integration, (c) noisy EDC obtained by Schroeder's integration and (d) averaged LS RIR (ALS RIR).

In this research, a basic moving average implemented in the software package Matlab is used for generation of ALS RIR. This averaging method replaces each data point with the average value of neighboring data points defined by the span or averaging window length (number of data points for mean value estimation) [10]. It is equivalent to low-pass filtering [11] where the result is defined by

$$y_a(i) = \frac{1}{2N+1}\left[y(i+N) + y(i+N-1) + \ldots + y(i-N)\right] \qquad (2)$$

where $y_a(i)$ represents the average (smoothed) value of the ith data point, and the span or averaging window is defined as $2N+1$. From (2), it is obvious that the averaged data point is located at the center of the window. Full averaging window spanning equally on both sides of the averaged data point can not be defined for the starting and ending data points. Illustration on how the averaging is done for the starting points in the case of the span equal to 7 is given in (3):

$$\begin{aligned} y_a(1) &= y(1) \\ y_a(2) &= \left[y(1)+y(2)+y(3)\right]/3 \\ y_a(3) &= \left[y(1)+y(2)+y(3)+y(4)+y(5)\right]/5 \\ y_a(4) &= \left[y(1)+y(2)+y(3)+y(4)+y(5)+y(6)+y(7)\right]/7 \\ &\ldots \end{aligned} \qquad (3)$$

Besides the EDCs of noiseless and noisy RIR obtained by the Schroeder's backward integration, Fig. 2 also shows the ALS RIR obtained by the moving average method. It can be seen that the noisy ALS RIR has different shape than the

noisy EDC. The effects of cumulative summing of noise and finite upper limit of integration are not present in the former curve, that is, in the ALS RIR.

IV. Method of Research

For the research purpose, noiseless RIRs are synthesized using the image source method (ISM) [12]. Noisy RIRs are generated by adding white or pink noise of different levels to the noiseless RIRs. Fig. 3 shows the waveforms of one of noisy and noiseless synthesized RIRs used in the analysis.

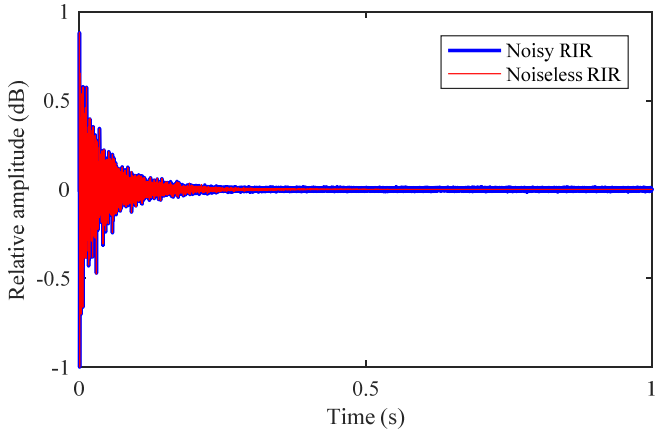

Fig. 3 Waveform of noisy and noiseless synthesized RIRs used in the analysis.

The question is how to evaluate the decay curves. A curve generated from a noiseless RIR by the Schroeder's backward integration is defined as the target or reference curve. Deviation of any considered decay curve from the reference one is calculated as a root mean square error (difference) given by

$$RMSE = \sqrt{\frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{n}} \qquad (4)$$

where $\hat{y}_i$ are the data points of the reference curve, y_i are the data points of the considered decay curve, and n represents the number of points (time interval) where RMSE is calculated, called RMSE interval.

This time interval is determined in the following way: for every particular RIR and third-octave frequency band, the ALS RIR (generated using averaging window of length of 1000 data points) is applied for the RMSE interval calculation. The lower RMSE interval limit is set in the time point where the reference EDC has a decay level of -5 dB, this is t_{low}. The difference between the considered ALS RIR and reference EDC is positive going from the curve end. At the first cross of these curves, their difference changes the sign. This time point is set as an initial the end of the RMSE interval, that is, the initial t_{up}. Then, the decay level of the reference EDC is determined in the initial t_{up}. This decay level is then reduced by the margin, which can be a few decibels yielding L_{RMSE}. Here, the value of 2 dB is used for the margin. The final the end of the RMSE interval (the final t_{up}) is set at the time point where the reference EDC has the decay level equal to L_{RMSE}. Number of points present in the RMSE interval between t_{low} and t_{up} is equal to n. The described procedure for determination of RMSE interval is illustrated in Fig. 4. The determined RMSE interval is then used for various averaging window lengths applied to that particular RIR and in that particular frequency band.

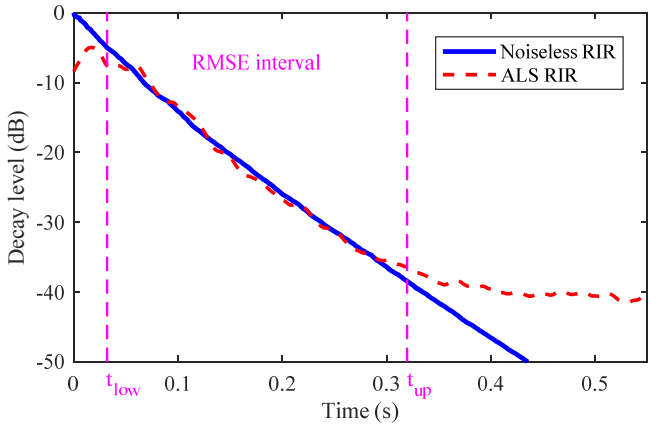

Fig. 4. Illustration of determination of RMSE interval where the RMSE between the considered (ALS RIR) and the reference EDC is calculated.

A number of data points that are averaged or averaging window leading to a single averaged value is considered to be an averaging parameter. The effects of changing this parameter are analyzed here. The analysis is carried out on both broadband RIRs and RIRs filtered in third-octave bands. The goal is to find an optimal averaging window length leading to the smallest deviation of this curve (ALS RIR) from the reference one, which is quantified by the RMSE.

During the analysis, besides the deviation of the considered decay curve from the reference one (RMSE), time necessary for performing the averaging is taken into account, too. Processing such as averaging was not possible some time ago due to limited processing power. Now, the processing power is considerably higher, and some new possibilities become available. The research was carried out on the PC computer under the Windows 7 Professional operating system. PC configuration includes Intel Core i7 870 CPU and 8GB of DDR3 ram memory.

The programming part of this research is realized using the software package Matlab. For that purpose, relevant Matlab scripts for the RIR synthesis, processing of RIRs in order to generate EDCs, evaluation of the decay curves and plotting the results are developed. Possibilities of generating an appropriately smooth decay curve by the averaging are first explored using the broadband RIRs. Then, the procedure is applied to the RIRs filtered in third-octave bands in the frequency range from 100 Hz to 8 kHz.

V. AVERAGING RESULTS

Although a number of RIRs are used for the analysis, the results are here illustrated using a representative example of a RIR. When the mean average method is applied to this broadband RIR, the generated ALS RIRs for 6 different averaging windows are presented in Fig. 5. These windows contain 100, 500, 1000, 2000, 5000 and 10000 data points. The same averaging windows are chosen for other figures given in this paper.

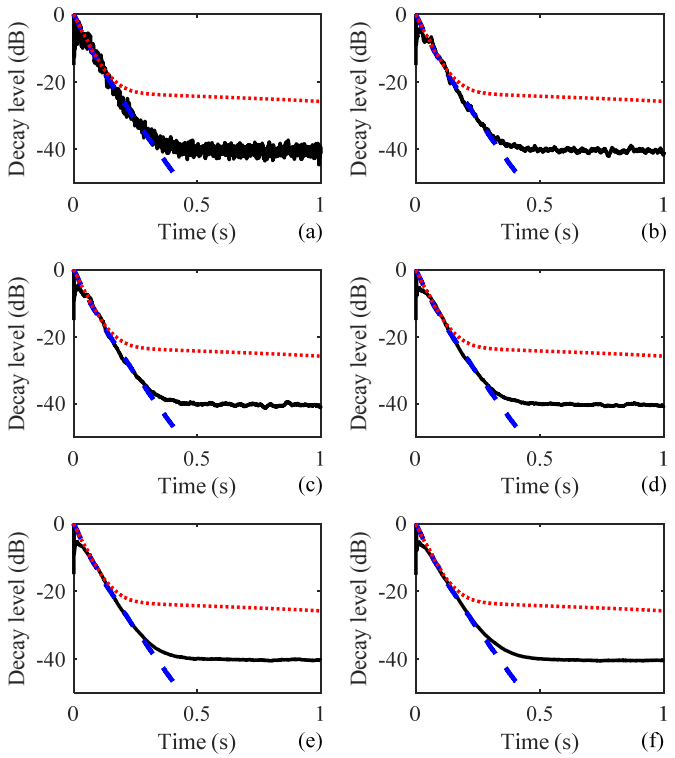

Fig. 5 Decay curves obtained from broadband synthesized RIR: reference EDC (- - -), noisy EDC (· · ·) and ALS RIR (—) generated by using averaging window of 100 (a), 500 (b), 1000 (c), 2000 (d), 5000 (e) and 10000 (f) data points.

Strong fluctuations of the LS RIR (see Fig. 2) are reduced by averaging in the ALS RIR. By increasing the averaging window length, the fluctuations become smaller and smaller. However, at the same time, due to specific averaging explained by (3), a certain disturbance appears at the beginning of the ALS RIR. This disturbance becomes more prominent with an increase of the averaging window length. For the averaging window of 100 data points, this effect is hardly visible.

When the moving average method is applied to the LS RIR obtained from the RIR filtered in third-octave bands at low frequencies, two above mentioned behaviors of reduction of fluctuations and appearance of disturbance in the ALS RIR beginning are also noticed, see Fig. 6. At low frequencies, even the reference EDC has certain fluctuations due to the nature of response decay in this frequency range. These fluctuations are not filtered out by the averaging. However, the reverberation and random fluctuations present in both the reverberation decay and noise are reduced by the averaging.

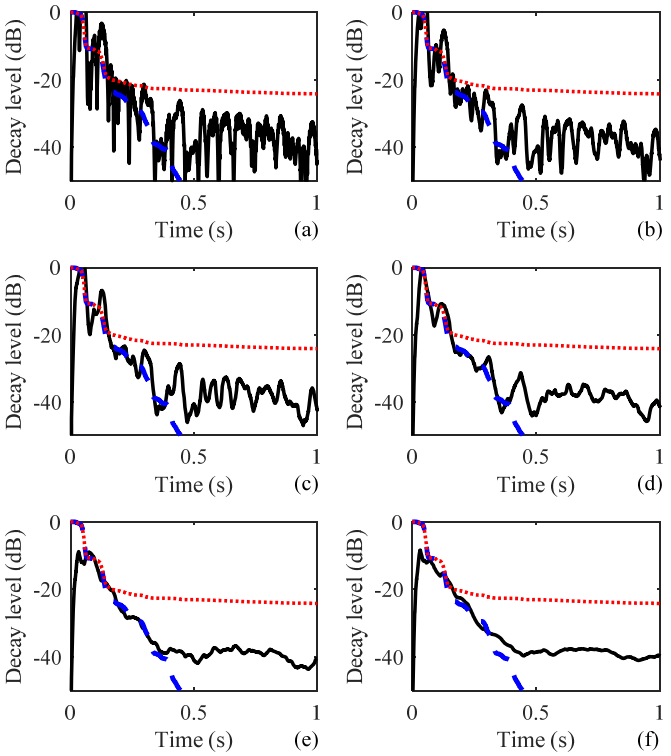

Fig. 6 Decay curves obtained from synthesized RIR filtered in the third-octave band at 200 Hz: reference EDC (- - -), noisy EDC (· · ·) and ALS RIR (—) generated by using averaging window of 100 (a), 500 (b), 1000 (c), 2000 (d), 5000 (e) and 10000 (f) data points.

Fluctuations of the LS RIR generated from the RIR filtered in third-octave bands at higher frequencies are reduced by the averaging even more efficiently. The results in one third-octave band are presented in Fig. 7. The situation regarding two noticed behaviors (fluctuation reduction and disturbance at the curve beginning with an increase of the averaging window length) is the same here.

Observing Figs. 5, 6 and 7, it can be concluded that the ALS RIRs coincide rather well with the reference EDCs in the RMSE interval. The deviations are somewhat larger at low frequency ranges where the ALS RIRs do not follow the reference EDCs completely. However, it seems that the decay rates of the ALS RIRs are very close to those of the EDCs. This will be quantified through the RMSE in the rest of the section.

Besides the disturbance of the ALS RIR at its beginning, the deviation of this curve from the reference EDC becomes larger with an increase of the averaging window in vicinity of the knee. This point represents the intersection of the reverberation decay and noise level. This is a consequence of taking more and more data points where the noise is dominant for averaging when a particular data point is close to the knee.

One more important observation from these figures is that the dynamic range of the ALS RIRs is considerably greater than the corresponding dynamic range of the noisy EDCs obtained by the Schroeder's backward integration. This is an

expected result since there is no cumulative summing of noise in the ALS RIRs.

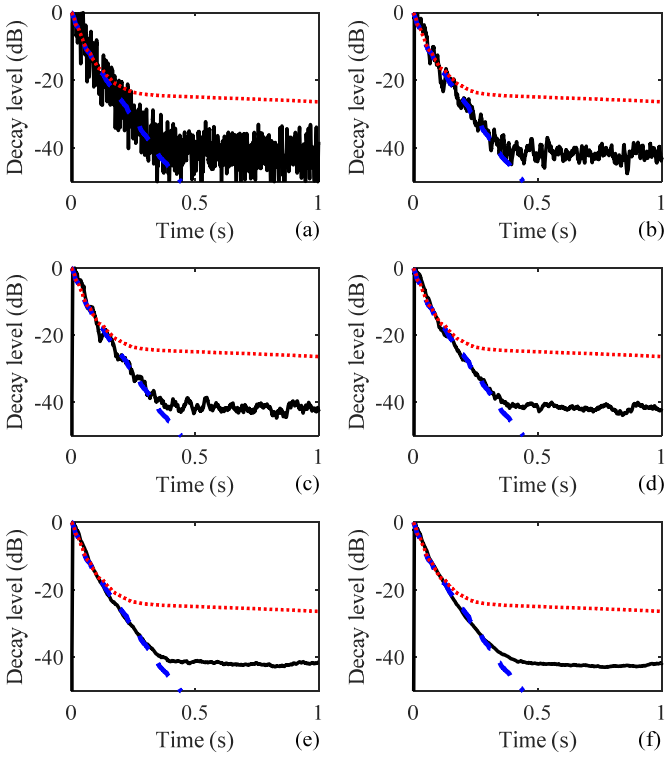

Fig. 7 Decay curves obtained from synthesized RIR filtered in the third-octave band at 2000 Hz: reference EDC (- - -), noisy EDC (· · ·) and ALS RIR (—) generated by using averaging window of 100 (a), 500 (b), 1000 (c), 2000 (d), 5000 (e) and 10000 (f) data points.

Deviation of an ALS RIR from the reference EDC is quantified by the RMSE calculated in the RMSE interval as described in the method section. This error for the representative example of RIR for both broadband response and response filtered in third-octave bands from 100 Hz to 5 kHz is given in Fig. 8. The first observation is that the RMSE is reduced by an increase of the averaging window length. This is the case in every frequency band, but also in the broadband RIR. The error reduction is the largest in the beginning of these plots, with initial increase of the averaging window length from several tens of data points to several hundreds of data points. However, after this initial reduction of the RMSE, there is a region of saturation of the RMSE reduction, and at the end of the plots the RMSE is even increased with an increase of the averaging window length. The saturation region is reached for shorter average window lengths at higher frequencies, see Fig. 8(c). The shape of presented RMSE at higher frequencies contains relatively wide plateau.

The previous observation indicates that there is an optimal length of the averaging window, that is, an optimal number of data points to be averaged. Now, the question is whether this optimal averaging window length is the same for all frequency bands or not. At low and mid frequencies, the optimal averaging window length is from 5000 to 10000 data points. With an increase in frequency, this optimal window length becomes a bit smaller, and it ranges from a few thousands to 5000 data points. For broadband RIR, optimal length of the averaging window is about 5000 data points. Taking all these data into account, it can be concluded that the optimal length of the averaging window is about 5000 data points in the considered situation.

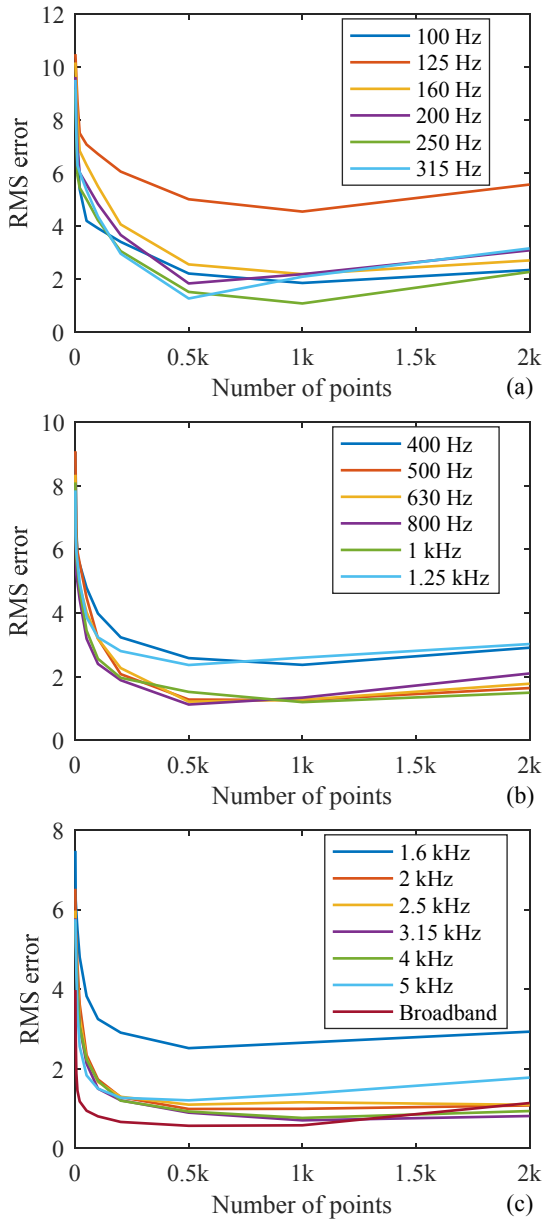

Fig. 8 RMSE calculated in the RMSE interval as RMS error between the considered ALS RIR and reference EDC for both broadband RIR and RIR filtered in third-octave bands.

Regarding the processing time necessary for moving average method, the longest time is required for the longest averaging window length of 20000 data points. For this window length, the averaging lasts about a few tens of seconds per frequency band. Having 18 frequency bands in overall, the processing for all bands will last about 5 minutes.

VI. Conclusion

An EDC generated by the Schroeder's backward integration exhibits drawbacks of cumulative summing of background noise and finite upper limit of integration of a noisy RIR. These drawbacks can be (fully or at least partly) overcome by generating the decay curve using an alternative method based on averaging of a logarithmic squared RIR (LS RIR). The averaging reduces the fluctuations of LS RIR, and at the same time, it enables generation of the decay curve of larger dynamic range than the one generated by the Schroeder's integration. This curve has a certain disturbance at its beginning since there is no full averaging window for data points close to the LS RIR start. Besides, the averaged LS RIR (ALS RIR) can be curved in vicinity of the knee due to effect of averaging noise points together with reverberation decay points when the averaging window is large enough.

By increasing the averaging window length (number of data points of the LS RIR to be averaged), fluctuations of the LS RIR are reduced to a higher extent. However, the disturbance effect at the decay curve (ALS RIR) beginning and curvature close to the knee indicate that the averaging window should not be too large. The investigation presented here shows that the optimal averaging window length is about 5000 data points for the analysed cases. The proposed procedure will be applied to the measured RIRs in the next phase of research.

Noise Control Solution of the HVAC System

Marko Ličanin, Darko Mihajlov, Momir Praščević, and Ana Đorđević

***Abstract*—Building construction trends in designing the modern buildings very often exploit the use of the centralized Heated Ventilated Air Conditioning (HVAC) units to maintain optimal water and air condition. These systems need fair amount of space and require significant airflow to operate properly. Being often placed at the open areas, where airflow is sufficient, they create the high noise levels that influence the living environment. This becomes a challenge for the noise control engineers to find the proper solutions for attenuating the generated noise, without enclosing the space around HVAC units. To account for the necessary airflow while still perform noise reduction, here, a simulation of the particular type of segmented barrier is done. Results of the simulation are, together with a noise measurements, then applied on the real case scenario of the HVAC units noise control. Results showed that the simulated barrier can be used as solution for this type of problems.**

***Index Terms*—Noise Control, Acoustic Barrier, COMSOL, HVAC, Absorption**

I. Introduction

Heated Ventilated Air Conditioning (HVAC) units are very often integral parts of modern buildings, especially those that have a community purposes (offices buildings, supermarkets, shopping malls, hospitals etc.). Those units are very convenient in the term of the efficiency, size, maintenance and heating/cooling power outputs, thus representing the logical choice instead of using many local wall mounted units. However, in many cases these types of machine systems are positioned on the rooftops of buildings, where the best cooling of the sub units, such as fans, pipes and compressors is provided. To perform sufficient cooling, air intake and exhaust should be given enough airflow [1]. Since the HVAC units often move a massive amount of air around them, they can become a noise sources with a significant acoustic power. This parameter is usually provided in the technical data-sheets of the units, where normal operation mode is very often used as reference by technicians who mount the units. As a result, noise reduction is in many cases neglected.

Working load of the HVAC systems is largely influenced by the nature of climate in which they operates. During the hot summers and cold winters HVACs put more power into providing desired temperatures, working beyond the normal operational mode. This translates into generation of a higher noise levels, thus grater disturbance on the environment. This is especially prominent during the summer, where people in residential areas and office buildings tend to open windows and balconies for fresh air. Noise problem then becomes on of the biggest environmental disturbance and quick, as well as effective, engineering solutions are sought. Unfortunately very fast solutions can do more harm than good, increasing the costs and creating additional problems.

Engineering challenge when performing the noise control of the HVAC systems is to provide the proper noise attenuation [2, 3] while at the same time allow sufficient airflow for units subsystems cooling. This paper tries to address one of the possible solutions to the problem, that can be applied in different situations. These solutions are studied through the project that has be successfully implemented for the central office building of one international bank in Belgrade. After identifying the problem at the site location, a series of simulation has been performed in COMSOL that exploits certain geometry of absorption panels. Based on the chosen geometry and measured noise spectrum, an optimal metal perforated panels has been designed and noise reduction calculated. Placement of the panels has been observed in the 1:1 built 3D model, and in the cooperation with a construction engineer, supporting structure designed. After the construction and panel mounting is performed, measurements have been retaken, and results of the practical application observed. Although, there is a lot of technical documentation behind the realized project, this paper tries to summarize most important aspects of this particular noise control design.

II. Analysis of the Problem

The initial step of the project was the existing condition evaluation at the site. Machine elements are located in the support building, next to the office building of the international bank. Three HVAC units (chillers) are located next to each other in the technical area enclosed with three walls covered with metal sheets, and one partition consisting of the metal blinds. Here is no ceiling above and this area is considered as a rooftop. These three units create excessive amount of noise which creates disturbance in the office building across the small parking access street. Sketchup representation of the described situation is presented in figure 1. The evaluation step included initial measurements of the noise level that has been taken at several positions at the site using Norsonic Nor 140 sound analyzer. Three measurement positions have been chosen at 1m distance from the each of

the noise sources (1, 2 and 3 on Fig. 1), while three positions has been considered on the noise path near the affected building (4, 5, 6 on Fig. 1).

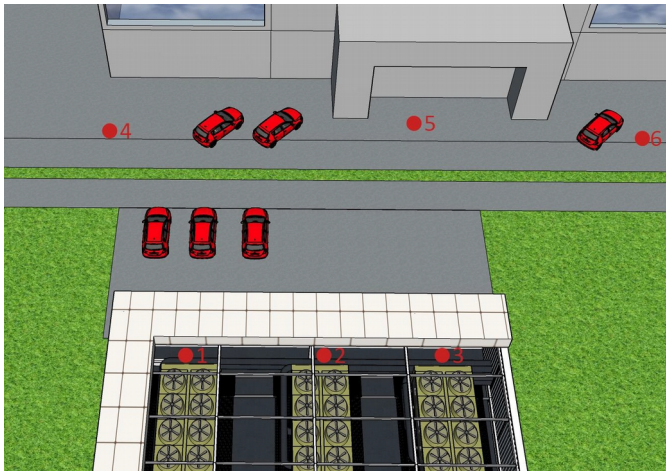

Fig. 1. Sketchup representation of the noise sources, affected office building and noise level measurement positions during the initial evaluation

Measurement interval has been set to 5 min, and measurements have been taken three times at each chosen position. HVAC units can be set in different operation modes and under the different output loads. For the measurement conditions, all of three chillers has been set to cooling and output load increased significantly beyond usual operation. This was done to account for the stationary noise that will be produced by the noise source during the hot summer days. To determine the equivalent noise disturbance, measurements would be done to account the all operational mode, and measurement time increased to at least 15 min [4]. However, for the purpose of establishing base line before noise control application, and evaluate relative noise level reduction after the noise control application, this measurement method was sufficient. Noise levels of measurement position 2 and 5 are presented in the Fig. 2 (top). Resolution of the observed noise levels is in the third octave bands.

In front of the units, measured noise level was similar for positions 1, 2 and 3, while for positions 4, 5 and 6 there was slight different in the spectrum due to the noise traffic. Even, though the street that separates the bank support facility and affected office building is somewhat secluded from the main road, noise influence from the parking zone was present. For this reason, background noise on positions 4, 5 and 6 has been also measured. However, the total broad spectrum noise level was not as different, as the variations in the spectrum. In front of the units (positions 1, 2 and 3), measurement showed between 79.8 dB and 81.8 dB, while at the street noise was 64.3 and 65.2 dB (positions 4, 5 and 6). When chiller units was turned off, background traffic noise levels were between 54.6 dB and 55.3 dB (positions 4, 5 and 6). After presenting the results to the investor, decision is made that noise control should provide at least of 8 dB of noise attenuation. The reason is that Belgrade is not yet acoustically zoned, but this is a process that will probably be executed in the near future. If the city area at the position of the bank office, area can become denoted as residential. In this case, all off the noise sources must not exceed 55 dB during the day and 45 during the night. By reducing more than 8 dB of noise, problem will be solved even by the most strict noise level regulations [5].

After the noise level evaluation, using the construction blueprint of the technical room, entire object has been made in 3D in 1:1 ratio so different engineering solutions can be visually exploited.

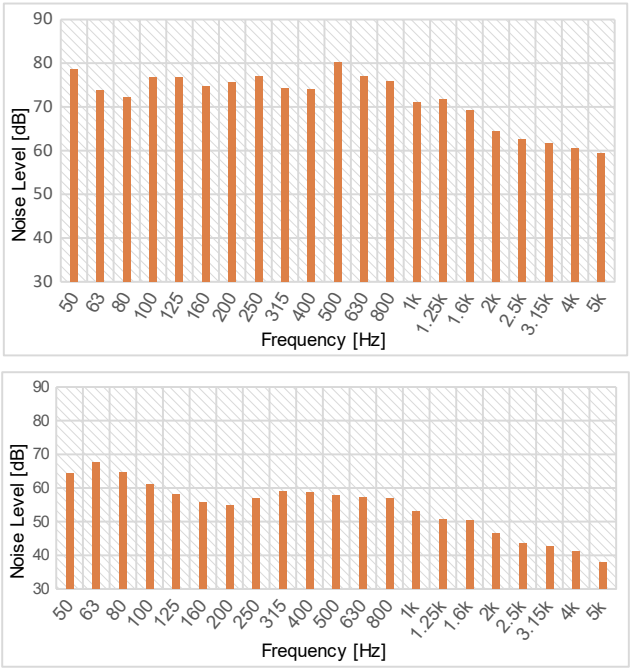

Fig. 2. Noise levels in third octave band, averaged per each band for three repeated measurements at position 2 (Top) and position 5 (bottom)

The engineering solution for this particular problem has been thoroughly observed from many different aspects. Air flow necessary for the proper operation of the HVAC subsystems has proved to be one of the major challenges. At one point, before the start of the project, chiller maintenance engineer was impatient and wanted a quick solution of the noise problem. As a result, hard styrodur barrier was installed which redirected the noise to the upper floors of the affected building and increased the temperature around the chillers. This influenced their operational stability. Eventually, barrier has been removed which created significant waste of time and effort, creating unnecessary costs.

III. DESIGN OF THE NOISE CONTROL SYSTEM

To solve the problem of the needed air transparency, investigation of the multi segment barrier has been considered. Traditional single segment barrier has proved to be of no use in this kind of situation. It has been clear from the start that some portion of the noise has to be redirected to a longer path, which will naturally attenuate the sound energy. This has been exploited, as the location of another office building where redirection was intended lies at much longer air distance from the HVAC units. At the entrance of this building noise level has been dominant by traffic along nearby busy street.

A. *Simulation*

For the purpose of the investigation, a simulation of the noise propagation has been performed in COMSOL Multiphysics. Designed segmented barrier that was tested in the simulation is composed of absorption metal perforated panels angled at the 25 degrees from the barrier axis. Fig. 3 shows the simulation results in the case where there was no barrier, and the case where barrier is included. Results are presented at frequencies of 100 Hz (Fig. 3 - top), 500 Hz (Fig. 3 - middle) and 1 kHz (Fig. 3 – bottom). As it can be seen, when barrier is placed, more noise energy is contained inside the technical room where chillers are placed. This is especially observable at middle to high frequency. Beside presented results, simulation has been done in much higher resolution of frequencies, and only some of them are presented here. It is important to note that during the simulation, no absorption on the segmented barrier has been set and only noise propagation is observed.

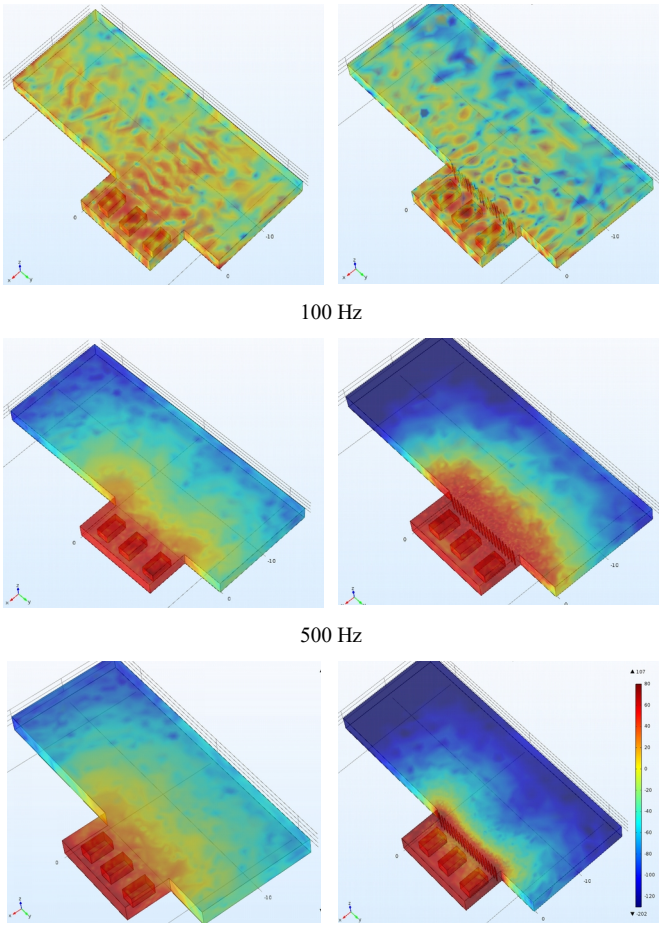

Fig. 3. Simulation results the sound propagation for different frequencies, without barrier (left) and with barrier (right)

Beside observation of the sound propagation, another simulation has been preformed using Raytrace method. As mention before, some of the noise has to redirected to the longer path and simulation has been used for evaluation of the geometry of the segmented barrier. In Fig. 4, results has been presented in a way that left portion of the figures represent the case without segmented barrier (barrier influence is disabled), while on the right side situation with barrier is shown (barrier is enabled). Ray trace metod works by releasing the vectors from the noise source in all aof the directions. By following the paths of these vectors, one can observe geometrical propagation of the sound at the chose n frequency. In presented simulation, a 10 000 rays ahas been released and the reflection influence of barrier redirection of sound observed. Main goal is to evaluate the number of rays, as well as the ray intensity that reaches the noise receiver after a certain points in time. Simulation length is 120 ms, with a 4 steps 30 ms each. In Fig. 4, first row is a situation after the first step, where each subsequent row represents the another step. As it can be observed, placement of the segmented barrier (Fig. 4 - right) truly redirects the sound to a longer path.

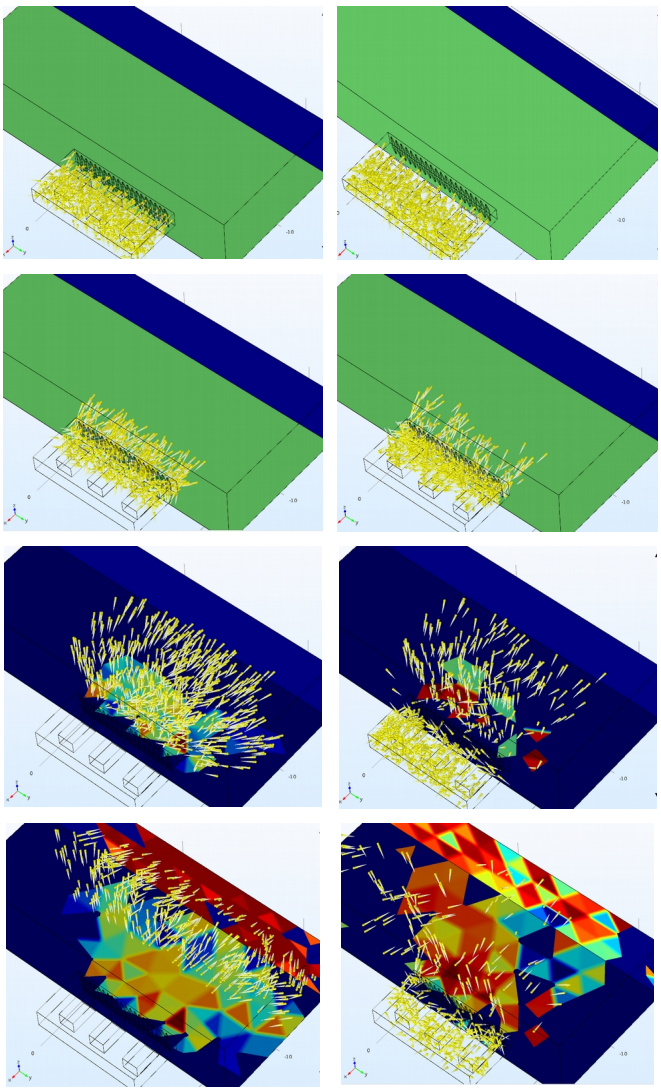

Fig. 4. Simulation results the segmented barrier noise redirection in the case where barrier is disabled in the model (left) and enabled (right). First step (0 ms), second step (60 ms), third step (90 ms) and fourth step (120 ms) shows the flow of the simulation.

B. *Segmented barrier*

Simulation results has confirmed that the assumed geometry of the segmented barrier can be used for solving the problem of the HVAC noise. To maximize the effectiveness

of the barrier, metal perforated panels has to be designed as well. The process of calculating the absorption coefficient of the perforated panels is well known in literature, and it not a subject of this paper. This process accounts for the front perforated panel thickness, hole repeat distance, hole radius, cavity depth, absorber thickness, air space thickness and flow resistivity[2, 3, 5]. Absorption can be calculated for each third octave band, and frequency dependent curve fitted to match the noise spectra of the HVAC, obtained by measurements in the initial phase of the project. Cross section of the designed metal perforated absorption panel (top), and its absorption coefficient (bottom) are presented in Fig. 5. Panel is filled with the mineral wool of 30 kg/m density.

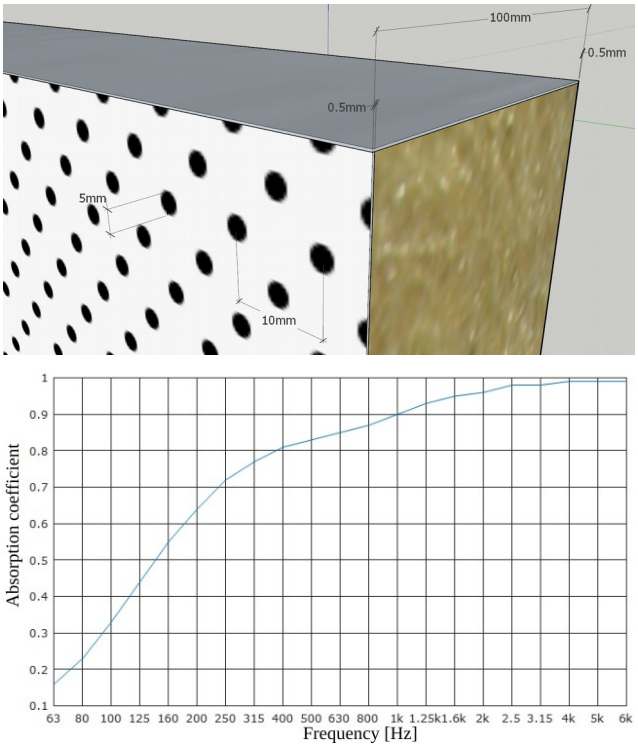

Fig. 5. Designed metal perforated panel cross-section (top) and the absorption coefficient curve (bottom)

Barrier is composed by connecting multiple panels using the metal construction material to form the rigid cage that will provide the sufficient static to the weight of the panels. In the design process, another segmented barrier has been consider. To ensure that noise generated by the fans of the chiller units will not reach the upper floors of the affected building, this additional barrier has been included on the top of the existing metal support beam structure on the site. Beside the absorption effect, it will also redirect the noise towards the sky. Sketchup representation of both of these barriers is presented in Fig. 6. For the easier observation, the rooftop and the upper barrier is removed from the 3D model (Fig. 6 – top). Support structure where upper barrier is placed is also visible on the Fig. 6. This metal beam structure is responsible for the static of the entire roof segment. The construction consultant has calculated that even with a strong wind stress on the support beams there will be no disturbance of the structural integrity of this section. If this has not been the case, additional support structure would have to be built.

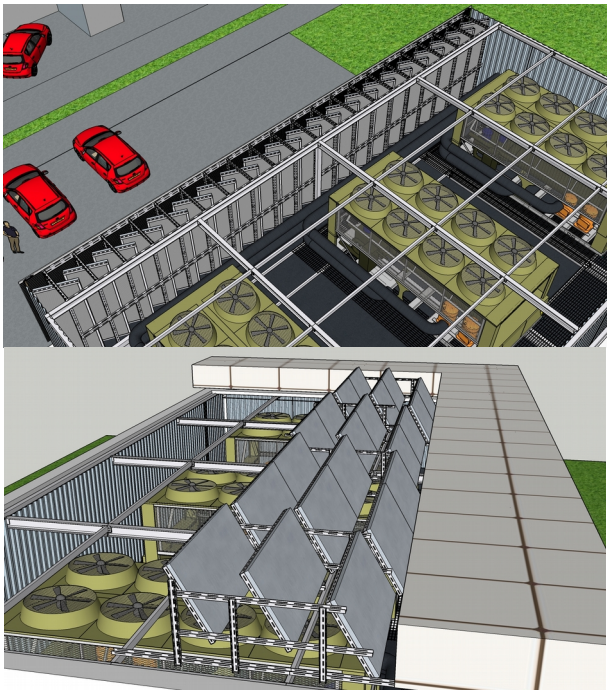

Fig. 6. Graphical representation in 3D of the lower barrier (top) and the barrier above the chiller (bottom)

IV. RESULTS

After the construction works and barriers mounting has been finished, validation process took place. This has been done by retaking all of the measurements in the same way as in the initial stage. Measurements has been performed in six positions with a 5 min averaging. For each position, noise level has been recorded three times and values averaged. HVAC units as a noise source has been set under the same working load as it was the case at the beginning of the process, thus the stationary noise conditions were established. At the positions 4, 5 and 6, background noise has been also measured, where chiller units were turned off. This has been done to determine the traffic noise level. If the noise levels of the background noise are similar to the noise levels when HVAC units are turned, at measurement positions 4, 5 and 6 (see Fig. 1), this would mean that the background noise is dominant. In this situation, for the project validation purpose, only measurement positions 1, 2 and 3, on the side of the lower barrier opposite to the noise sources positions, can be used to evaluate the effectiveness of the project. Results of the validation process can be observed in the Table I. In all of the measurement positions, noise level has been reduced more than 9 dB. Comparison of the background noise during the first and second measurements (measurement positions 4, 5 and 6), as well as the resulting noise level when units are working, is presented in Table II. We observe that background noise levels are consistent between measurements, which indicates that there was no significant change in the traffic density at this particular location during noise analysis. It is also very interesting to see that resulting noise levels after the application of the noise control are within the boundaries of the background noise as well. This is yet another proof that

project has been successful, as the noise level in the measurement positions will be masked by the background traffic noise. In the Fig. 7, several photos of the mounted barriers at the site are presented.

Fig.7. Documented photos during and after the mounting process

TABLE 1
MEASUREMENT RESULTS OF THE VALIDATION. COMPARISON BETWEEN INITIAL AND VALIDATION STAGE OF THE PROJECT

Meas. position	1.	2.	3.	4.	5.	6.
	Noise level [dB]					
Initial phase	81.8	79.8	80.1	64.4	65.2	64.3
Validation phase	71.9	70.1	70.2	54.4	54.8	54.3
Noise reduction	9.6	9.7	9.9	10.0	10.4	10.0

TABLE 2
COMPARISON OF THE BACKGROUND NOISE BETWEEN INITIAL STAGE, VALIDATION STAGE AND NOISE LEVEL WHEN NOISE SOURCE IS ACTIVE

Meas. position	4.	5.	6.
	Noise level [dB]		
Initial phase background noise	55.2	53.2	54.1
Background noise levels	53.8	54.8	54.2
Validation phase noise HVACs are active	54.4	54.8	54.3

V. CONCLUSION

When designing the noise control system around HVAC systems, there are many challenges that creates constraints and significantly influence the flow of the project. Here, a study case of one of the noise control projects is described from initial steps to the installation and finally validation. Measurements in the first stage has provided useful inputs on the noise level, spectrum of the noise and constraints related to the HVAC units. In the simulation stage, noise propagation and the behavior of the proposed segmented barrier has been observed. Gather data showed promising results that was used in the following stage of designing the physical barrier and absorption panel. After the material production and mounting stage, validation process has been performed by measuring noise levels in the same way as in the first stage. Results showed that total noise reduction achieved, at each of the measurement positions, is more than 9 dB. This exceeds the expectation of the project and proves the feasibility of this type of noise control application. Different types of segmented barrier geometry and configuration could provide even better results, which is a topic for the future research.

ACKNOWLEDGMENT

This paper is presented as a part of the projects "Development of the methodology and means for noise protection in urban areas" (No. TR - 037020). Authors would like to express gratitude to the Ministry of education, science and technological development of Republic of Serbia, for the financing support in these research.

Određivanje zavisnosti ostvarene vrednosti izolacione moći fasadnih pregrada od tipa izvora u urbanim sredinama

Miodrag Stanojević, Miloš Bjelić, Dragana Šumarac Pavlović, Miomir Mijić, Tatjana Miljković

***Apstrakt*— Oblik ugaone raspodele incidentne energije utiče na ostvarenu vrednost izolacione moći fasadne pregrade. U opštem slučaju oblik ove raspodele nije poznat. Primenom mikrofonskog niza i algoritama za prostorno-vremensku obradu signala moguće je eksperimentalno utvrditi funkciju gustine verovatnoće ugaone raspodele incidentne energije na fasadi zgrada. U urbanim uslovima postoji veliki broj izvora različitog tipa, spektralnog sadržaja buke koju emituje, snage itd. Zbog toga je uvedena pretpostavka da oblik ugaone raspodele, a samim tim i ostvarena izolaciona moć pregrade, zavisi od tipa izvora buke. U ovom radu prikazana je upotreba metodologije za eksperimentalno određivanje ugaone raspodele sa ciljem da se posmatraju razlike u ostvarenim vrednostima izolacione moći iste pregrade prilikom delovanja različitih tipova zvučnih izvora u urbanim uslovima. Ostvarena izolaciona moć izračunata je korišćenjem dobijenih funkcija gustine raspodele i pokazano je da se ona menja u vremenu i zavisi od trenutne strukture zvučnog polja. Takođe, izvršeno je poređenje ostvarenih vrednosti izolacione moći izračunatih za pojedinačne događaje i izolacione moći izračunate za duži vremenski period. Na taj način moguće je sagledati uticaje pojedinih tipova izvora na generalno stanje zvučne izolacije fasada.**

***Ključne reči*— lokalizacija, mikrofonski niz, proračun zvučne izolacije, saobraćajna buka, ugaona raspodela, urbani uslovi.**

I. UVOD

U literaturi je pokazano da vrednost zvučne izolacije, odnosno izolacione moći pregrade *R*, zavisi od frekvencije i ugaone raspodele incidentne energije [1-2]. Raspodela incidentne energije spoljašnje buke u opštem slučaju nije poznata. Uniformna ugaona raspodela je polazna pretpostavka u radovima u kojima se izračunava izolaciona moć pregrade. U literaturi se mogu pronaći merenja zvučne izolacije fasada korišćenjem standardizovanih tehnika merenja pomoću zvučnika i pomoću saobraćaja, i pokazano je da vrednosti $D_{2m,nT}$ mogu varirati i do 8 dB [3]. Izvesno je da ove varijacije potiču od razlike između incidentnih uglova realne saobraćajne buke i incidentnog ugla 45±5°, koji se koristi u tehnikama merenja sa zvučnikom [4]. Na osnovu toga zaključuje se da ugaona raspodela incidentne energije zavisi od konfiguracije terena u kom se analizirana zgrada nalazi. Konfiguraciju terena određuje širina ulice, broj saobraćajnih traka, prisutnost naspramnih zgrada, visina zgrada i sl.

Upotrebom optimizovanog neregularnog mikrofonskog niza i algoritama za prostorno-vremensku obradu signala moguće je odrediti nepoznate ugaone raspodele incidentne energije spoljašnje buke na fasadi zgrada u urbanim uslovima [5, 6]. Izvršeno je nekoliko merenja u urbanim uslovima kako bi se sagledale razlike u oblicima ugaonih raspodela za različite konfiguracije terena ispred ravni fasade [7]. Eksperimentalno određene ugaone raspodele incidentne energije spoljašnje buke i poznate vrednosti građevinskih parametara korišćene su za predikciju izolacione moći fasadnih pregrada [8, 9]. Pokazano je da vrednosti izolacione moći mogu varirati i do 10 dB za istu pregradu u različitim uslovima za pojedinačne frekvencijske opsege i oko 5 dB za merodavne vrednosti. Na osnovu oblika ugaonih raspodela definisane su kategorije konfiguracija terena u urbanim uslovima. Pokazano je da merna mesta koja pripadaju istoj kategoriji imaju sličan uticaj na izolaciona svojstva fasadnih pregrada [7].

U ovom radu analiziran je uticaj pojedinačnih izvora buke na ostvarene vrednosti izolacione moći pregrade. U urbanim uslovima postoji veliki broj izvora različitog oblika, veličine, snage i spektralnog sadržaja buke koji emituju. Zbog toga će se javiti razlike u oblicima funkcija gustina verovatnoće ugaonih raspodela incidentne energije na fasadnoj pregradi za različite tipove izvora. Različiti oblici ugaonih raspodela mogu dovesti do toga da ista fasadna pregrada ispoljava različita izolaciona svojstva u zavisnosti od toga koji izvori buke trenutno postoje ispred fasade. Za jednu situaciju iz [7] definisano je nekoliko tipova zvučnih izvora koji su snimani mikrofonskim nizom, a zatim je nad snimljenim signalima primenjen algoritam za prostorno-vremensku obradu signala pomoću koga je određen oblik ugaonih raspodela. Izvršen je proračun ostvarenih vrednosti izolacione moći za dva tipa materijala od kojih je izrađena pregrada, a zatim sprovedena analiza dobijenih rezultata.

Motivacija za ovo istraživanje je potreba da se smanji vreme potrebno za dobijanje ugaonih raspodela incidentne energije na mernom mestu. Da bi se predloženom metodom odredila ugaona raspodela potrebno je izvršiti snimanje buke mikrofonskim nizom u dužem intervalu vremena. Nakon toga potrebno je primeniti algoritme za obradu signala sa mikrofonskog niza kako bi se dobili oblici ugaonih raspodela. Vremenska i računska kompleksnost ovog

Dragana Šumarac Pavlović – Elektrotehnički fakultet, Univerzitet u Beogradu, Bulevar kralja Aleksandra 73, 11020 Beograd, Srbija (e-mail: dsumarac@etf.rs).

Miomir Mijić – Elektrotehnički fakultet, Univerzitet u Beogradu, Bulevar kralja Aleksandra 73, 11020 Beograd, Srbija (e-mail: emijic@etf.rs).

Tatjana Miljković – Elektrotehnički fakultet, Univerzitet u Beogradu, Bulevar kralja Aleksandra 73, 11020 Beograd, Srbija (e-mail: tm@etf.rs).

postupka direktno je srazmerna trajanju snimljenog signala. Ideja je da se izvrši snimanje ključnih događaja koji se javljaju na toj lokaciji, da se izvrši određivanje oblika ugaone raspodele za te događaje i da se na osnovu toga odredi ukupan oblik raspodele, odnosno ispoljena vrednost izolacione moći pregrade. Time bi se značajno smanjilo vreme merenja ali i vreme obrade signala. Ovaj rad predstavlja uvodno istraživanje u kome bi se sagledao uticaj pojedinačnih događaja na oblik funkcije gustine verovatnoće ugaone raspodele incidentne energije. Poređenjem oblika raspodele za pojedinačne događaje i oblika dobijenih za duže vremenske intervale snimanja moglo bi se doći do veze koja bi omogućila smanjivanje vremena potrebnog za izračunavanje globalnog oblika raspodele.

Rad je organizovan kako sledi. U drugom poglavlju prikazani su mikrofonski niz, algoritam za prostorno-vremensku obradu signala sa mikrofonskog niza, postupak za izračunavanje ugaone raspodele i model za proračun izolacione moći pregrade. U trećem poglavlju prikazana je postavka eksperimenata. U četvrtom poglavlju prikazani su rezultati i njihova diskusija. U poslednjem poglavlju izneti su zaključci.

II. METODE

A. Mikrofonski niz

Mikrofonski niz se u ovom radu koristi kao merni alat za određivanje lokacije izvora u prostoru u odnosu na fasadnu pregradu. Korišćen je planarni mikrofonski niz sa 24 mikrofona. Na osnovu referentnog spektra buke u urbanim uslovima [10] i spektra dobijenog merenjem u urbanim uslovima [11] određen je frekvencijski opseg od interesa za analizu. Pozicije mikrofona u mikrofonskom nizu izabrane su tako da se u opsegu od 250 Hz do 2000 Hz dobiju što bolje karakteristike mikrofonskog niza. Širina glavnog loba određuje prostornu rezoluciju sa kojom je moguće odrediti pozicije zvučnih izvora, dok nivo bočnih lobova određuje prisustvo lažnih zvučnih izvora u rezultatima lokalizacije [7]. Postupak optimizacije i konstrukcije mikrofonskog niza dat je u [7, 13-14].

B. Algoritmi za prostorno-vremensku obradu signala

Određivanje ugaone raspodele incidentne energije bazira se na određivanju lokacije pojedinačnih zvučnih izvora pomoću mikrofonskog niza i algoritama za obradu signala sa mikrofonskog niza. Bazični algoritmi za obradu signala, kao što su *Delay and sum* algoritam (*DaS*) [15] i konvencionalni *beamforming* algoritam (CB) [16], nisu pogodni za korišćenje u ovoj aplikaciji zbog male dinamike koja se pomoću njih može ostvariti. U ovom radu za lokalizaciju izvora u prostoru korišćen je algoritam DAMAS2 [17]. Ovaj algoritam koristi rezultat dobijen pomoću CB algoritma, a zatim dekonvolucionim postupkom eliminiše uticaj mikrofonskog niza iz rezultata. Na taj način ostvaruje se veća dinamika, odnosno mogu se lokalizovati izvori koji su značajno tiši od dominantnih zvučnih izvora [18]. Kao rezultat algoritma dobija se „zvučna mapa“ na kojoj je vrednost zvučne energije predstavljena bojama.

C. Izračunavanje funkcije gustine verovatnoće ugaone raspodele incidentne energije na fasadi

Ugaonu raspodelu incidentne energije spoljašnje buke na fasadi potrebno je odrediti za uglove u odnosu na normalu, koji ne odgovaraju direktno vrednostima uglova korišćenim u algoritmima za prostorno-vremensku obradu signala. To znači da je potrebno izvršiti svođenje prostornih uglova azimuta i elevacije na uglove u odnosu na normalu. Uglovi se nalaze u opsegu od 0° do 90°, gde ugao od 0° odgovara normali na fasadu, a ugao 90° ima krak koji je paralelan sa fasadom. Postupak za svođenje prostorne raspodele energije, izračunate pomoću algoritama i mikrofonskog niza, na ugaonu raspodelu u odnosu na normalu opisan je u [5-7].

D. Proračun izolacione moći fasadne pregrade

Izolaciona moć monolitne fasadne pregrade može se izračunati na osnovu sledeće jednačine [19]:

$$R = -10\log(\tau), \tag{1}$$

gde τ predstavlja koeficijent transmisije analizirane pregrade. Koeficijent transmisije se izračunava na sledeći način [19]:

$$\tau(\omega) = \sum_{k=0}^{\pi/2} \frac{p(\theta_k)}{\left(1+\eta\frac{\omega m'}{2\rho c}\left(\frac{f}{f_c}\right)^2\cos\theta\sin^4\theta\right)^2 + \frac{\omega^2 m'^2}{4\rho^2 c^2}\cos^2\theta\left(1-\left(\frac{f}{f_c}\right)^2\sin^4\theta\right)^2}, \tag{2}$$

gde je:

- η faktor gubitaka u materijalu
- f frekvencija za koju se računa izolaciona moć
- ω kružna učestanost
- ρc specifična impedansa u vazduhu
- f_c karakteristična frekvencija materijala
- θ incidentni ugao
- m' površinska masa pregrade
- $p(\theta)$ funkcija gustine verovatnoće ugaone raspodele incidentne energije na površini pregrade

Poznavanjem građevinskih karakteristika pregrade i frekvencijski zavisnih funkcija gustine verovatnoće ugaone raspodele incidentne energije moguće je izračunati vrednosti izolacione moći.

III. POSTAVKA EKSPERIMENATA

U ovom poglavlju biće prikazana postavka eksperimenata koji su realizovani u urbanim uslovima pomoću mikrofonskog niza, kao i važni parametri algoritama za prostorno-vremensku obradu signala.

Sl. 1. Profil ulice u kojoj je vršeno merenje i pozicija mikrofonskog niza na fasadi (Ulica cara Nikolaja II)

Mikrofonski niz se postavlja direktno na fasadu zgrade koja je okrenuta ka ulici. Na Slici 1 prikazana je merna situacija u kojoj se naspram zgrade na koju je postavljen mikrofonski niz nalazi parking za automobile i park sa zelenilom. Ova ulica je dvosmerna i u njoj se odvija gust saobraćaj koga čine automobili, motocikli i vozila javnog gradskog prevoza (autobusi i trolejbusi).

Ukupno trajanje merenja iznosilo je 30 minuta i u tom periodu ulicom je prošao veliki broj vozila svih navedenih tipova. Za potrebe ovog rada izvršeno je izdvajanje tipskih događaja iz ukupnog signala sa svih mikrofona mikrofonskog niza. Prilikom izdvajanja tipskih događaja održani su vremenski odnosi između signala sa pojedinačnih mikrofona. Pod tipskim događajima se podrazumeva: prolazak automobila (u jednoj saobraćajnoj traci ili obe), prolazak trolejbusa (u jednoj saobraćajnoj traci ili obe) i tišina (nema prolazaka motornih vozila). Događaji su izabrani tako da predstavljaju najčešće izvore zvuka koji se mogu javiti na prikazanom mernom mestu. Poslednji tip izdvojenih događaja sadrži zvukove koji nisu nastali u blizini mernog mesta već potiču od udaljenih zvučnih izvora do kojih nema optičke vidljivosti. Za svaki tip događaja izdvojeno je nekoliko signala. Za akviziciju signala sa mikrofonskog niza korišćena je merna oprema opisana u [7, 13]. Mikrofonski niz je udaljen od ulice 3 m. Frekvencijski opseg u kom se vrši lokalizacija zvučnih izvora je [250 2000] Hz. Elevacioni ugao θ i azimutni ugao φ uzimaju vrednosti iz opsega [80 160]° i [-90 90], respektivno. Opseg vrednosti prostornih uglova izabran je u skladu sa time gde se realno mogu naći zvučni izvori na ulici i njenoj neposrednoj okolini. Trajanje bloka T nad kojim se vrši obrada signala sa mikrofonskog niza je 20 ms. Broj iteracija u dekonvolucionom algoritmu iznosi 2000.

IV. Rezultati i diskusija

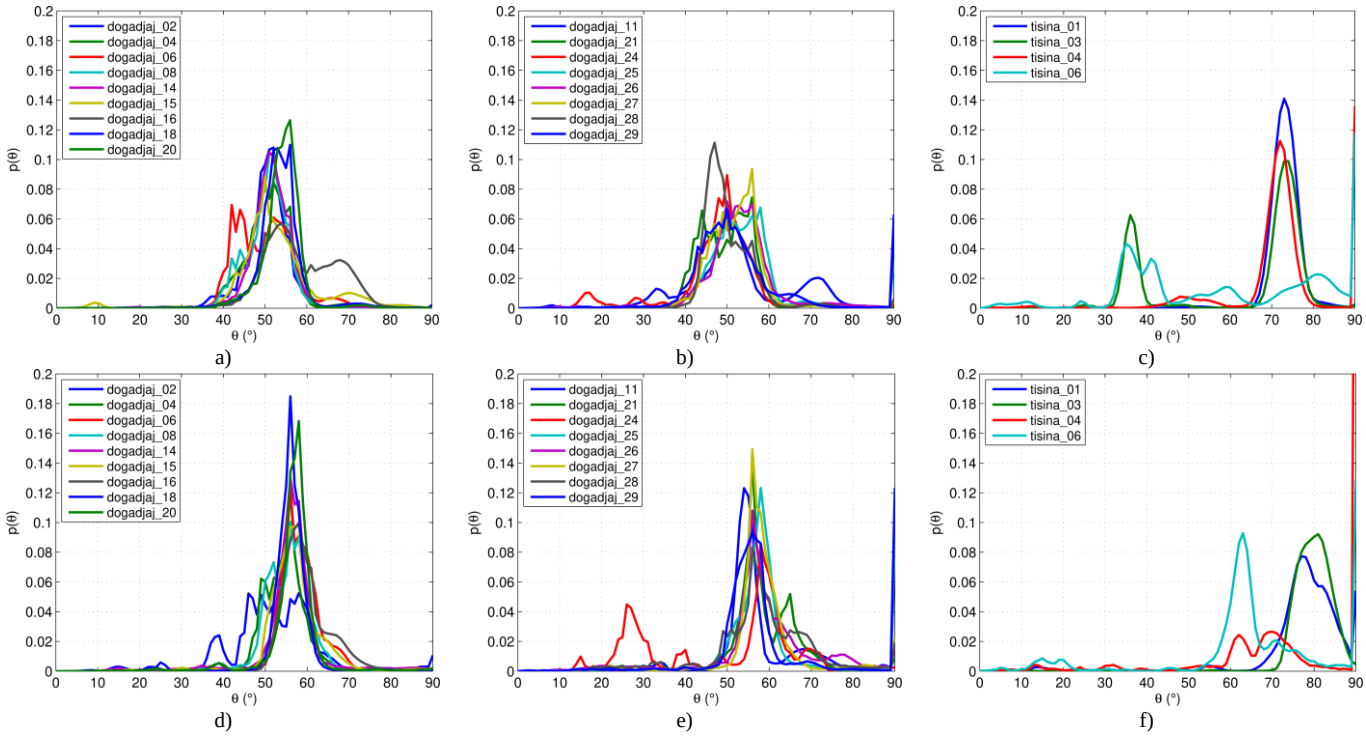
U ovom poglavlju prikazani su izgledi eksperimentalno određenih funkcija gustina verovatnoća ugaonih raspodela incidentne energije spoljašnje buke na fasadi zgrada. Raspodele su određene za različite događaje koji su se javili na mernoj lokaciji sa ciljem da se odredi razlika u ostvarenim vrednostima izolacione moći. Oblici raspodela izračunati su za 1/3 oktavne frekvencijske opsege, ali su zbog ograničenog obima rada prikazani samo neki frekvencijski opsezi. Zaključci koji su izvedeni za prikazane oblike važe i u ostalim opsezima. Na osnovu prikazanog modela za izračunavanje izolacione moći pregrade i eksperimentalno određenih ugaonih raspodela incidentne energije izračunate su ostvarene vrednosti izolacione moći fasadnih pregrada. U ovom poglavlju prikazane su vrednosti ostvarene izolacione moći fasadnih pregrada. Analizirane su fasadne pregrade izrađene od betona i stakla, kao dva najzastupljenija građevinska materijala u urbanim uslovima.

Na Slici 2 prikazani su izgledi funkcija gustina verovatnoće ugaonih raspodela incidentne energije na fasadi zgrade, prikazane na Slici 1. Izgledi raspodela dati su za tri tipa događaja i dva 1/3 oktavna frekvencijska opsega sa centralnim frekvencijama 1600 Hz i 2000 Hz. Analizirano je 9 događaja koji predstavljaju prolazak automobila, 8 događaja koji predstavljaju prolazak trolejbusa i 4 događaja koji predstavljaju ambijentalnu buku (tišinu). Ukupno trajanje snimaka prolaska automobila je 61 sekunda, prolaska trolejbusa 54 sekunde, a tišine 20 sekundi. Na Slikama 2 a) do c) uočavaju se određene razlike u oblicima raspodela za različite tipove događaja. Prolasci automobila saobraćajnicom ispred dovode do toga da se u ugaonoj raspodeli incidentne energije pojavljuje povećanje verovatnoće u oblasti prostornih uglova od 40° do 60°. Buka usled prolaska automobila nastaje zbog motora vozila, sistema za izduvne gasove i kontakta pneumatika automobila sa podlogom. Bliske pozicije dominantnih izvora prilikom prolaska automobila rezultovale su relativno malim opsegom prostornih uglova za koji se dobija povećana verovatnoća zvučne energije.

Trolejbusi kao drugi tip događaja koji se javljaju na ovom mernom mestu proizvode buku zbog kontakta pneumatika sa podlogom, elektromotora vozila kao i zbog kontaktne mreže preko koje se vrši napajanje vozila. Zbog veće prostorne raspodeljenosti izvora po površini vozila javlja se i širi opseg prostornih uglova u kojima se javlja povećanje verovatnoće nailaska zvučne energije. Prilikom prolaska trolejbusa taj opseg je širi nego prilikom prolaska automobila i iznosi od 30° do 70°. Posmatrajući treću vrstu tipskih događaja u kojoj nema prolaska vozila već samo postoji ambijentalna buka, primetno je da se oblast povećane verovatnoće zvučne energije razlikuje u velikoj meri u odnosu na dva prethodno pomenuta tipa događaja. Na Slici 2 c) se uočava više lokalnih minimuma i povećanje vrednosti verovatnoći u funkciji gustine raspodele za uglove bliske 90°. Povećanje verovatnoće u oblasti uglova bliskih 90° je značajno sa stanovišta vrednosti izolacione moći jer se za te incidentne uglove ostvaruje manja vrednost izolacione moći.

Na Slikama 2 d) do f) prikazane su funkcije gustine verovatnoće ugaone raspodele incidentne energije za tri tipa događaja i 1/3 oktavni frekvencijski opseg sa centralnom frekvencijom 2000 Hz. Razlike koje su postojale za prethodni frekvencijski opseg važe i u ovom slučaju. Izvesna odstupanja postoje u tome što su opsezi u kojima se javlja povećana verovatnoća zvučne energije pomereni za nekoliko stepeni ka većim vrednostima uglova. Na Slici 2 f) uočava se da postoji dominantna energija koja pogađa fasadu pod uglovima koji su bliski 90°, za razliku od slučaja prikazanog na Slici 2 c) kod koga je zvučna energija bila više distribuirana. Drugi i treći tip događaja, u odnosu na prvi događaj, imaju povećanu verovatnoću za prostorne uglove bliske 90°. To znači da će vrednost izolacione moći za ove događaje potencijalno biti manja za posmatrane frekvencijske opsege.

Izolaciona moć monolitne pregrade zavisi od funkcije gustine verovatnoće ugaone raspodele incidentne energije pa će razlike u oblicima ugaonih raspodela za analizirane događaje dovesti do toga da će ista fasadna pregrada ispoljiti različita izolaciona svojstva. Na Slici 3 punim crnim linijama prikazane su ostvarene vrednosti izolacionih moći fasadnih pregrada u slučaju kada je funkcija gustine verovatnoće incidentne energije određena na osnovu snimka od 30 minuta. Gornji red na Slici 3 predstavlja frekvencijsku zavisnost vrednosti izolacione moći betonske pregrade debljine 16 cm, dok donji red na istoj slici predstavlja frekvencijsku zavisnost vrednosti izolacione moći fasadne pregrade izrađene od stakla debljine 5 mm.

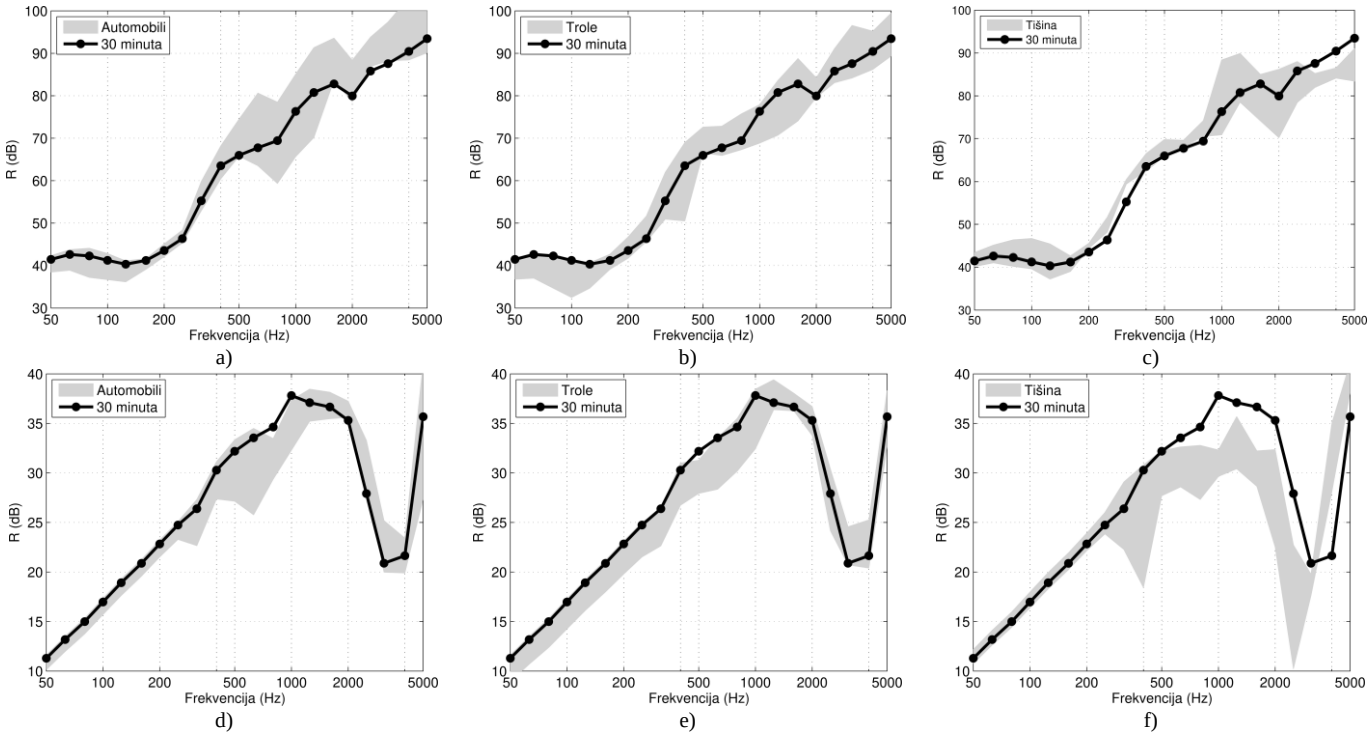


Sl. 2. Funkcije gustine verovatnoće ugaone raspodele incidentne energije spoljašnje buke za izdvojene događaje i 1/3 oktavne frekvencijske opsege: a) automobili 1600 Hz, b) trolejbusi 1600 Hz, c) tišina 1600 Hz, d) automobili 2000 Hz, e) trolejbusi 2000 Hz, f) tišina 2000 Hz

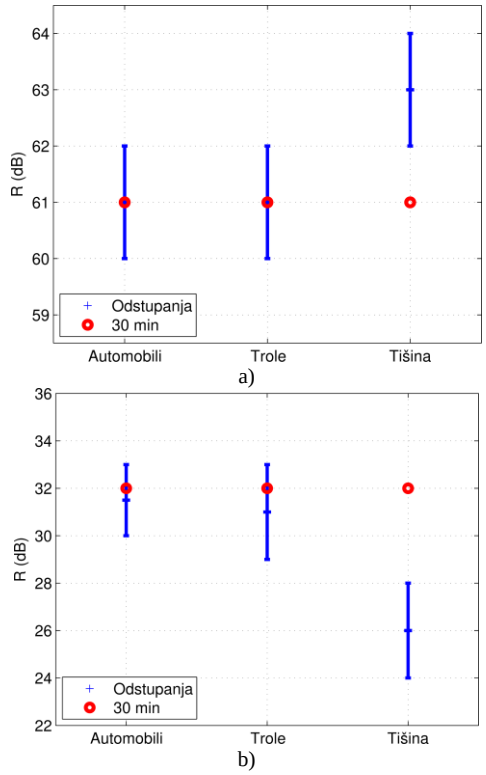
Građevinski podaci ovih prerada, potrebni za proračun izolacione moći, preuzeti su iz [20]. Na Slici 3 sivom bojom prikazana su odstupanja vrednosti izolacione moći za 1/3 oktavne frekvencijske opsege izračunate za nekoliko događaja istog tipa.

Na Slici 3 a) prikazana je frekvencijska zavisnost vrednosti izolacione moći betonske fasadne pregrade u slučaju prolaska automobila ispred mesta merenja. Odstupanja koja se javljaju u ostvarenim vrednostima izolacione moći za različite prolaske automobila iznose i do 20 dB za određene frekvencijske opsege. Najveća odstupanja javljaju se u opsegu od 500 Hz do 2000 Hz. Vrednosti izolacione moći betonske pregrade izračunate sa ugaonim raspodelama određenim za vremenski interval od 30 minuta nalaze se u gabaritima odstupanja vrednosti izolacione moći izračunatim za prolaske automobila. Za frekvencije veće od 2000 Hz vrednosti izolacione moći betonske pregrade izračunate na osnovu ukupnog trajanja snimka od 30 minuta nalaze se na donjoj granici gabarita odstupanja za ovaj tip događaja. Na Slici 3 b) prikazana je frekvencijska zavisnost odstupanja vrednosti izolacione moći betonske pregrade prilikom prolaska trolejbusa. Odstupanja su nešto manja u odnosu na slučaj prolaska automobila. Maksimalna odstupanja javljaju se u frekvencijskom opsegu od 500 Hz do 2000 Hz i iznose maksimalno 15 dB. Vrednosti izolacione moći izračunate za ukupno trajanje snimka, prikazane punom linijom, i u ovom slučaju nalaze se u granicama gabarita odstupanja. Na niskim frekvencijama, manjim od 500 Hz, vrednosti izolacione moći za snimak od 30 minuta nalaze se na gornjoj granici odstupanja za ovaj tip događaja. Odstupanja vrednosti izolacione moći za slučaj kada je analizirana ambijentalna tišina su manja u odnosu na dva prethodno analizirana tipa događaja. Sa Slike 3 c) može se videti da su odstupanja manja od 5 dB, izuzev nekoliko 1/3 oktavna frekvencijska opsega na srednjim frekvencijama. Vrednost izolacione moći određene na osnovu snimka od 30 minuta ne nalazi se unutar gabarita odstupanja za ovaj tip događaja za ceo frekvencijski opseg.

Na Slikama 3 d) do 3 f) prikazana su odstupanja vrednosti izolacione moći fasadne pregrade izrađene od stakla za tri analizirana tipa događaja, zajedno sa frekvencijskom zavisnošću vrednosti izolacione moći izračunate za ukupan signal, za isti tip pregrade. Najveća odstupanja za pojedinačne događaje javljaju se u slučaju kada nema prolaska vozila, odnosno za tip događaja nazvan tišina. Najveća odstupanja kod ovog tipa događaja javljaju se u opsegu od 2000 Hz do 2500 Hz, gde se nalazi i frekvencija incidencije staklene pregrade. U ovoj frekvencijskoj oblasti staklena pregrada ispoljava najmanje vrednosti izolacione moći. Za pomenuti opseg, funkcija gustine verovatnoće ima maksimum za uglove bliske 90° (Slika 2 f)), što doprinosi dodatnom smanjenju ostvarene izolacione moći analizirane pregrade. Sa Slike 3 f) može se uočiti da se ostvarene vrednosti izolacione moći staklene fasadne pregrade izračunate za ukupno trajanje signala ne nalaze u gabaritima odstupanja vrednosti izolacione moći izračunate za ambijentalnu tišinu. Rastojanje od gabarita u pojedinim frekvencijskim opsezima iznosi 10 dB. Za druga dva tipa analiziranih događaja odstupanja su približno ista, i manja u odnosu na slučaj kada je analizirana betonska pregrada. U oba slučaja izolaciona moć izračunata za ukupan snimak izlazi van granica gabarita odstupanja. Na Slici 4 plavom bojom prikazana su odstupanja jednobrojnih (merodavnih) vrednosti izolacionih moći [10] za pojedinačne događaje istog tipa i dve analizirane fasadne pregrade. Crvenom bojom prikazane su jednobrojne vrednosti izolacione moći izračunate za ceo snimak sa mikrofonskog niza. Vrednosti izolacione moći izračunate za ukupno trajanje snimka iznose 61 dB za betonsku pregradu, odnosno 32 dB za staklenu fasadnu pregradu.



Sl. 3. Frekvencijska zavisnost vrednosti izolacione moći različitih pregrada za izdvojene događaje: a) automobili beton, b) trole beton, c) tišina beton, d) automobili staklo, e) trole staklo, f) tišina staklo



Sl. 4. Odstupanja jednobrojnih vrednosti izolacione moći za izdvojene događaje i a) betonsku pregradu, b) staklenu pregradu

Sa Slike 4 se uočava da se jednobrojna vrednost izolacione moći izračunata na osnovu ukupnog signala nalazi u granicama odstupanja za događaje tipa prolaska automobila i događaje prolaska trolejbusa. Za slučaj betonske pregrade i dva navedena tipa događaja ova odstupanja iznose 2 dB, dok je odstupanje u slučaju staklene pregrade izračunate na osnovu snimaka prolaska trolejbusa 3 dB. U slučaju izračunavanja vrednosti izolacione moći na osnovu snimaka ambijentalne tišine, odstupanja su ista kao i u slučaju druga dva tipa događaja, ali se značajno razlikuju od vrednosti izolacione moći dobijene za ukupan signal. U slučaju betonske pregrade jednobrojna vrednost se nalazi u granicama od 62 dB do 64 dB za pojedinačne snimke tišine i ove vrednosti su veće od vrednosti dobijene za ukupno trajanje snimka. U slučaju kada se analizira pregrada od stakla jednobrojna vrednost se nalazi u granicama od 24 dB do 28 dB za pojedinačne snimke tišine i ove vrednosti su manje od vrednosti dobijene za ukupno trajanje snimka.

Prikazani rezultati ukazuju da se ispoljena vrednost izolacione moći fasadne pregrade u urbanim uslovima menja u vremenu i da zavisi od tipa događaja na mernom mestu u urbanim uslovima. Uticaj tipa događaja na vrednost izolacione moći posmatrane u dužem vremenskom intervalu zavisi od frekventnosti tog tipa događaja. Posmatrajući rezultate dobijene za snimke ambijentalne tišine zaključuje se da je doprinos ovog tipa događaja u ostvarenoj vrednosti izolacione moći za 30 minuta relativno mali, jer vrednost izolacione moći u ovom slučaju u većoj meri odstupa u odnosu na ukupnu. Broj prolazaka automobila i trolejbusa na ovoj mernoj lokaciji je veliki, pa je njihov uticaj na ostvarenu vrednost izolacione moći u intervalu od 30 minuta veliki.

V. ZAKLJUČAK

U ovom radu prikazana je upotreba metodologije za određivanje ugaone raspodele incidentne energije spoljašnje buke za karakteristične tipove izvora na jednoj mernoj lokaciji u urbanim uslovima. Pokazano je da ostvarena vrednost izolacione moći zavisi od tipa izvora jer postoji promena ugaone raspodele incidentne energije koja „napada“ fasadu. U urbanim uslovima postoje izvori različitih tipova (automobili, autobusi, trolejbusi itd.) što dovodi do promene strukture zvučnog polja. Promena strukture polja u vremenu ima za posledicu vremensku

zavisnost vrednosti izolacione moći. Uticaj određenih tipova izvora zavisi od konkretne konfiguracije terena u kome se nalazi fasadna pregrada ali i od veličine izvora, spektralnog sadržaja buke koju izvor emituje itd. Zbog toga se i za pojedinačne događaje istog tipa mogu javiti različite ostvarene vrednosti izolacione moći. U ovom radu pokazani su gabariti odstupanja. Za analiziranje zvučnog komfora u zgradama potrebno je generalno sagledati ostvarene vrednosti izolacione moći, što zahteva primenu metodologije za određivanje oblika raspodele nad signalima veće dužine, kako bi se obuhvatio veliki broj događaja svih tipova. Obrada i analiza takvih rezultata je vremenski i računski kompleksna. Ukoliko bi se definisali ključni događaji na posmatranoj mernoj lokaciji bilo bi dovoljno snimiti samo njih, što bi smanjilo vreme merenja, a samim tim i vreme potrebno za obradu signala. Međutim, na osnovu rezultata prikazanih u ovom radu zaključuje se da svi tipovi događaja nemaju isti uticaj na ostvarenu vrednost izolacione moći. To znači da se prostim sabiranjem uticaja malog broja pojedinačnih događaja neće dobiti rezultat kao kada se merenje izvrši u dužem vremenskom intervalu, npr. 30 minuta. Broj događaja određenog tipa, kao i ugaona raspodela incidentne energije koju oni stvaraju utiču na ukupan rezultat. Zbog toga je potrebno uvesti korekcione faktore koji bi uvažili uticaj pojedinih tipova događaja na generalnu sliku o stanju izolacione moći na analiziranoj lokaciji. Uvođenje korekcionih faktora u cilju smanjenja vremena potrebnog za globalno sagledavanje izolacione moći u urbanim uslovima biće tema budućih istraživanja.

ZAHVALNICA

Ovaj rad je realizovan u okviru projekta TR 36026 koga finansira Ministarstvo prosvete, nauke i tehnološkog razvoja Republike Srbije.

ABSTRACT

The shape of angular distribution of the incident energy influences in-situ values of the sound reduction index of façade elements. In general case, the shape of this distribution is unknown. Utilizing a microphone array and space-time signal processing algorithms it is possible to experimentally obtain a probability density function of the angular distribution of the incident energy on the building envelope. In urban environments there is a large number of sources which differ in type, spectral content they emit, power, etc. This leads to the assumption that the shape of angular distribution, and hence the value of in-situ sound reduction index will depend on the sound source type. This paper presents the methodology for experimental determination of noise angular distribution and its application in observing the differences of the in-situ sound reduction index of the same façade element, when it is exposed to different sound sources in urban environments. The in-situ sound reduction index is calculated using the experimentally obtained probability density functions and it is shown that it varies in time and depends on the momentary structure of the sound field. Furthermore, a comparison is presented of the in-situ values calculated for individual events and calculated for a longer time interval. In this way, it is possible to observe the influences of certain sound sources types on the façade sound insulation performance.

Estimation of the dependency of façade sound reduction in-situ values on the type of noise sources in urban environments

Uticaj „tišine“ na zvučni komfor

Miomir Mijić, Dragana Šumarac Pavlović, Miloš Bjelić, Tatjana Miljković

***Apstrakt*— U novije građenim zgradama, stambenim i poslovnim, sve su češće pritužbe na nedostatak privatnosti govora kao bitnog elementa zvučnog komfora. Jedini numerički pokazatelj koji se danas koristi kao formalni indikator stanja je građevinska izolaciona moć pregrada između prostorija na osnovu koje se izvodi zaključak o postignutom akustičkom komforu. Međutim, iskustva iz prakse pokazuju da se pri istim vrednostima izolacione moći u zgradama mogu zateći različita stanja privatnosti. Zbog toga se u radu razmatraju uzroci te pojave i mogućnosti primene kompleksnijih numeričkih pokazatelja stanja privatnosti. Na osnovu toga se predlaže dopuna forme standardnih izveštaja o merenju zvučne izolacije za pouzdaniju procenu stanja privatnosti govora i mogući pravci delovanja u projektovanju i izgradnji zgrada.**

***Ključne reči*— ambijentalna buka, tišina, zvučna izolacija, zvučni komfor**

I. Uvod

Stanje koje bi se moglo nazvati „potpunom tišinom“ predstavlja jedan zanimljiv ideal o kome pričaju i o kome maštaju mnogi ljudi. Oni takvo akustičko stanje vide kao ambijent u kome će naći svoj mir, i u kome im nikakav zvuk neće skretati pažnju. Takve stavove često prati i interesovanje za načinima na koji se „potpuna tišina“ može postići u stanu, ili bar u jednoj sobi.

Sa druge strane, u današnje vreme čini se da je broj žalbi na neadekvatan zvučni komfor u stambenim zgradama u stalnom porastu. Neke od njih na kraju dovedu i do vrlo ozbiljnih sporova. U dugom vremenskom periodu žalbe su se pretežno odnosile na izvore buke u okruženju: na industriju, na tuđe klima uređaje, na saobraćaj, muziku iz ugostiteljskih objekata i slično. Takve žalbe adresirane su na vlasnike izvora buke sa zahtevima da se oni isključe ili utišaju. Problemi te vrste uglavnom se rešavaju pomoću inspekcijskih službi i komunalne policije, drugim rečima postoji nekakav pravni sistem kojim je to regulisano.

U novije vreme dešava se sve češćeg pomeranja fokusa stanarskog nezadovoljstva zvučnim komforom sa klasičnih izvora buke, pa se žalbe ljudi na njegov nedostatak sve ćešće odnose na okolnost da u svojoj sobi čuju razgovor iz susednih stanova. Pri tome je jasno da taj problem ima dva smera – sa druge strane zida podjednako će se čuti njihov glas. Razgovor iz komšiluka jeste ometajući, ali istovremeno i važan signal ljudima da je ugrožena njihova privanost [1]. U takvim okolnostima novo je to da su žalbe, umesto ka vlasnicima izvora buke, usmerene protiv građevinara i eventualno investitora koji su zgradu napravili. Zanimljivo je da su u tome vrlo retko žalbe usmerene na projektante zgrade, mada se pokazalo da su takvi problemi najčešće rezultat njihovih propusta.

Nisu samo stambene zgrade mesta gde se javljaju pritužbe na nedovoljan zvučni komfor, to jest privatnost. I u novim poslovnim zgradama postoje okolnosti, možda još češće nego u stambenim, u kojima se ljudi žale na nedostatak privatnosti ili na ometanja govorom. Sudeći po broju poziva u novije vreme koji dolaze iz raznih firmi sa molbom da se nekako rešava problem čujnosti razgovora iz njihovih „važnih“ prostorija, čini se da je danas privatnost razgovora važan, ali zanemaren aspekt poslovnih zgrada. Očigledno je da ima mnogo drugih faktora koji su u projektovanju važniji od pitanja privatnosti.

Nesumnjivo je da problem zvučnog komfora u stanovanju nije novi, ali izgleda da su ga neke okolnosti, bar u Srbiji, vremenom učinile izraženijim. Žalbe na nedovoljan zvučni komfor najšećće dolaze iz novih zgrada, stambenih i poslovnih. Reklo bi se da pojave ometanja iz okruženja ljudi više ne prihvataju kao neumitnost stanovanja ili kao deo poslovnog folklora. Jedno objašnjenje za porast takvih žalbi je da se prag tolerancije ljudi na ometanja vremenom spustio. Može se takođe pretpostaviti da u novim, luksuznim zgradama koje podrazumevaju i višu cenu prostora ljudi generalno imaju veća očekivanja, pa u tom smislu i veće zahteve u domenu zvučnog komfora. U Srbiji to znači da se u projektovanju zahtevi izolacije pregrada između stanova i pregrada oko sala za sastanke moraju preispitati u kontekstu promena u stavu prema zvučnom komforu.

Zvučni komfor u zgradama nominalno se rešava u fazi projektovanja zgrade kada se usvajaju pregrade sa adekvatnim zvučnoizolacionim svojstvima. Postoji regulativa koja definiše minimalne zahteve za izolacione moći zidova i tavanica kojima su okruženi boravišni prostori u zgradama [2]. Karakteristično za takav problem kada se javi je i u tome što je njegovo rešavanje, to jest popravljanje zvučne izolacije, vrlo kompleksno i po nekada nema elegantnog rešenja. Takođe postoje i okolnosti kada je to sasvim nemoguće.

Zbog toga je veoma važno da se razumeju kompleksni razlozi koji dovode do nezadovoljstva zvučnim komforom kako bi se na adekvatan način rešavali takvi problemi, presvega u projektovanju, ali i pri sanaciji nekog zatečenog stanja. U

ovom radu je razmatran uticaj jednog specifičnog faktora zvučnog komfora, a to je nivo ambijentale buke, odnosno tišine u sobama na osećaj privatnosti ljudi u zgradama. U tome postoji kompleksno pitanje načina da se takav uticaj na neki način kvantifikuje. U radu su diskutovane neke mogućnost za to kao i načini za prevazilaženje neadekvatnog stanja privatnosti.

II. FAKTORA KOJI ODREĐUJU PRIVATNOST U ZGRADAMA

Čujnost i razumljivost govora iz susednih prostorija u zgradama, a to znači iz stana u stan, iz kancelarije u kancelariju ili iz kancelarije u zajednički prostor, prevashodno je određena stanjem zvučne izolacije pregradne konstrukcije koja ih deli. To je tema koja se obrađuje u procesu projektovanja zgrada, pri čemu se ne polazi od apsolutnog zahteva da se svaka prekomerna buka u prostorijama učini nečujnom u okruženju. Normativi koji propisuju uslove za pregrade u zgradi, to jest njihova izolaciona svojstva, zasnivaju se na podacima o očekivanom nivou zvuka koji nastaje pri razgovoru ljudi u prostorijama i očekivanom nivoa ambijentalne buke. U stambenim zgradama to je u izvesnom smislu limitirano kućnim redom, a u poslovnim zgradama zahtevima tehnologije rada. Prema korišćenom normativu u Srbiji [2] očekivani ekvivalentni nivo zvuka u normalnim prostorijama u zgradama (takozvane boravišne prostorije) ne prelazi 70 dBA. Prostorije u kojima nivo zvuka premašuje tu vrednost spadaju u posebne kategorije označene kao „bučne“, ili „veoma bučne“. Njihova zvučna izolacija se u projektovanju posebno tretira, pa one nisu tema u razmatranju problema privatnosti.

Jedno ranije istraživanje je pokazalo kakvo je stanje nivoa zvuka u boravišnim prostorijama stanova, to jest koliko ozbiljna može biti buka u prosečnim domaćinstvima kada se u njima odvijaju svakodnevne aktivnosti [3]. Isto istraživanje je takođe dalo rezultate koji pokazuju stanje nivoa zvuka u stanovima pri ekscesnim dešavanjima kao što su proslave, slušanje glasne muzike i slično. U sklopu publikovanih rezultata tog istraživanja nalaze se i informacije o izmerenim nivoima zvuka pri razgovoru ljudi u stanovima. Oni pokazuju da se ekvivalentni nivo govora u sobama kreće u opsegu od 60 dBA do 73 dBA. To znači da su rezultati merenja potvrdili stav unet u regulativu da je očekivani ekvivalentni nivo buke u stanovima pri normalnim životnim aktivnostima do 70 dBA.

U poslovnim zgradama nivoi buke u prostorijama su po prirodi stvari u granicama kontrolisanim zahtevima rada. U literaturi postoje rezultati istraživanja koji pokazuju stanje nivoa zvuka pri razgovoru ljudi u salama za sastanke kakve se uobičajeno nalaze u poslovnim zgradama [4,5]. Na osnovu merenja u 79 sala zaključeno je da se ekvivalentni nivo govora u njima kreće oko 60 dBA, sa varijacijama u opsegu ±2 dB. Očigledno je da se u takvoj govornoj komunukaciji ljudi neguje izvesna kultura govora, pa se nivo glasa podeša da bi se govor razumeo u prostoriji, čak i kada se koristi sistem za doozvučavanje. Ovi rezultati pokazuju da su očekivani nivoi govora u stanovima viši od nivoa u konferencijskim salama. To je posledice pre svega manje zapremine boravišnih prostorija u stanovima u odnosu na konferencijske sale u poslovnim zgradama, kao i načina kako se govori u domaćoj atmosferi u odnosu na prostorije za zvanične sastanke.

Zahtevi zvučne izolacije definisani u normativima za zvučnu zaštitu u zgradama podešavani su sa idejom da se govor ljudi pri ovakvim nivoima zvuka ne razume, ili uopšte ne čuje sa suprotne strane zidova. Šta to sa aspekta razumljivosti govora može da znači u kvalitativnom smislu nalazi se, između ostalog, u tekstu predloga jednog novog ISO standarda (postupak za klasifikaciju zgrada) u pogledu postignute zvučne izolacije u njima [6]. U njemu se kao ilustracija navodi moguća čujnosti govora između susednih prostorija pri određenim vrednostima zvučne izolovanosti D_{nT}. Ova ilustracija je prikazana u Tabeli I. Vidi se, na primer, da je pri izolovanosti između prostorija 52 dB očekivano da glasan govor bude razumljiv, a normalan govor jedva razumljiv. Iz ovog prikaza sledi da bi govor postao teško razumljiv tek pri izolovanosti većoj od 56 dB. Vidi se razlika između pojmova razumljivosti i čujnosti govora, pri čemu čujnost podrazumeva da se prepoznaje zvuk govora, ali ne i šta se izgovara.

TABELA I
PREGLED ČUJNOSTI GOVORA PRI RAZLIČITIM STANJIMA IZOLACIJE

D_{nT}	**glasan govor**	**normalan govor**
52 dB	razumljiv	jedva razumljiv
56 dB	jedva razumljiv	teško razumljiv
60 dB	čujan	čujan
64 dB	jedva čujan	jedva čujan
68 dB	retko čujan	nečujan

Međutim, dosadašnja praksa autora ovog rada na sanaciji zvučne izolacije po zgradama pokazala je da izolovanost između prostorija ili izolaciona moć pojedinačnih pregrada ne određuju jednoznačno stanje razumljivosti govora, a to znači i stanje privatnost. Drugim rečima, stečeno iskustvo u izvesnom smislu relativizira opise iz Tabele 1. Opšta je činjenica u telekomunikacijama da odnos signal/šum određuje da li će neki signal biti detektabilan. Isto važi i za detekciju govora čulom sluha, pa je odnos signal/šum na mestu slušanja ono što određuje da li će se neki govor čuti i razumeti. Pri tome se pod signalom podrazumeva akustički govorni signal koji deluje na čulo sluha slušaoca, sa svim njegovim dinamičkim specifičnostima, a pod šumom se podrazumeva ambijentalna buka u okruženju tog slušaoca.

Jasno je da se zbog dinamičkih karakterstika signala govora o veličini odnosa signal/šum može govoriti samo statistički, ali se u prvoj aproksimaciji može problem posmatrati i kroz njihove ekvivalentne vrednosti, kako god da su izmerene. Nivo govornog signala na mestu njegovog nastanka u svakodnevnoj govornoj komunikaciji u stanovima i kancelarijama određen je ograničenom zvučnom snagom vokalnog trakta i naučenim načinom na koji ga ljudi uobičajeno koriste.

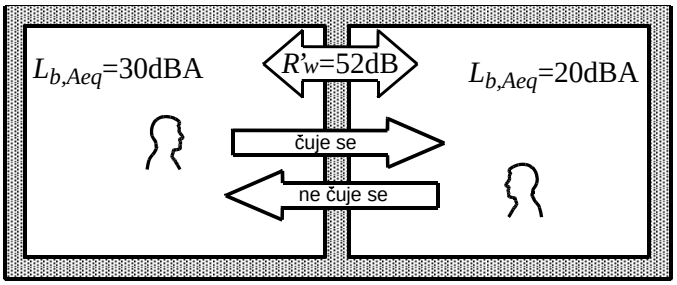
U literaturi je ukazano da odnos signal/šum ono što određuje čujnost i razumljivost govora [4]. Pokazano je da govor postaje nerazumljiv kada srednja vrednost odnosa signal/šum po opsezima 1/3 oktave približno opadne ispod −2 dB [4]. Pri tome se taj odnos posmatra u frekvencijskom opsegu od

značaja za govor, što je ograničeno na raspon od 160 Hz do 5 kHz. Tako je privatnost govora funkcija nivoa govora na mestu slušanja, što je samo po sebi jasno, ali i nivoa ambijetalne buke na tom istom mestu, što je skreće pažnju i na ambijent u kome se sluša kao faktor. Prema tome, i privatnost govora u zgradama zavisiće od ta dva faktora: zvučne izolacije i stanja „tišine“. To je objašnjenje zašto u istim uslovima zvučne izolacije i pri istom intenzitetu govora on može biti primetan u susednoj prostoriji, ali i ne mora – odnos signal/šum može biti različit.

U urbanoj sredini ambijentalna buka u zgradama potiče od više izvora: saobraćajna i druga buka koja dospeva kroz prozore i druge fasadne otvore, buka od raznih izvora u zgradi koja dospeva u sobe kroz konstrukciju zgrade i instalacije, kao i buka uređaja u prostorijama (u stanovima frižider, vodovod, klima uređaj, u poslovnim zgradama ventilacija i klimatizacija, računari, razna kancelarijska oprema, itd.).

III. Jedna praktična ilustracija problema privatnosti

Brojni su primeri koji dokazuju da privatnost zavisi od stanja ambijentalne buke u prostorijama. Jedan slučaj iz novije konsultantske prakse zabeležen u stambenoj zgradi prilikom merenja zvučne izolacije šematski je objašnjen na slici 1. Merenje stanja izolacije urađeno je po žalbi jednog stanara. Izmerena merodavna vrednost građevinske izolacione moći između dva stana bila je 52 dB, kao što je naznačeno na slici. To je vrednost propisana kao zahtev u normativu [2] koja je najšire primenjuje kao kriterijum pri projektovanju zgrada. To znači da stanje zvučne izolacije zadovoljava danas važeći normativ.



Sl. 1. Ilustracija jednog analiziranog slučaja koji je pokazao da vrednost zvučne izolacije ne utvrđuje jednoznačno stanje privatnosti u prostorijama.

Međutim, utvrđeno je da se stanje privatnosti u dve susedne prostorije doživljava različito, iako ih razdvaja ista pregrada sa nominalno zadovoljavajućom vrednošću građevinske izolacione moći. U jednom smeru utvrđeno je da se govor iz susedstva može čuti, što je i iniciralo žalbu stanara, dok u suprotnom smeru takva pojava nije konstatovana i stanari nisu imali primedbe na privatnost. Ova razlika u čujnosti govora naznačena je na slici. U analizi stanja razumljivosti govora koja je sprovedena u oba smera, to jest sa obe strane zida, korišćena je ista grupa ljudi kao izvor govora i isti slušaoci sa druge strane, tako da je eliminisan mogući uticaj individualnih razlika govornika i slučalaca.

Da bi se objasnio ovaj fenomen, pored zvučne izolacije, izvršeno je merenje ekvivalentne vrednosti nivoa ambijentalne buke u obe prostorije. Rezultati su takođe prikazani u slici. U prostoriji u kojoj nije konstatovano da se čuje govor iz susednog stana ekvivalentna vrednost ambijentane buke je bila oko 30 dBA. Upravo ova vrednost je u domaćim normativima navedena kao maksimalno odzvoljeni nivo buke tokom noći u boravišnim prostorijama stambenih zgrada. Ovakvo stanje buke je dominantno posledica zatečenog stanja izolacione moći prozora i raznih izvora zvuka u stanu. U prostoriji susednog stana u kojoj se registruje govor iz susedstva izmerena vrednost ekvivalentnog nivoa ambijentalne je bila samo oko 20 dBA. Utvrđeno je da su u tom stanu stavljeni novi fasadni prozori velike izolacione moći i svi kućni uređaji su novi, sa niskim nivoom buke koju stvaraju. Iako je stanje zvučne izolacije jedinstveno, ta razlika u nivou ambijentalne učinila je da odnos signal/šum u dve prostorije bude različit, pa je zbog toga različito i stanje privatnosti, to jest stanje čujnosti i razumljivost govora.

Pokazani primer jasno pokazuje da stanje privatnosti kao elementa zvučnog komfora ne određuje samo vrednost izolacione moći građevinskih pregrada koje okružuju prostorije, već i stanje ambijentalne buke u okolini potencijalnih slušaoca. I pored toga u dve faze provere stanja – u projektovanju i pri merenju zvučne izolacije za tehnički prijem zgrade – proračunava se i meri samo zvučna izolacija. To naravno da ima opravdanja jer se time proverava kalitet projekta i same gradnje. Ali, da bi se dobila pouzdanija slika o zvučnom komforu u zgradi analiza stanja se mora proširiti sa podacima o nivou ambijentalne buke u prostorijama. Tek tada se mogu izvoriti kvalitetni zaključci o stanju zvučnog komfora u zgradi i procenjivati realno stanje privatnosti.

Standardno testiranje akustičkog kvaliteta novoizgrađenih zgrada danas obuhvata isključivo merenje merodavne vrednosti građevinske izolacione moći R'_w, pa su za nekakvu ocenu stanja privatnosti na raspolaganju samo vrednosti tog parametra. Činjenica je da ambijentalna buka nije predmet merenja u izgrađenim zgradama, osim kada se pojave žalbe, a one su u praksi gotovo isključitvo inicirane nekom mašinskom opremom postavljenom u blizini. Činjenica je takođe da u ovom trenutku ne postoje podaci o prosečnom stanju ambijentalne buke u stanovima. Tema za buduće istraživanje je i stanje ambijentalne buke u stanovima tokom tihih perioda kao što je noć, kada se problem privatnosti dodatno intenzivira. Zbog toga se ne mogu izvoditi relevantni zaključci o očekivanoj privatnosti u zgradama čak i kada postoje podaci o zvučnoj izolaciji.

IV. Pregled mogućih pristupa kompleksnijem kvantifikovanju privatnosti u zgradama

Opisani primer iz prakse pokazao je nedostatak koji se javlja kada se značenje pokazatelja zvučne izolacije u zgradama ekstrapolira i na indikaciju privatnosti i čujnosti govora. To ukazuje na potrebu da se skup indikatora akustičkog kvaliteta zgrada na neki način dopuni i drugim podacima koji će zaokružiti sliku o stanju privatnosti. U literaturi se mogu naći neka rešenja za kvantifikovanje stanja poverljivosti govora na

način koji je kompleksniji od jednostavnog navođenja podatka o vrednosti izolovanosti D_{nT} ili merodavne vrednosti građevinske izolacione moći R'_w. Jedan mogući pristup bio bi pokušaj da se ono što postoji u tom domenu u literaturi prilagodi specifičnoj nameni ocene akustičkog kvaliteta zgrada.

Jedno moguće rešenje pronađeno je u američkom standardu ASTM E2638 [7]. Postupak koji je u njemu izložen zasnovan je na radovima Bredlija i saradnika [8,9]. Taj standard definiše parametar nazvan Speech Privacy Class (SPC). To je kvantitativna mera stanja privatnosti govora u prostoriji sa aspekta potencijalnog slušaoca koji se nalazi izvan nje. Parametar SPC se u standardu definiše kao mera bezbednosti i poverljivosti govora u salama za sastanke. Iako s takvom specifičnom namenom, on ima potencijal da se primenjuje i za ocene u stambenim zgradama. Vrednost SPC je definisana kao zbir dva faktora koji određuju čujnost govora između susednih prostorija: nenormalizovane zvučne izolovanosti D između njih i nivoa buke L_b u tački gde se može nalaziti potencijalni slušalac. Podrazumeva se da su obe veličine u decibelima.

Da bi se došlo do vrednost SPC sve relevantne veličine se mere u opsezima 1/3 oktave, pa se i izolovanost računa po tim opsezima:

$$D_i = L_{pred,i} - L_{prij,i} \tag{1}$$

gde je $L_{pred,i}$ nivo zvuka u predajnoj prostoriji u i-tom opsegu 1/3 oktave, a $L_{prij,i}$ nivo zvuka u prijemnoj prostoriji u istom frekvencijskom opsegu. Obe veličine se u standardu posmatraju u opsegu relevantnom za govor, a to je od 160 Hz do 5000 Hz, što je ukupno 16 opsega, to jest 16 vrednosti D_i. Za potrebe izračunavanja vrednost SPC ukupna izolovanost se definiše kao neponderisana srednja vrednost po svim opsezima 1/3 oktave:

$$D = \sum_{i=0}^{16} D_i/16 \tag{2}$$

gde je i oznaka opsega 1/3 oktave. Na isti način se izračunava i nivo buke u prijemnoj prostoriji:

$$L_b = \sum_{i=0}^{16} L_{b,i}/16 \tag{3}$$

S obzirom da je standard ASTM E2638 namenjen oceni poverljivosti razgovora i curenja akustičkog signala izvan nekog prostora, nivo zvuka na prijemnoj strani L_{prij} i ambijentalna buka L_b mere se u tački koja je na 25 cm od pregradnog zida prema predajnoj prostoriji i na visini između 1,2 m i 2 m.

Prethodno pomenuta istraživanja nivoa zvuka govora u salama za sastanke i u stanovima pokazala su statističke osobine ovih zvukova i limite u kojoma se kreću. To je omogućilo da se u nalaženju odnosa signal/šum pri slušanju govora iz susednog stana nivo signala posmatra kroz vrednost izolovanosti D. U skladu s tim u standardu ASTM E2638 definisan je parametar Speech Privacy Class (SPC) kao:

$$\text{SPC} = D + L_b \tag{4}$$

Kao što se vidi iz izraza (4) ovako koncipiran parametar predstavlja zbir dva nezavisna faktora koji određuju privatnost. Jedan član, izolovanost D, pokazuje stanje zvučne izolacije, ali indirektno i nivo govornog signala. Drugi član, nivo ambijentalne buke, definiše efekat maskiranja zvukovima iz okruženja. Sabrane, ove dve veličine pokazuju ukupni efekat na stanje privatnosti govora. Što je veća vrednost SPC, manji je odnos signal/šum na mestu slušanja.

U radu Bredlija [4], kao i u prilogu standarda ASTM E2638 [7] opisana su očekivana stanja privatnosti govora za različite vrednosti parametra SPC. U Tabeli 2 predstavljeni su ti opisi da bi se stekao uvid u značenje njegovih numeričkih vrednosti. Opisi definišu verovatna stanja razumljivosti i čujnosti govora. Iz prikazanih opisa može se zaključiti da tek pri vrednostima SPC preko 70 privatnost postaje relativno zadovoljavajuća, ali ne i apsolutna, to jest maksimalno moguća. Jasno je da se zbog svoje dinamike u okviru dužeg govora, ali i dinamike unutar svake rečenice, nivo govora može posmatrati samo statistički preko dugovremene efektivne vrednosti. U tom smislu tumačenje značaja pojedinih vrednosti SPC iz Tabele II može samo da definišu najverovatiju učestanost pojavljivanja manje ili više čujnih segmenata.

TABELA II
OPISI STANJA PRIVATNOSTI ZA RAZLIČITE VREDNOSTI PARAMETRA SPC

SPC	opis stanja
< 60	govor je skoro uvek čujan i često se razume
60-65	zvuk govora uglavom čujan, kratke izgovorene fraze se povremeno razumeju
65-70	zvuk govora često čujan, kratke izgovorene fraze su ređe razumljive
70-75	zvuk govora je retko čujan, govor suštinski nerazumljiv (kratke fraze čujne najviše jednom u 15 minuta)
75-80	zvuk govora retko čujan, govor nerazumljiv
80-85	zvuk govora eventualno čujan na svakih 15 minuta, govor nerazumljiv
> 85	zvuk govora neprimetan

U delu sveta gde se primenjuje ISO standardizacija uvrđivanje faktora koji određuju zvučni komfor zasnovano je na merenju građevinske izolacione moći prema standardu ISO 16283-1 [10], i ekvivalentnog nivoa ambijentalne buke L_{Aeq} izraženog u dBA prema standardu ISO 1996-1 [11]. Rezultat merenja zvučne izolacije iskazuje se merodavnom vrednošću izolacione moći R'_w koja se izračunava prema standardu IS0 717-l [12]. Autori ovog rada u jednom svom ranijem radu predložili su jednu modifikaciju u definiciji SPC da bi se bazirala na vrednostima iskazanim kao rezultati merih postupaka prema ISO standardizaciji primenjivanoj u Evropi [13]. Predložen je ekvivalent SPC nazvan Indeks privatnosti govora (IPG) koji je definisan kao:

$$IPG = R'_w + L_{A,eq} \quad (2)$$

U prethodnom istraživanju autora ovog rada eksperimentalno je pokazano da vrednosti IPG sa dovoljnom tačnošću estimira vrednost SPC, a to znači da se u istom smislu može korisiti i za ocenu stanja privatnosti govora između prostorija koristeći standardne pokazatelje defnisane ISO standardima koji se rutinski mere [13].

Zanimljivo je da je značaj nivoa ambijentalne buke u zaštiti privatnosti prepoznat i u standardnim postupcima za kvantifikovanje stanja privatnosti u *open space* kancelarijama. U standardu koji definiše relevantne parametre za ocenu kvaliteta ovih specifičnih prostora predviđeno je i merenje ekvivalentnog nivoa ambijentalne buke [14]. U proceduri opisanoj u tom standardu uticaj buke se posmatra posredno, i to kroz opadanje vrednosti indeksa prenosa govora sa rastojanjem. Posmatra se rastojanje od govornika na kome se govorni signal utopi u postojeću ambijentalnu buku i tako praktično nestane razumljivost govora. U mnogim okolnostima se u poslovnim prostorijama za te namene koruste pomoćna sredstva za kontrolu nivoa buke u prostorijama.

Mada je SPC izvorno definisan kao parametar koji treba da pokazuje mogućnost prisluškivanja razgovora u okruženju sala za sastanke poslovnih zgrada, ideja sadržana u tom konceptu može se iskorititi za ocenu zvučnog komfora u drugim okolnostima, pa i u stambenim zgradama. Parametar IPG kao njegov pandan može se direktno koristiti za izvođenje zaključaka o stanju privatnosti, jer je u saglasju sa postojećim metodama ocenjivanja zgrada.

V. DISKUSIJA O MOGUĆIM PRISTUPIMA U PRAKSI

U prostorijama savremenih stanova i poslovnih zgrada ideal „tišine“ o kome maštaju mnogi ljudi danas je skoro pa dostignut, čak i u urbanoj sredini, ako se pod time podrazumeva da je u njima vrlo nizak ekvivalentni nivo buke, praktično ispod praga primetnosti čulom sluha. Do toga je došlo zahvaljujući opštoj težnji u građevinarstvu ka višem standardu ambijenata za stanovanje i rad. U korenu toga su i savremeni zahtevi termičke izolacije i energetske efikasnosti, proizvodnja sve tiših uređaja koji se koriste u stanovima i kancelarijama, pa i veći prostorni standardi zbog kojih se u zgradama u proseku broj kvadratnih metara prostora po osobi izgleda vremenom povećao. Sve je to na svoj način doprinelo toliko željenom stanju „tišine“ u zgradama.

Međutim, u praksi svakodnevnog života pokazalo se da je ideal „potpune tišine“ postao uzrok specifičnog problema koji se najpribližnije može označiti kao „prekomerna tišina“. Takvo stanje kome se težilo neočekivano je otvorilo „pandorinu kutiju“ neželjenih zvukova iz okruženja, a među njima je i razgovor suseda. Naime, u takvim uslovima nestaje blagotvorno zaštitno dejstvo umerene ambijentalne buke koja maskira mnogo toga što bi bilo ometajuće, iako ljudi toga nisu svesni jer je ne primećuju i ne skreće im pažnju.

U praksi projektovanja poslovnih prostorija odavno je postalo standard da se problem „prekomerne tišine“ rešava dodatnim sistemima za maskiranje pomoću nekog generisanog šuma. Negde je to prosto šum ventilacije ili sistema za klimatizaciju. Kada to nije dovoljno, pribegava se veštačkim sredstvima. Istorijski gledano, počelo je sa fontanama u „open space“ kancelarijama, a danas na tržištu postoje brojna rešenja namenskih audio sistema za maskiranje. Postoji ISO standard koji definiše parametre za ocenu postignute privatnosti govora u takvim kancelarijskim prostorima, među njima i za kvantifikovanje postignutog efekta maskiranja govora [14]. U proceduri njihovog merenja vrši se i određivanje ekvivalentnog nivoa buke $L_{A,eq}$.

Međutim, u praksi projektovanja i izgradnje stambenih zgrada taj aspekt je i dalje potpuno zanemaren jer je nepoznat kako projektantima, tako i stanarima. U njima postoje dva moguća pravca delovanja da se spreči „prekomerna tišina“ i tako obezbedi privatnost govora. Prvi je da se zanemari činjenica o ekstremno niskim nivoima ambijentalne buke koji postoje u zgradi, ali da se zahtevi u odnosu na izolaciona svojstva pregrada značajno povećaju kako bi se obezbedio očekivani zvučni komfor. To bi zahtevalo da zidovi između stanova imaju građevinsku izolacionu moć i do 60 dB, a ne minimalnih 52 dB kao što je zapisano u domaćoj regulativi. U zemljama Evrope gde postoji klasifikacija zgrada u pogledu akustičkog kvaliteta vrednosti izolacione moći preko 60 dB još ranije je propisana za najvišu klasu. Međutim, realno je da takav zahtev u praksi veoma komplikuje izbor materijalizacije pregradnih zidova, često zahteva i poseban pristup u rešavanju konstrukcije zgrade, a svakako poskupljuje gradnju. Ono što je možda najveći problem u tome je što nužno zahteva izvestan otklon od ustaljene graditeljske prakse u Srbiji, kako projektantske, tako i izvođačke.

Drugi pravac je da se i u stanovima, kao što se radi u poslovnim prostorijama, deluje u domenu ambijentalne buke, to jest da se na neki način spreči pojava „prekomerne tišine“. To se može postići inovativnim rešenjima u domenu zvučne izolacije. To bi značilo da se na neki način omogući doziranje prodora spoljašnje buke, a ne samo njeno maksimalno potiskivanje. Međutim, u praksi to može biti delikatno za realizaciju jer podrazumeva usložnjavanje standardnih građevinskih elemenata (na primer prozora). Znatno jednostavniji put sprečavanja „prekomerne tišine“ je da se kontrola nivoa ambijentalne buke realizuje nekim pomoćnim, „negrađevinskim“ sredstvima. Naravno, u granicama nivoa unutar kojih ne privlači pažnju ljudi i sa pažljivo odabranim karakterom emitovanog signala.

Kroz primer parametra Speech Privacy Class (SPC), odnosno novopredloženog Indeksa privatnosti govora (IPG), pokazan je način na koji se može kvantifikovati stanje čujnosti i razumljivosti govora. Ovo bi trebalo da inicira neke praktične korekcije standardnih procedura akustičkih merenja u zgradama kako bi korisnici prostora imali jasniju indikaciju postignutog stanja.

Prvi korak ka tome moglo bi biti proširenje formulara za prikaz rezultata merenja zvučne izolacije sa poljem u koji bi se unosili dodatni podaci o izmerenoj vrednosti ekvivalntnog nivoa buke u prostorijama između kojih je izvršeno merenje (prredajna i prijemna). Za realizaciju takve ideje potrebno je preciznije definisati uslove za takvo merenje da bi dobijeni

rezultat bio merodavan za ocenu stanja pri realnoj upotrebi prostorija. Ovakav pristup je posebno svrsishodan u slučajevima kada se merenje vrši u postojećim zgradama povodom žalbi stanara.

Drugi korak bi bio traganje za načinima sanacije kada stanje privatnosti ne zadovoljava korisnike zgrade. Do sada je to uvek vodilo ka nekakvim korekcijama zvučne izolacije, ali je to po pravilu destruktivno za postojeći enterijer. Ova analiza je pokazala da se rešenja mogu tražiti i u domenu kontrole ambijentalne buke unutar boravišnih prostorija stanova. Time se otvara široko polje za istraživanje koje uključuje razvoj tehnoloških ili građevinskih sredstava, ali takođe i istraživanje u oblasti koja je u literaturi nazvana *soundscape*. Ta tema za prostore stanova još nije obrađivana.

VI. ZAKLJUČAK

Primer iz prakse opisan na početku i definicija SPC u američkom standardu na direktan način su pokazali značaj“tišine“ u prostorijama za stanje privatnosti govora. Iz svega prikazanog jasno proizilazi da prekomerna, bolje rečeno „nekontrolisana“ tišina, ako nije praćena odgovarajućim merama zvučne izolacije, otvara potencijalni problem nedovoljne privatnosti govora. Zanimljivo je da stanje prekomerne tišine u zgradama nastaje kao sekundarna posledica čitavog niza zahteva i procesa u savremenom građevinarstvu, a ne kao neki unapred postavljeni cilj kome se svesno težilo.

U radu je pokazano da podatak o građevinskoj izolacionoj moći iskazan u projektu ili izmeren u zgradi nije dovoljan da se proceni stanje privatnosti govora između stanova ili kancelarijskih prostorija. Zbog toga je analizirana moguća upotreba parametra koji u svojoj definiciji integrišu doprinos zvučne izolacije i ambijentalne buke. Predloženo je da se formular izveštaja o merenju vrednosti građevinske izolacione moći dopuni podacima o ekvivalentnom nivou ambijentalne buke u prijemnoj i predajnoj prostoriji. To bi omogućilo da se za svaku okolnosti merenja procenjuje i Indeks privatnosti govora, a iz toga i stanje privatnosti koje korisnici zgrade mogu očekivati.

Najzad, rad aktuelizuje pitanje metodologije za kontrolu nivoa ambijentalne buke u prostorijama kada pregradni elementi zgrade učine da je njen nivo u prostorijama nepotrebno nizak. Načini za to mogu ići u pravcu maskiranja elektroakustičkim sredstvima ili posebnim konstrukcijama drugih elemenata zgrade, kao na primer prozora, koji će na neki način omogućiti doziranje „tišine“.

ZAHVALNICA

Ovaj rad je napravljen kao deo istraživanja u okviru projekta broj TR36026 koga finansira Ministarstvo prosvete, nauke i tehnološkog razvoja Republike Srbije.

ABSTRACT

In newly built buildings, both residential and business, there are increasing of complaints about a lack of speech privacy as an essential element of acoustic comfort. The only numerical indicator that is used today as a formal information about acoustic comfort is the sound reduction index of the partitions between the dwellings. Any conclusion about the achieved acoustic comfort in the building can be based only on such an information. However, some recent experience shows that with same value of sound reduction index different privacy can be identified. The paper discusses the causes of such occurrence, as well as the possibilities of applying more complex numerical indicators if the speech privacy. On that basis, the paper proposes an upgrading of the standard form for sound insulation measurement report for more accurate information about speech privacy, as well as the possible solution in the design and construction of buildings.

Influence of “silence” on acoustic comfort

Platforma za realizaciju napredne akustičke kamere

Iva Salom, Vladimir Čelebić, Vladimir Ćatić, Jovana Novaković, Bratislav Planić, Veljko Janić, Marko Ralić i Dejan Todorović

***Apstrakt*—U ovom radu prikazana je jedna realizacija napredne akustičke kamere, koja obuhvata specijalno projektovane module sa digitalnim MEMS mikrofonima, platformu za akviziciju do 32 signala i skladištenje podataka, dodatne module, koji se mogu priključiti u zavisnosti od primene akustičke kamere (GPS, meteorološki moduli) i video kameru. *Beamforming* algoritam realizovan je u programskom paketu MATLAB i kao rezultat postprocesiranja dobija se akustička mapa snimanog područja sa zadatom rezolucijom. Realizovan sistem pokazao se kao pouzdana platforma za realizaciju različitih mikrofonskih nizova sa dodatnim opcijama u zavisnosti od konkretne primene.**

***Ključne reči*—akustička kamera; mikrofonski niz; beamforming; MEMS mikrofon; FPGA; DSP.**

I. Uvod

Akustička kamera je jedna od mogućih primena mikrofonskog niza u kombinaciji sa video kamerom. Vizuelizacija zvučnog polja vrši se primenom određenog algoritma za prostorno-vremensku obradu signala sa mikrofonskog niza, i preklapanjem dobijene akustičke mape snimanog područja sa snimkom sa video kamere.

Od kako se početkom dvehiljaditih godina pojavila prva akustička kamera na tržištu, kreće nagli razvoj ove tehnologije, tako da danas akustička kamera predstavlja moderan inženjerski alat koji se, kroz identifikaciju i utvrđivanje položaja izvora zvuka, kao i kvantifikovanje i analizu pojedinačnih izvora zvuka, sve više koristi za različite namene: za određivanje i karakterizaciju izvora buke, u analizi akustike prostorija, za ispitivanje zvučne izolacije, za utvrđivanje kvarova u industrijskim postrojenjima (detekcijom/praćenjem poremećaja zvučnog polja), prilikom dizajniranja i testiranja vozila (auto-industrija, avio-industrija), u robotskim sistemima itd. [1]-[12]. Kao posledica toga, danas je na tržištu dostupan veliki broj akustičkih kamera različitih karakteristika i realizacija, u zavisnosti od primene [13]-[17].

Performanse akustičke kamere zavise od nekoliko parametara [2]: frekvencijski opseg - donju graničnu frekvenciju načelno određuje najveća dimenzija mikrofonskog niza, dok gornju graničnu frekvenciju određuje minimalno rastojanje između mikrofona, kao i frekvencija odabiranja audio signala; prostorna rezolucija predstavlja mogućnost razdvajanja dva izora zvuka na malom rastojanju i zavisi od frekvencije odabiranja audio signala, kao i udaljenosti izvora od mikrofonskog niza; selektivnost zavisi od širine glavnog luka i potiskivanja bočnih lukova, što je u direktnoj vezi sa konfiguracijom mikrofonskog niza (prostornim rasporedom mikrofona), tj. njegove karakteristike usmerensti (*beampattern*); pojava lažnih izvora zavisi od potiskivanja bočnih lukova, što takođe zavisi od karakteristike usmerenosti mikrofonskog niza; dinamički opseg zavisi od broja i osetljivosti mikrofona u mikrofonskom nizu.

Nakon akvizicije audio signala mikrofonskim nizom vrši se obrada signala (*array processing*). Svi ovi algoritmi mogu se definisati kao prostorno filtriranje (*beamforming*), odnosno izdvajanje akustičkog signala iz određenog pravca. *Beamforming* algoritmi se koriste za određivanje pravca nailska zvuka (*Direction of Arrival* - DoA) [1]-[3]. Postoji veliki broj *beamforming* algoritama koji se razlikuju po svojim karakteristikama pa je za konkretnu primenu potrebno izabrati odgovarajući algoritam (preciznost, složenost u pogledu zahtevanih resursa, brzina, potreban broj signala itd.) [1]-[3],[18],[19].

Ukoliko se javi potreba za specifičnom primenom akustičke kamere, kao što je na primer snimanje buke iz vazduha, kada je akustičku kameru neophodno montirati na bespilotnu letilicu pa mora zadovoljavati određene zahteve za malom težinom, autonomnim napajanjem, uzimanjem u obzir dodatnih parametara, kao što su meteorološki i slično, često gotova rešenja nisu pogodna za upotrebu. Sa druge strane, može se javiti i potreba za prilagođenjem postojećeg ili razvojem novog algoritma. U takvim slučajevima pristupa se razvoju sopstvenog rešenja.

U ovom radu prikazano je jedno razvijeno rešenje akustičke kamere bazirano na *Xilinx* Zynq-7000 platformi [20], koje predstavlja unapređenu verziju akustičke kamere opisane u [21]. Zynq-7000 platforma je tipa AP SoC (*All Programmable System on Chip*), koja uključuje procesor (PS – *Processing System*) i FPGA (*Field Programmable Gate Array*) programabilnu logiku (PL – *Programmable Logic*). Ovakva konfiguracija posebno je pogodna za realizaciju akustičke kamere jer omogućava optimalno iskorišćenje resursa kroz implementaciju odgovarajućih funkcija sistema na odgovarajućem podsistemu [22]. Ovde se pre svega misli na mogućnosti paralelnog procesiranja FPGA logike i implementaciju akvizicije i obrade

velikog broja ulaznih signala u realnom vremenu, zbog čega FPGA tehnologija poslednjih godina preuzima primat u realizaciji sistema sa mikrofonskim nizovima [23].

Pored platforme za akviziciju i skladištenje podataka na memorijski medij (SD karticu) u realnom vremenu, koja omogućava akviziciju sa maksimalno 32 mikrofona, sistem uključuje i specijalno projektovane module sa digitalnim MEMS mikrofonima, dodatne module koji se mogu priključiti u zavisnosti od primene (*Global Positioning System* – GPS modul, meteorološki moduli - temperatura, vazdušni pritisak, vlažnost) i video kameru, kao nezavisan uređaj sa sopstvenim napajanjem i memorijom.

Prilikom projektovanja najpre je bilo neophodno ispitati karakteristike sistema. U tu svrhu realizovana je simulacija u softverskom paketu MATLAB sa implementiranim *delay-and-sum beamforming* algoritmom [1]-[3]. Pomoću simulacije, u skladu sa mogućnostima primenjene platforme i zahtevima primene, izabrana je realizovana konfiguracija mikrofonskog niza [24]. Posebna pažnja posvećena je mehaničkoj realizaciji nosača akustičke kamere sa zadatim karakteristikama, kao i izboru komponenata da bi se zadovoljio uslov za malom težinom.

Program za obradu snimljenih podataka zajedno sa korisničkim interfejsom realizovan je u softverskom paketu MATLAB na osnovu programa za simulaciju, uz preklapanje dobijenih akustičkih mapa sa snimcima sa video kamere i kombinovanjem sa podacima sa drugih modula. U radu su data poređenja simulacije sa realnim snimcima na jednm primeru karakterističnog signala.

II. Softverska simulacija i izbor parametara

Osnovni zadatak realizovane MATLAB simulacije je da što preciznije prikaže ponašanje mikrofonskog niza sa mogućnošću podešavanja svih parametara, kako bi se izabrala optimalna konfiguracija za konkretnu primenu. Na Sl. 1 prikazan je korisnički interfejs realizovane simulacije, na kojoj se uočavaju parametri simulacije koji se mogu podešavati, kao i rezultat simulacije.

Konfiguracija mikrofonskog niza podrazumeva zadavanje broja i prostornog rasporeda mikrofona. Položaj mikrofona se zadaje izborom standardnih konfiguracija (zvezda, krug i sl.) sa ravnomerno raspoređenim mikrofonima (izbor do 4 kružnice sa nezavisnim izborom poluprečnika, broja mikrofona na krugu i ugaone rotacije u odnosu na *x* osu). Pored planarne konfiguracije mikrofonskog niza dodatno je moguće realizovati prostornu konfiguraciju zadavanjem *z* pomeraja svakog od krugova (paralelno *xy* ravni) ili definisati položaj mikrofona na sferi zadatog poluprečnika. Pri izboru predefinisanih konfiguracija smatra se da je centar mikrofonskog niza u koordinatnom početku.

Karakteristika mikrofona - mikrofoni imaju podrazumevanu omnidirekcionu karakteristiku usmerenosti, ali se može zadati proizvoljna karakteristika usmerenosti. U simulaciji se može uključiti slučajano pojačanje ulaznih signala koji odgovaraju pojedinim mikrofonima do ±2 dB što odgovara odstupanju u kalibraciji realnih mikrofona.

Izvori zvuka zadaju se polarnim koordinatama, koeficijentom slabljenja i odgovarajućim *.wav* fajlom. Proizvoljan *.wav* fajl može biti izabran kao izvor zvuka. Generisana je baza audio fajlova koji se najčešće koriste u simulacijama (*Dirac*-ov impuls, sinusni tonovi različitih frekvencija, beli i roze šum itd.). U trenutnoj realizaciji mogu se uneti do dva izvora zvuka.

Izbor algoritma – u trenutnoj realizaciji implementiran je *delay-and-sum beamforming* algoritam. Kašnjenja signala na mikrofonima, nastala kao posledica prostiranja akustičkog talasa, predstavljaju izvor informacija za *beamforming* algoritam.

Prostorni ugao proračuna, koji se koristi kao jedinica rezolucije, podešava se u stepenima i predstavlja vertikalni i horizontalni ugaoni krak.

Filtriranje ulaznih signala standardnim tercnim i oktavnim filtrima u opsegu od 200 Hz do 20 kHz omogućava ispitivanje osetljivosti mikrofonskog niza u različitim opsezima učestanosti.

Prikaz rezultata simulacije predstavlja normalizovani nivo zvuka u zavisnosti od prostornog ugla mapiran na ravan korišćenjem azimutne ekvidistantne projekcije, obrađen prema zadatom opsegu prikazivanja i preklopljen sa zadatom statičnom fotografijom scene, koja uzima u obzir zadati ugao snimanja video kamere postavljene u centru akustičke kamere.

Imajući u vidu primenu projektovane akustičke kamere određen je frekvencijski opseg od 250 Hz do 9 kHz, i s obzirom da realizovana platforma podržava akviziciju sa maksimalno 32 mikrofona vršene su simulacije sa nekoliko različitih konfiguracija mikrofonskog niza od 32 mikrofona sa različitim izvorima zvuka, koje su poređene po pitanju različitih parametara, a pre svega po selektivnosti i potiskivanju signala u odnosu na posmatrani pravac. Da bi se obezbedilo veće potiskivanje zvuka sa zadnje strane akustičke kamere izabrana je prostorna konfiguracija.

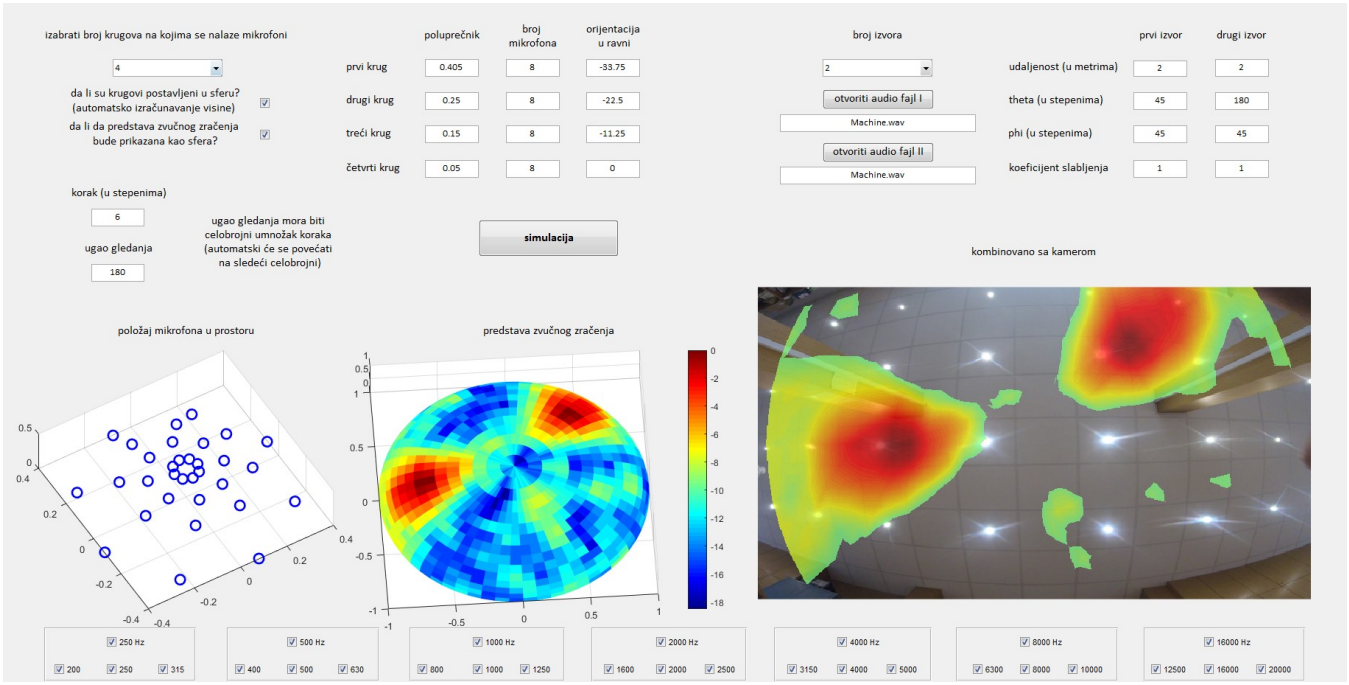
Konfiguracija mikrofonskog niza izabrana za realizaciju sastoji se od 4 kružnice sa po 8 ravnomerno raspoređenih mikrofona, pri čemu se kružnice nalaze na sferi poluprečnika 40 cm, a poluprečnici kružnica su 5 cm, 15 cm, 25 cm i 40 cm. Pri tome su mikrofoni na različitim kružnicama međusobno rotirani za po 11.25 stepeni. Izabrana konfiguracija mikrofonskog niza može se uočiti na prozoru korisničkog interfejsa simulacije, prikazanom na Sl. 1.

III. Opis sistema

Razvijena akustička kamera, prikazana na Sl. 2, obuhvata 1) senzorski blok (mikrofonski niz), 2) platformu za akviziciju, obradu i skladištenje podataka, 3) GPS modul, 4) modul za prikupljanje meteoroloških podataka (temperatura, vlažnost vazduha i pritisak), 5) video kameru, 6) napajanje sistema, 7) mehanički nosač. Blok za obradu podataka (*postprocessing*) i korisnički interfejs predstavlja PC računar sa odgovarajućim programima.

A. Senzorski blok

Osnovna uloga senzorskog bloka je odabiranje akustičkog signala i AD konverzija. Mikrofonski niz se sastoji od 32 mikrofona koji su postavljeni u odgovarajuću konfiguraciju. Za konkretnu primenu zahteva se da mikrofoni imaju omnidirekcionu karakteristiku usmerenosti, širok frekvencijski odziv, zadovoljavajuću osetljivost, kao i zadovoljavajući odnos signal/šum. Zbog svojih malih dimenzija i otpornosti na smetnje, naročito zbog relativno dugačkih linija od samog mikrofona do modula za akviziciju, korišćeni su digitalni MEMS mikrofoni [25]. Odabrani su omnidirekcioni mikrofoni



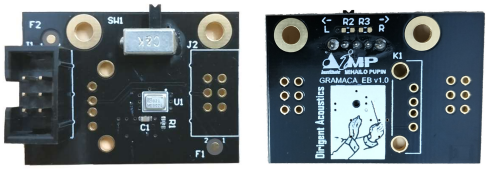
Sl. 1. Korisnički interfejs MATLAB simulacije sa rezultatom za odabranu konfiguraciju mikrofonskog niza i zvuk motora u opsegu 1.5 kHz – 2.5 kHz.

ADMP621 proizvođača *TDK InvenSense* [26] zbog prihvatljivog frekvencijskog odziva u rasponu frekvencija od 100 Hz do 16 kHz, dobrog odnosa signal-šum od 65 dBA i osetljivosti od -46 dBFS. Interesantna je činjenica da su se konkretni mikrofoni pojavili na tržištu pre više od pet godina, a pri tome i dalje sa datim karakteristikama predstavljaju najbolji izbor za primenu u ovakvom sistemu.

Sl. 2. Realizovana akustička kamera.

Odabrani digitalni MEMS mikrofoni predstavljaju integrisano rešenje koje obuhvata akustički pretvarač, predpojačavač audio signala i sigma-delta konvertor unutar jednog integrisanog kola. Male dimenzije pakovanja digitalnih MEMS mikrofona omogućavaju lako postavljanje komponenti na elektronsku štampanu ploču pomoću mašina za automatsko ulaganje komponenata. Digitalni interfejs ovakvih mikrofona omogućava njihovo direktno povezivanje sa digitalnim integrisanim kolima, kao što su FPGA programabilna integrisana kola, bez potrebe za dodatnim komponentama poput analogno-digitalnog konvertora koji bi bio neophodan pri upotrebi analognih mikrofona. Mikrofoni ovakvog tipa zahtevaju, pored veza sa napajanjem i masom sistema, jedino ulazni signal takta frekvencije između 1 MHz i 3 MHz. Svaki od mikrofona povezan je preko četiri signala tj. signala takta, mase, napajanja i izlaznog signala podataka. Izlazi signala podataka grupe koju čine dva mikrofona multipleksirani su impulsno-širinskom modulacijom, PDM (*Pulse Density Modulation*). Na ovaj način mikrofoni iz iste grupe dele izlazni signal podataka i sinhronišu se na isti ulazni signal takta. Ovakva raspodela konekcija rezultuje smanjenjem fizičkog broja veza sa FPGA programabilnom logikom na polovinu od ukupnog broja implementiranih digitalnih MEMS mikrofona.

Digitalni MEMS mikrofoni, svaki ponaosob, asemblirani su na jednostavnu elektronsku štampanu ploču, označenu kao EB (*Extension Board*). EB ploča, pored MEMS mikrofona i pasivnih komponenti sadrži i prekidač, kojim se podešava na koju ivicu takta se vrši odabiranje podataka sa MEMS mikrofona iz mikrofonskog para koji su povezani na zajedničke linije. Svaka od ploča realizovana je na takav način da se lako može povezati sa flet kablom za ostvarivanje fizičke veze preko odgovarajućeg konektora. Ovakvom realizacijom omogućena je laka zamena akustičkih senzora u slučaju pojedinačnih otkaza, kao i jednostavne izmene u konfiguraciji senzorskog niza. Elektronska štampana ploča EB sa digitalnim MEMS mikrofonom prikazana je na Sl. 3.



Sl. 3. Štampana ploča EB sa digitalnim MEMS mikrofonom.

B. Platforma za akviziciju, obradu i skladištenje podataka

U platformi za akviziciju, obradu i skladištenje podataka vrši se:

- prikupljanje više digitalnih akustičkih signala u PDM formatu,
- konverzija digitalnih akustičkih signala u zahtevani oblik (PDM signal u PCM signal zahtevane frekvencije odabiranja i bitske rezolucije),
- povezivanje sa GPS modulom,
- povezivanje sa modulom za prikupljanje meteoroloških parametara,
- skladištenje audio zapisa sa svih mikrofona na memorijskom modulu (SD kartica), kao i podataka sa GPS i meteoroloških modula.

S obzirom na to da optimalno rešenje problema akvizicije i obrade većeg broja akustičkih signala u realnom vremenu zahteva paralelno procesiranje signala svakog od senzora, za realizaciju je odabrana platforma bazirana na FPGA programabilnoj logici [10]-[12],[27]-[31]. Pored mogućnosti paralelne obrade velike količine podataka dodatne prednosti programabilne logike ogledaju se u povećanoj pouzdanosti, vremenu izvršenja i maloj potrošnji. Za realizaciju funkcionalnog prototipa iskorišćeno je gotovo rešenje - razvojna ploča *Digilent* Arty Z7-10 [32], bazirana na AP SoC čipu *Xilinx* Zynq-7000 [20], koji uključuje dvojezgrani ARM Cortex A-9 procesor (PS) i FPGA programabilnu logiku iz serije Xilinx-7 (PL). Glavna prednost ove platforme ne ogleda se samo u ovim njenim pojedinačnim delovima (PS i PL), već i u mogućnosti njihovog zajedničkog funkcionisanja u okviru jednog sistema, uz brzu komunikaciju, ostvarenu pre svega njihovim povezivanjem preko AXI (*Advanced eXtensible Interface*) interfejsa. Akvizicija podataka i deo obrade vrše se u programabilnoj logici (PL), dok se skladištenje podataka vrši na jednom od procesora (PS). Razvojna ploča *Digilent* Arty Z7-10 odabrana je jer omogućava povezivanje velikog broja digitalnih I/O signala, kao i dodatnih modula preko Pmod konektora, sadrži interfejs za povezivanje sa mikro SD karticom, a pri tome se odlikuje optimizacijom potrošnje, cene i veličine.

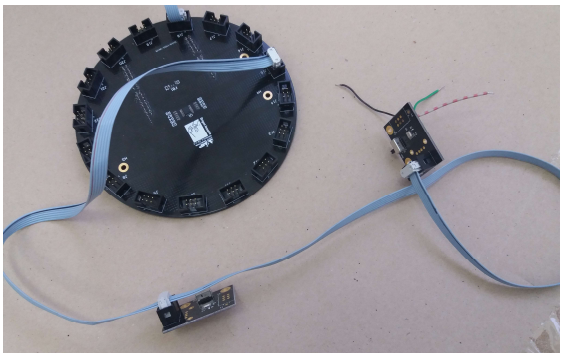
Za povezivanje senzorskog bloka i platforme za akviziciju, obradu i skladištenje podataka projektovana je centralna štampana ploča, označena kao CB (*Central Board*), koja pored potrebnih pasivnih komponenata, sadrži konektor za povezivanje sa *Digilent* Arty Z7-10 razvojnom pločom, sa jedne strane, i 16 odgovarajućih konektora za povezivanje sa EB pločama preko flet kablova zadatih dužina i sa odgovarajućim konektorima, sa druge strane. Na svaki flet kabl povezane su po 2 EB ploče. Na Sl. 4 prikazan je način povezivanja pomenutih komponenata.

C. GPS modul

GPS modulom se preko UART interfejsa prihvataju podaci u obliku informacija o trenutnom položaju sistema (geografske širine i dužine, i nadmorske visine) i tačnog vremena. Izabran je *Digilent* Pmod GPS [33], sa preciznošću geografskih koordinata od 3 m koja zadovoljava potrebe razvijenog sistema.

D. Modul za prikupljanje meteoroloških podataka

Modul za prikupljanje meteoroloških podataka sastoji se iz *Digilent* modula Pmod HYGRO [34] (temperaturni i senzor vlažnosti vazduha) i Pmod NAV [35] (senzor atmosferskog pritiska) sa kojih se očitavaju potrebni parametri.



Sl. 4. Povezivanje CB ploče sa komponentama sistema.

E. Video kamera

Video kamera je deo sistema akustičke kamere koji predstavlja nezavisan uređaj sa sopstvenim napajanjem i memorijom.

F. Napajanje

Za napajanje sistema izabrano je autonomno baterijsko napajanje velikog kapaciteta i malih dimenzija i težine, u vidu eksterne baterije za punjenje mobilnih telefona sa USB mikro konektorom. Namenjeno je za napajanje same akustičke kamere, kao i određenih modula koji se povezuju na platformu. Cilj je da se potrošnja sistema svede na minimum, tako da se obezbedi kontinualno snimanje (od bar 1 h), nakon čega je moguće napuniti ili zameniti bateriju.

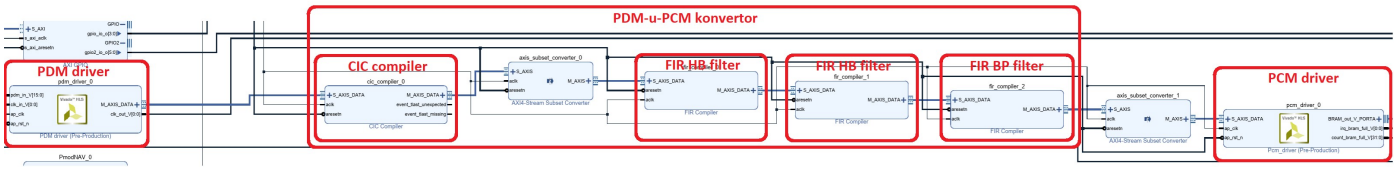
G. Mehanički nosač

Mehanički nosač morao je da zadovolji uslove za malom težinom, kao i za jednostavnim montiranjem ostalih komponenata sistema, a pre svega mikrofona na tačno zadatim pozicijama. Mehanički nosač je projektovan i izdeljen na segmente u softverskom paketu *Solid Works*, a zatim je odštampan pomoću 3D štampača. Masa nosača je oko 0.5 kg.

H. Blok za obradu podataka i korisnički interfejs

Blok za obradu podataka (*postprocessing*) i korisnički interfejs predstavlja PC računar sa specijalno napisanim programom za izdvajanje audio podataka iz vremenskog multipleksa, kao i softverskim paketom MATLAB, u kome je realizovan *delay-and-sum beamforming* algoritam za obradu podataka sa mikrofonskog niza. Iako je među različitim algoritmima najjednostvniji za realizaciju i hardverski najzahtevniji u smislu zahtevanih kapaciteta, pokazao se kao veoma dobro rešenje za veliki broj primena, pa i za konkretnu realizaciju akustičke kamere. Dodatno, moguće je implementirati i druge algoritme, izvršiti poređenje između različitih algoritama, i izabrati odgovarajući algoritam za određenu primenu. U sam algoritam je moguće uključiti podatke dobijene sa dodatnih modula, kao i uključiti napredni algoritnmi za potiskivanje neželjene buke, kao što je buka propelera bespilotne letilice.

Obrada audio zapisa i primena algoritma sprovodi se na delovima signala trajanja 125 ms, nakon čega se vrši preklapanje dobijenih akustičkih mapa sa snimcima dobijenim sa video kamere. Sinhronizacija audio i video zapisa realizovana je na osnovu tačnog vremenskog trenutka impulsne pobude (pljesak) u oba zapisa i skraćivanjem zapisa kod koga je ovaj događaj detektovan kasnije. Na ovaj način je dobijena sinhronizacija sa tačnošću od oko 250 ms.



Sl. 5. Deo realizacije PL (*Xilinx* Vivado Design Suite): PDM-u-PCM konvertor.

IV. SOFTVERSKA REALIZACIJA

FPGA sistemi najčešće se dizajniraju primenom jezika kao što je VHDL (*Very high-speed integrated circuit Hardware Description Language*). Za realizaciju dela sistema u FPGA komponenti (PL) korišćeno je softversko razvojno okruženje *Xilinx* Vivado Design Suite, koje, između ostalog, pruža mogućnost dizajniranja pojedinih delova sistema u vidu IP (*Intellectual Property*) blokova pomoću Vivado HLS softverskog paketa za projektovanje na osnovu alogoritama pisanih u nekom od viših programskih jezika, kao što je C/C++. Za realizaciju PS dela sistema korišćeno je *Xilinx* SDK razvojno okruženje za aplikativni razvoj.

Analizom zahteva sistema za konkretnu primenu određene su potrebne karakteristike izlaznih audio fajlova: frekvencija odabiranja 32 kHz sa rezolucijom od 24 bita.

A. Realiacija PL dela sistema

U okviru PL dela sistema realizovana je akvizicija podataka sa mikrofona u PDM formatu i konverzija u PCM format. Deo realizacije PL dela sistema, realizovanog u *Xilinx* Vivado Design Suite okruženju prikazan je na Sl. 5. Za manipulisanje podacima koji se vode na blok u kome se vrši konverzija iz PDM formata u PCM format, kao i izlaznim podacima iz tog bloka, kreirani su IP blokovi **PDM drajver** i **PCM drajver** u Vivado HLS softverskom paketu. Blok **PDM-u-PCM konvertor** dobijen je kaskadnim povezivanjem postojećih filtarskih blokova (*Xilinx* CIC Compiler v4.0 i FIR Compiler v7.2).

S obzirom na to da performanse jednog ovakvog sistema (pre svega u smislu ispravne akvizicije podataka u realnom vremenu sa zadatog broja ulaznih signala) zavise od načina na koji se pristupa memoriji, veoma je važno da sistem bude strukturiran tako da se omogući što veći protok podataka uz korišćenje minimalne količine resursa. U ovoj realizaciji zadovoljavajuć kvalitet postignut je korišćenjem DMA (*Direct Memory Access*) kontrolera.

1) PDM drajver

Na digitalne MEMS mikrofone dovodi se signal takta frekvencije 3.072 MHz, kojom se vrši odabiranje PDM signala na izlazu iz mikrofona. Akvizicija se vrši paralelno sa svih kanala na uzlaznu/silaznu ivicu signala takta. Jednobitni PDM podaci šalju se na izlaz bloka u vidu dvobitne predstave u komplementu dvojke, prema zahtevu formata ulaza u naredni blok (CIC (*Cascaded Integrator Comb*) filtar). Podaci se šalju u strimu, u TDM (*Time-Division Multiplexing*) formatu.

2) PDM-u-PCM konvertor

U okviru bloka **PDM-u-PCM konvertor** vrši se konverzija signala: ulazni jednobitni PDM signal frekvencije odabiranja 3.072 MHz konvertuje se u 24-bitni 32 kHz PCM signal pa je faktor decimacije 96. Ova konverzija realizovana je u tri koraka: 1) decimacija korišćenjem CIC filtra; 2) filtriranje korišćenjem dva 2:1 HB (*Half Band*) filtra; 3) filtriranje FIR (*Finite Impulse Response*) filtrom propusnikom opsega [36]-[38]. S obzirom na to da je sigma-delta modulator u MEMS mikrofonu četvrtog reda, CIC decimator je petog reda, sa faktorom decimacije 24, dok su faktori decimacije HB filtara 2.

3) PCM drajver

Ovaj blok realizovan je tako da prima 24-bitne PCM podatke sa više kanala u strimu i slaže ih u vremenski multipleks, kako bi se podaci skladištili na SD kartici u tom obliku.

B. Realiacija PS dela sistema

Za realizaciju PS dela sistema korišćeno je *Xilinx* SDK razvojno okruženje za aplikativni razvoj. Ono je kompatibilno sa *Xilinx* Vivado Design Suite okruženjem iz kog je eksportovana konfiguracija dizajnirane hardverske platforme, kako bi na njoj mogao da se razvija softver. Softver se bazira na obradi prekida generisanih po skupljanju određene količine podataka u PCM drajveru. Ovi podaci se dalje smeštaju u bafer i skladište na SD karticu zajedno sa podacima sa dodatnih modula (GPS, meteorološki moduli) u fajlovima određene veličine i formata. Na PC računaru na kome se vrši obrada ovih podataka napisan je program za izdvajanje pojedinačnih audio zapisa sa svakog od mikrofona, kao i podataka sa dodatnih modula.

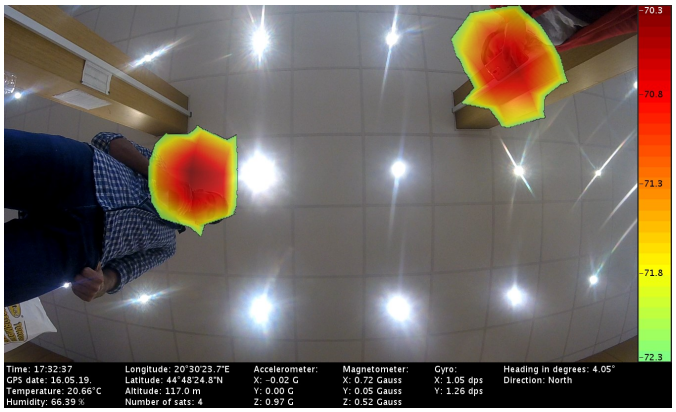
V. REZULTATI

Verifikacija rada realizovanog sistema izvršena je snimanjem realnih signala i poređenjem dobijenih rezultata sa rezultatima simulacije. Na Sl. 6 prikazan je jedan frejm dobijen u programu za obradu na osnovu snimljenih signala sa realizovanom akustičkom kamerom. Tačkasti izvori su zvučnici mobilnog telefona, koji se nalaze na rastojanju od oko 2 m od centra mikrofonskog niza i sa kojih je emitovan zvuk motora, filtriran u opsegu od 1.5 kHz do 2.5 kHz. Na slici se mogu uočiti podaci dobijeni sa GPS i meteoroloških modula. Na Sl. 1 prikazani su rezultati simulacije za istu konfiguraciju i izvor zvuka. Sa slika se može uočiti dobro poklapanje rezultata simulacije i merenja. Generalno, snimanjem različitih izvora zvuka i analizom dobijenih rezultata potvrđen je zadovoljavajuć rad projektovanog sistema.

VI. ZAKLJUČAK

U ovom radu prikazana je jedna platforma za realizaciju napredne akustičke kamere bazirana na *Xilinx* Zynq-7000 AP SoC čipu. Pokazano je da je platforma pogodna za implementaciju dodatnih mogućnosti, kao što su dodavanje odgovarajućih modula, implementiranje i testiranje različitih *beamforming* algoritama, a zbog svoje fleksibilnosti pored konkretne primene može se primenjivati u svim sistemima gde se zahteva akvizicija sa većeg broja senzora. Realizovana akustička kamera ispunila je i zahtev za što manjem težinom (ukupna težina kamere sa svim komponentama je 1.3 kg).

Dodatno, moguća je brza i jeftina proizvodnja, i povezivanje većeg broja ovakvih platformi. Autori nastavljaju rad na poboljšanu karakteristika realizovane platforme u smeru dodatnog povećanja broja ulaznih signala, implementiranja novih algoritama, a pre svega na proširenju mogućnosti same platforme, kao što je realizacija *beamforming* algoritma u realnom vremenu na jednom od procesora sistema, koji je u trenutnoj realizaciji neaktivan.



Sl. 6. Rezutat merenja sistemom – zvuk motora u opsegu 1.5 kHz – 2.5 kHz.

ZAHVALNICA

Ovaj rad je delimično finansiran od strane Inovacionog Fonda u okviru programa saradnje nauke i privrede (projekat ID 50038), kao i od strane Ministarstva prosvete, nauke i tehnološkog razvoja Republike Srbije (projekat TR32038).

ABSTRACT

This paper presents a realization of an advanced acoustic camera, consisting of digital MEMS microphone modules, a platform for acquisition and storing of 32 input signals, additional modules (such as GPS and meteorological modules), and a video camera. Beamforming algorithm is implemented in MATLAB which results in an acoustic map of the analyzed space with a given resolution. The system can be used for realization of various types of microphone arrays with advanced characteristics depending on the application.

Pozicioniranje mikrofona prilikom snimanja audio karakteristika motora putničkih vozila

Marko Milivojčević, Filip Pantelić, Dejan Ćirić

***Apstrakt*— U ovom radu je izvršena analiza audio zapisa dobijenih snimanjem zvuka u oblasti ispod motornog prostora putničkih vozila pokretanih motorima sa unutrašnjim sagorevanjem. Snimanje je ralizovano za tipove vozila sa longitudinalno i transverzalno postavljenim motorom u devet tačaka na površini sa izraženom refleksijom. Prilikom snimanja korišćena su dva tipa mikrofona, merni mikrofon sa omnidirekcionom karakteristikom i pzm (boundary) mikrofon sa kardioidnom karakteristikom. Izvršena analiza ima za cilj da ukaže na mogućnost upotrebe pzm mikrofona za snimanje zvučnih karakteristika motora sa unutrašnjim sagorevanjem prelaskom vozila iznad mikrofona koji su svojom kontrukcijom daleko pogodniji za postavljanje na tlo, kao i da prikaže uticaj relativnog položaja mikrofona u odnosu na izvor zvuka na analizirane karakteristike audio zapisa.**

***Ključne reči*—Akvizicija zvuka, pozicioniranje mikrofona; pzm (boundary) mikrofoni; motori vozila sa unutrašnjim sagorevanjem; spektralna analiza; karakteristike mikrofona.**

I. Uvod

Prilikom frekvencijske analize zvuka generisanog radom motora vozila sa unutrašnjim sagorevanjem sa ciljem određivanja pogonskog goriva realizovane u radu [1], utvrđeno je da se audio zapis najpogodniji za analizu dobija pozicioniranjem mikrofona ispod motornog prostora vozila. Kako bi se kreirala banka audio zapisa potrebnih za mašinsko učenje sistema automatske identifikacije pogonskog goriva motora sa unutrašnjim sagorevanjem na osnovu zvuka potrebno je prikupiti veliki broj audio uzoraka. Za ovu akviziciju, praktično bi bilo najjednostavnije da se vozilo kratak vremenski period u radu pozicionira iznad mikrofona. Kako bi tako ostvarena merenja bila relevantna za dalju analizu, u ovom radu je izvršena analiza uticaja položaja mikrofona u oblasti ispod motornog prostora vozila. Dodatno je izvršena komparacija pzm mikrofona, koji je fizički, zbog svog oblika, najpogodniji za ovu vrstu akvizicije zvučnih zapisa, sa klasičnim mernim mikrofonom kako bi se procenila eventualna degradacija spektra identičnog uzorka zvuka.

U radu je opisan postupak pozicioniranja dva tipa mikrofona u oblasti ispod motornog prostora, neposredno iznad podloge, za dva vozila sa različitom konfiguracijom motora. Cilj je uočiti razlike u prostiranju zvuka koje bi mogle da utiču na kvalitet i karakteristike audio zapisa. U realnim uslovima, kada se prikupljaju uzorci zvuka velikog broja vozila, nije moguće uvek imati identičan položaj mikrofona u odnosu na izvor zvuka. Zbog toga je u ovom radu ispitan položaj mikrofona prilikom kreiranja audio zapisa koji je bio promenljiv. Drugim rečima, mikrofoni su postavljani u fiksne tačke ravnomerno geometrijski raspoređene u oblasti ispod motornog prostora. Simulacija realnih uslova prikupljanja velikog broja uzoraka je podrazumevala rad vozila u režimu praznog hoda, odnosno neopterećenog motora sa stabilnim brojem obrtaja radilice. Izvršena analiza je bazirana na nivou zvučnog polja (zvuka) i spektralnim karakteristikama snimljenih audio sekvenci. Pretpostavka je da su te karakteristike prvi preduslov da se merni mikrofon zameni pzm mikrofonom.

Rezultati komparacije zvučnih zapisa ukazuju da je moguće realizovati sistem za prikupljanje ovog tipa audio zapisa sa pzm mikrofonom i da njegov položaj ispod motornog prostora ne utiče na karakteristike bitne za dalju analizu.

II. Pregled literature

Pregledom literature može se zaključiti da akvizicija zvuka motora vozila sa unutrašnjim sagorevanjem i analiza karakteristika nije široko zastupljena tema. Većina prezentovanih radova se odnosi na snmanje vibro-akustičkih karakteristika, što je razumljivo, obzirom da je cilj uglavnom dijagnostifikovanje neispavnosti u radu motora sa unutrašnjim sagorevanjem [2][3][4]. Međutim, kod ovih primena se pozicioniranje mikrofona vrši u samom motornom prostoru, što u ovom radu nije od interesa. Pokušaji dijagnostifikovanja anomalija u radu motora sa unutrašnjim sagorevanjem rezultovalo je i određenim komercijalnim rešenjima poput pametnog mikrofonskog niza proizvedenog od strane velikog proizvođača automobilskih komponenti Magneti Marelli [5][6] koji se u motornom prostoru pozicionira čvrstom vezom u oblasti usisnog voda.

Klasifikacija vrste vozila na osnovu akustičkih signala (generisanog zvuka) je realizovana u okviru analize buke u saobraćaju sa fokusom na tip vozila (teretno, putničko ili motocikl) [7][8][9], bez osvrta na pogonsko gorivo datih vozila. Ukoliko bi cilj klasifikacije bio selekcija vozila pokretanih motorima sa unutrašnjim sagorevanjem na osnovu pogonskog goriva, kao što je opisano u radu [1] nijedan od navedenih načina pozicioniranja mikrofona nije u potpunosti pogodan, posebno ako se uzme u obzir evidentni napredak u zvučnoj izolaciji proizvođača vozila.

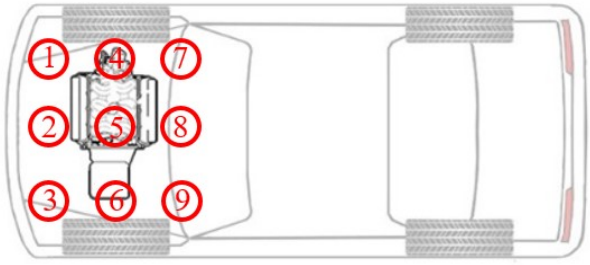
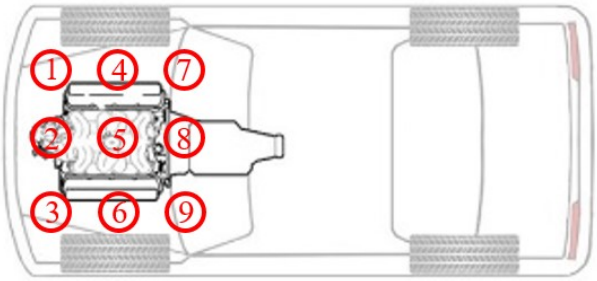
III. POZICIONIRANJE MIKROFONA I KARAKTERISTIKE OPREME

Za prikupljanje audio zapisa u oblasti ispod motornog prostora, korišćena su dva vozila, jedno vozilo je imalo uzdužno (longitudinalno) postavljen motor, dok je drugo vozilo imalo poprečno (transverzalno) postavljen motor: Razlog ovakvog izbora vozila je da bi se uvideo mogući uticaj položaja motora na dobijene rezultate. Vozila su pokretana motorima sa unutrašnjim sagorevanjem koji koriste benzin kao pogonsko gorivo i identičan sistem ubrizgavanja, kako bi zvučni zapisi bili što približnijih karakteristika. Za svako od vozila je merni, a zatim i pzm mikrofon postavljan u devet tačaka. Tačke u kojima su prikupljani audio uzorci su izabrane tako da pokrivaju celokupan motorni prostor, pri čemu je oblast ispod motornog prostora procenjena na dimenzije "1.2 m × 1.2 m", a zatim izdeljena na zone kvadratnog oblika i veličine "40 cm × 40 cm", merne tačke su zatim pozicionirane u centrima kvadrata. Tačka "1" se nalazi u centru prvog kvadrata, odnoso na koordinatama "x=20 cm, y=20 cm" posmatrano u odnosu na prednju stranu vozila. Položaj mernih tačaka je prikazan na Sl. 1 i 2.



Sl. 1. Položaj i raspored mernih tačaka za vozilo sa poprečno postavljenim motorom.

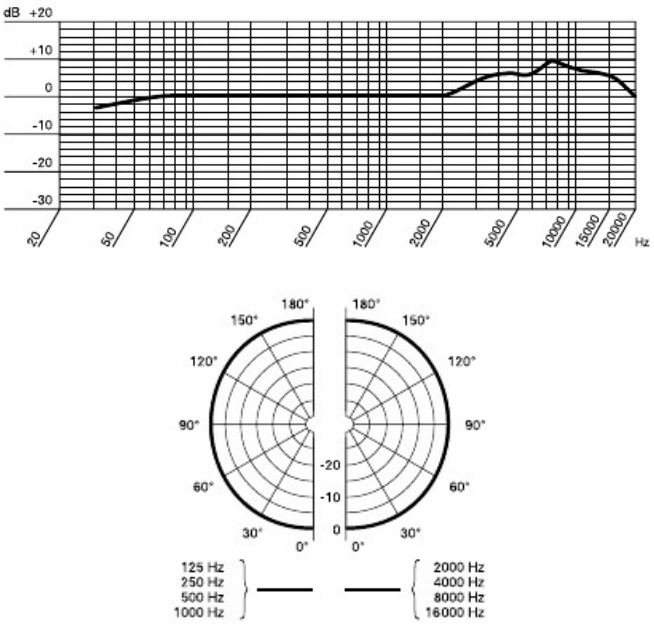


Sl. 2. Položaj i raspored mernih tačaka za vozilo sa uzdužno postavljenim motorom.

Merenje je vršeno u zatvorenoj prostoriji koja nije potpuno zvučno izolovana od okolnih uticaja. U svakoj od mernih tačaka snimani su audio uzorci trajanja 5 s. Uzimajući u obzir da motor sa unutrašnjim sagorevanjem i četiri radna takta u praznom hodu radi na približno 700 obrtaja radilice u minutu, i da je za četiri radna ciklusa sva četiri cilindra potrebno dva obrtaja radilice u sekundi, može se zaključiti da je potrebno približno 0.2 s kako bi motor prošao kroz sve radne cikluse u ovom režimu [10]. Izabrano vreme trajanja audio uzoraka je produženo zbog nesavršenosti mernog okruženja i mogućnosti usrednjavanja i lakše obrade u slučaju da se na snimku pojavi neki neželjeni zvuk.

Oprema korišćena za merenje se sastojala iz dva seta. Jedan set je bio vezan za merni mikrofon, dok je drugi bio praktičnije realizovan sa pzm mikrofonom. Set sa mernim mikrofon se sastojao od mernog mikrofona DBX RTA-M i audio interfejsa Behringer UMC404HD. Set sa pzm mikrofonom se sastojao od mikrofona AKG C562BL i ručnog snimača Zoom H4Nsp. Pzm mikrofon karakteriše robusna konstrukcija, mala visina od svega 9 mm [11] pogodna za postavljanje ispod vozila (Sl. 3), hemisferna karakteristika usmerenosti i frekvencijska karakteristika data na Sl. 4. Snimanje je obavljeno sa frekvencijom odabiranja fs=44100 Hz i dinamičkom rezolucijom od 16 bita.

Sl. 3. Izgled korišćenog pzm mikrofona AKG C562BL.



Sl. 4. Frekvencijska karakteristika mikrofona AKG C562BL [11].

Karakteristika nivoa zvučnog polja (nivoa zvuka) snimaka je računata u okviru softvera SoundForge, dok je frekvencijska analiza rađena u Matlab-u.

IV. KARAKTERISTIKE SNIMLJENIH ZVUKOVA MOTORA

Kao početni korak u analizi zabeleženih audio uzoraka izvršeno je izračunavanje srednje kvadratne vrednosti (RMS-a) za svaki od snimaka. Postupak analize dobijenih vrednosti je podrazmevao četiri slučaja: slučaj uzdužno postavljenog motora snimanog mernim mikrofonom, slučaj uzdužno postavljenog motora snimanog pzm mikrofonom, slučaj

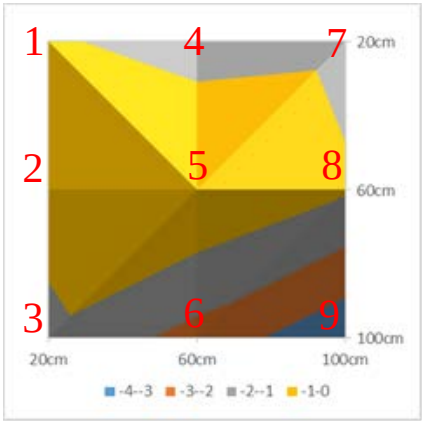
poprečno postavljenog motora snimanog mernim mikrofonom i slučaj poprečno postavljenog motora snimanog pzm mikrofonom. Analiza je sprovedena za režim rada motora u praznom hodu, odnosno neopterećenog motora. Izračunati nivoi RMS-a u odnosu na tip vozila, tip mikrofona i položaj mikrofona su dati u Tabeli I.

TABELA I
IZRAČUNATI NIVOI RMS U ZAVISNOSTI OD TIPA VOZILA I TIPA MIKROFONA

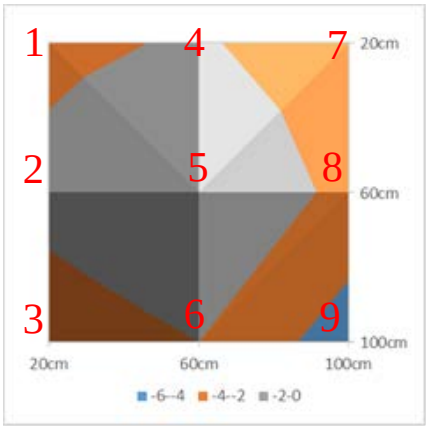
	Poprečno postavljen motor	Uzdužno postavljen motor
Tip mikrofona	PZM	
Merna pozicija 1	-23.95 dB	-20.94 dB
Merna pozicija 2	-23.04 dB	-22.93 dB
Merna pozicija 3	-25.01 dB	-22.73 dB
Merna pozicija 4	-22.61 dB	-19.56 dB
Merna pozicija 5	-21.34 dB	-19.37 dB
Merna pozicija 6	-23.89 dB	-20.62 dB
Merna pozicija 7	-24.52 dB	-20.73 dB
Merna pozicija 8	-23.34 dB	-19.10 dB
Merna pozicija 9	-26.37 dB	-20.13 dB
Tip mikrofona	Merni mikrofon	
Merna pozicija 1	-19.968 dB	-26.017 dB
Merna pozicija 2	-19.792 dB	-27.044 dB
Merna pozicija 3	-20.521 dB	-27.701 dB
Merna pozicija 4	-20.455 dB	-25.127 dB
Merna pozicija 5	-19.075 dB	-25.484 dB
Merna pozicija 6	-21.428 dB	-26.016 dB
Merna pozicija 7	-20.321 dB	-26.214 dB
Merna pozicija 8	-19.963 dB	-25.098 dB
Merna pozicija 9	-22.866 dB	-25.907 dB

Kako su se zbog razlike u konstrukciji vozila, apsolutni nivoi zvuka dva različita vozila razlikovali, prikazani rezultati su predstavljeni kao relativni nivoi - relativni u odnosu na tačku sa najvišim nivoom RMS-a. Na Sl. 5 i 6 su prikazana odstupanja RMS-a u odnosu na tačku sa najvišim nivoom RMS-a za vozilo sa poprečno postavljenim motorom u slučaju da su uzorci snimljeni mernim, odnosno pzm mikrofonom, respektivno. Na Sl. 5, 6, 8 i 9 su varijacije nivoa izračunatih RMS vrednosti izražene u dB prikazane različitim bojama koje su označene na legendi ispod svakog grafika.

U slučaju vozila sa poprečno postavljenim motorom može se zaključiti da je najviši nivo RMS zabeležen u mernoj tački "5", odnosno njegov nivo je -19.075 dB za merni i -21.34 dB za pzm mikrofon. Relativna odstupanja su za merni mikrofon u granicama od 0 dB do -3.791 dB, dok su za pzm mikrofon nešto veća i kreću se u granicama od 0 dB do -5.03 dB. Na Sl. 5. se posebno u mernoj tački "1" može uočiti uticaj usmerenosti pzm mikrofona koja utiče na niži nivo primljenog signala u odnosu na merni mikrofon.

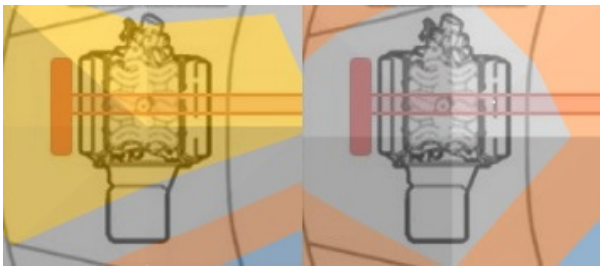


Sl. 5. Prikaz odstupanja RMS vrednosti nivoa zvuka u dB za vozilo sa poprečno postavljenim motorom snimano mernim mikrofonom.



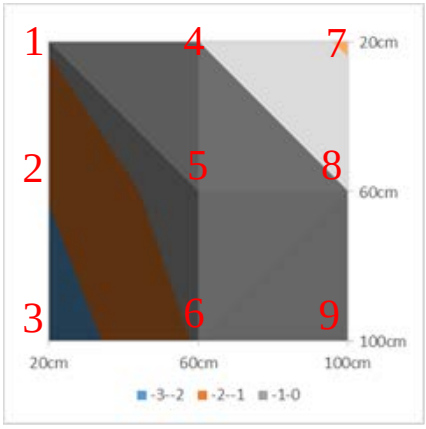
Sl. 6. Prikaz odstupanja RMS vrednosti nivoa zvuka u dB za vozilo sa poprečno postavljenim motorom snimano pzm mikrofonom.

Iako formirano polje RMS vrednosti nivoa zvuka nema velikih varijacija, ipak se može uočiti izvestan karakterističan oblik višeg nivoa koji se poklapa sa konstrukcijom i položajem izduvnog sistema vozila (označenog crvenom bojom), što je prikazano na Sl. 7. Varijacije u nivou RMS-a su na Sl. 7 i 10 prikazane različitim bojama oslanjajući se na grafike 5 i 6 odnosno 8 i 9.

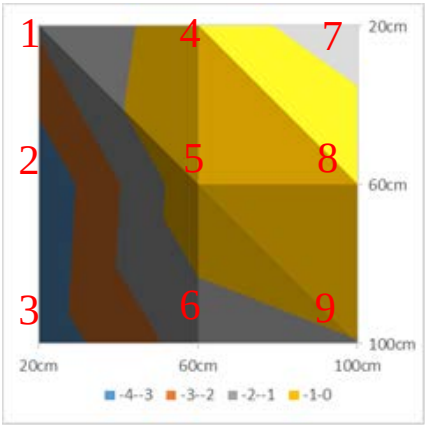


Sl. 7. Uporedni prikaz RMS nivoa kod vozila sa poprečno postavljenim motorom u odnosu na položaj izduvnog sistema.

Na Sl. 8 i 9 su prikazana odstupanja RMS vrednosti nivoa zvuka u odnosu na tačku sa najvišim RMS nivoom za vozilo sa uzdužno postavljenim motorom u slučaju da su uzorci snimljeni mernim odnosno pzm mikrofonom, respektivno.



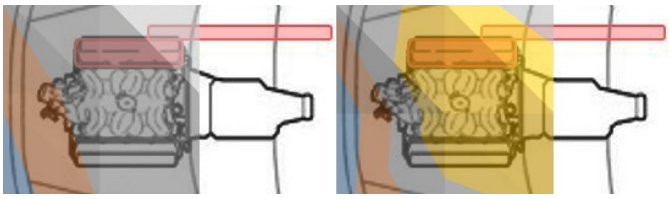
Sl. 8. Prikaz odstupanja RMS vrednosti nivoa zvuka u dB za vozilo sa uzdužno postavljenim motorom snimano mernim mikrofonom.



Sl. 9. Prikaz odstupanja RMS vrednosti nivoa zvuka u dB za vozilo sa uzdužno postavljenim motorom snimano pzm mikrofonom.

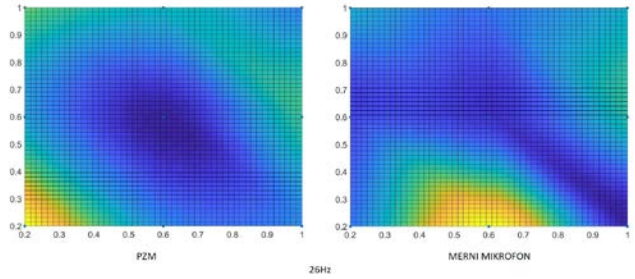
U slučaju vozila sa uzdužno postavljenim motorom može se zaključiti da je najviši RMS nivo zvuka takođe zabeležen u mernoj tački “5”, odnosno njegova vrednost je -25.484 dB za merni i -19.37 dB za pzm mikrofon. Relativna odstupanja su za merni mikrofon u granicama od 0 dB do -2.603 dB dok su za pzm mikrofon nešto veća i kreću se u granicama od 0 dB do -3.83 dB.

Kod vozila sa uzdužno postavljenim motorom formirano zvučno polje takođe nema velikih varijacija u RMS nivou, ali se može uočiti izvestan karakterističan oblik višeg nivoa koji se poklapa sa konstrukcom i položajem izduvnog sistema vozila (označenog crvenom bojom), što je prikazano na Sl. 10.

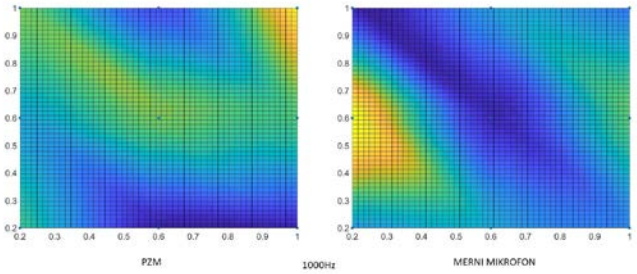


Sl. 10. Uporedni prikaz RMS nivoa kod vozila sa uzdužno postavljenim motorom u odnosu na položaj izduvnog sistema.

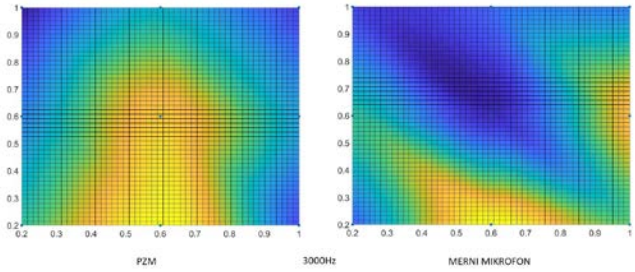
Osvrtom na rad [1] i imajući u vidu zaključak da bi pri klasifikaciji pogonskog goriva motora sa unutrašnjim sagorevanjem posebno bio značajan deo spektra u opsegu 3-4 kHz, izvršena je analiza nivoa zvučnog polja na odgovarajućim frekvencijama, kao i oblika spektra u ovom opsegu kako bi se uvideo uticaj tipa mikrofona. Na Sl. 11 do 15 dat je prikaz nivoa zvučnog polja samo za vozilo sa uzdužno postavljenim motorom, pri čemu su svetlijom bojom prikazani viši nivoi zvučnog polja.



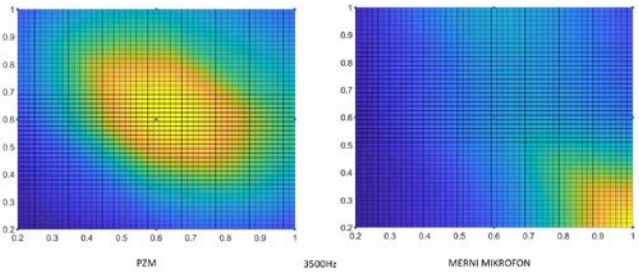
Sl. 11. Nivo zvučnog polja za vozilo sa uzdužno postavljenim motorom na učestanosti od 26 Hz



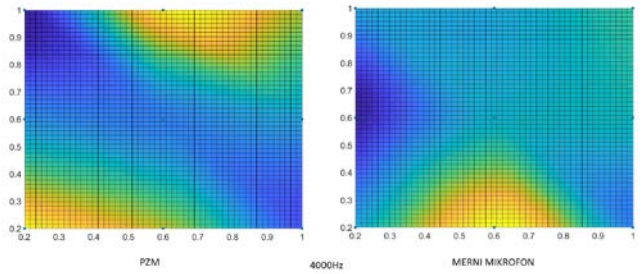
Sl. 12. Nivo zvučnog polja za vozilo sa uzdužno postavljenim motorom na učestanosti od 1000 Hz.



Sl. 13. Nivo zvučnog polja za vozilo sa uzdužno postavljenim motorom na učestanosti od 3000 Hz.



Sl. 14. Nivo zvučnog polja za vozilo sa uzdužno postavljenim motorom na učestanosti od 3500 Hz.



Sl. 15. Nivo zvučnog polja za vozilo sa uzdužno postavljenim motorom na učestanosti od 4000 Hz.

Posmatrajući uporedne karakteristike nivoa zvučnog polja snimane pomoću dva mikrofona sa Sl. 11 do 15 može se uočiti da postoje određene razlike između ovih karakteristika. One su pre svega posledica različitog frekvencijskog odziva i karakteristike usmerenosti mikrofona. Pored toga, može se reći da je oblik zvučnog polja formiran na osnovu snimaka u identičnim uslovima za pzm mikrofon uniformniji, pre svega u centralnom delu analiziranog motornog prostora. Na ovaj način su uzorci snimljeni pzm mikrofonom pogodniji za analizu u slučaju kada nije moguće predvideti tačnu poziciju izvora zvuka u odnosu na mikrofon.

V. ZAKLJUČAK

Posmatrajući rezultate merenja sa aspekta RMS vrednosti nivoa zvuka može se zaključiti da, iako pzm mikrofon ima usmereniju karakteristiku, to ne rezultira velikim varijacijama u nivou zvuka, a posebno ne na karakterističan oblik formiranog polja. Ukoliko se uzme u obzir njegova izuzetno mala visina od 9 mm, ovaj mikrofon je moguće koristiti umesto mernog mikrofona u cilju prikupljanja velikog broja uzoraka audio zapisa motora sa unutrašnjim sagorevanjem. Male varijacije u RMS nivoima zvuka, kao i relativno uniformna raspodela zvučnog polja ispod centralnog dela motornog prostora u frekvencijskom opsegu od interesa ukazuju da položaj mikrofona u oblasti ispod motornog prostora nema veliki uticaj na parametre zvuka. Ovo pruža mogućnost fiksiranja pzm mikrofona na podlogu iznad koje prelaze i kratko se zadržavaju vozila (naplatna rampa, ulazna rampa parkinga, benzinska pumpa) radi snimanja zvuka motora. Dalji rad podrazumeva izdvajanje novog seta parametara od interesa kao i analiza uticaja tipa mikrofona na karakteristike istih.

ABSTRACT

In this paper, analysis of audio samples obtained by recording of sound below the compartment of internal combustion engines of passenger vehicles is carried out. Sound is recorded using two vehicle types (with longitudinally and transversally set engine) in nine points located on a reflective surface. Recordings are made by two microphones – by an omni directional measurement microphone and by a pzm (boundary) microphone with cardioid polar pattern. The performed analysis has a goal to show the potentials for usage of the pzm microphone for recording of sound of internal combustion engine when a passenger car is passed above the microphone. This microphone has more convenient construction for mounting on a hard floor. Another goal of the presented analysis is to show the influence of the microphone relative position in reference to the sound source on the audio characteristics of recorded sound.

Positioning of Microphone while Recording the Audio Characteristics of Passenger Vehicle Engines

Krive opadanja dobijene u reverberacionoj komori pri merenju koeficijenta apsorpcije

Dejan Ćirić, Kristian Jambrošić, Nikola Stojković

***Apstrakt*—Jedan od klasičnih pristupa za merenje koeficijenta apsorpcije test uzorka je baziran na merenju vremena reverberacije prazne reverberacione komore i vremena reverberacije kada se test uzorak nalazi u komori. Dimenzije i osnovne karakteristike reverberacione komore su definisane u relevantnim standardima. Kada se ispune određeni uslovi, naročito kada je zapremina komore manja od preporučenih vrednosti, mogu se javiti neželjeni efekti sopstvenih modova prostorije na niskim frekvencijama. Uticaj ovih efekata pri merenju koeficijenta apsoprcije test uzoraka na krive opadanja zvuka je analiziran u radu. Merenja impulsnih odziva su izvršena u reverberacionoj komori zapremine oko 65 m^3. U opsezima terci ispod 160 Hz se mogu javiti specifična višestruka (najčešće dvostruka) opadanja zvuka koja daju konkavni oblik krivim opadanja. U ovakvim slučajevima se postavlja pitanje na koji način izračunati vreme reverberacije.**

***Ključne reči*—Krive opadanja; reverberaciona komora; koeficijent apsorpcije; sopstveni modovi prostorije.**

I. UVOD

KOEFICIJENT apsorpcije se meri primenom metoda impedansne cevi ili metoda reverberacione komore (prostorije) koji predstavlja standardizovani metod merenja [1]. Drugo pomenuti metod pretpostavlja da u ovakvoj prostoriji postoji difuzno zvučno polje [2]. Tokom godina primene bilo je dosta oprečnih mišljenja, pogotovu o preciznosti ovog metoda na niskim frekvencijama. Jedan od razloga može biti odstupanje od pretpostavljenog difuznog zvučnog polja, koje nije jednostavno realizovati u praksi.

Analiza kapaciteta reverberacione komore da aproksimira difuzno zvučno polje se bazira na raznim deskriptorima. U ove deskriptore spadaju granična frekvencija, broj modova, prostorna uniformnost reveberantnog zvučnog polja, zakrivljenost krivih opadanja zvuka i preciznost merenog vremena reverberacije [2].

U reverberacionim komorama se može očekivati da krive opadanja zvuka prikazane na logaritamskoj skali imaju oblik prave linije. Zbog toga primena klasičnog načina izračunavanja vremena reverberacije linearnom regresijom koristeći opseg od 20 ili 30 dB deluje sasvim prihvatljivo. Međutim, postoje slučajevi kada krive opadanja zvuka odstupaju od prave linije. Ove zakrivljenosti krivih opadanja se lakše detektuju kada su krive dobijene *Schroeder*-ovim integraljenjem unazad [3] nego kada su dobijene metodom prekinutog šuma (eng. *interrupted noise method*) [4].

Ovaj rad se bavi analizom krivih opadanja zvuka dobijenih pri merenju koeficijenta apsorpcije u reverberacionoj komori čija je zapremina manja od 150 m^3 koja se preporučuje u standardu ISO 354 [4]. Fokus je na krivama opadanja zvuka koje nemaju pravolinijski oblik. Ovakve krive pokazuju ili dvostruko opadanje ili jaku zakrivljenost tako da je njihov oblik konkavan. Ova pojava je dominantna na niskim frekvencijama, tipično ispod 160 Hz. Analizirani su rezultati merenja prazne reverberacione komore, kao i komore sa test uzorcima. Pored toga, merenja u praznoj prostoriji su obavljena sa i bez difuzora.

II. KRIVE SA VIŠESTRUKIM OPADANJEM

Višestruka opadanja zvuka su uobičajena pojava kada postoji više spojenih prostorija (eng. *coupled spaces*). Procena parametara opadanja u ovakvim slučajevima se često svodi na njihovu aproksimaciju sumom više eksponencijalnih opadanja [5,6]. Međutim, višestruka opadanja se mogu javiti i u prostorijama gde nema spojenih prostora već se radi o jedinstvenom celovitom prostoru [7]. U takvim slučajevima, sopstveni modovi prostorije dovode do toga da je opadanje zvuka zbir više eksponencijalnih opadanja umesto jednog jedinstvenog [8]. Na taj način se umesto pravolinijske krive opadanja dobija kriva koja je zakrivljena. Postoje i slučajevi kada se na krivoj opadanja mogu jasno primetiti višestruka pravolinijska opadanja sa različitim strminama.

Pomenuta višestruka opadanja se mogu javiti kako na niskim frekvencijama, tako i na srednjim i visokim frekvencijama. Pod niskim frekvencijama se često podrazumeva opseg ispod *Schroeder*-ove frekvencije [2,9,10]. Karakteristično za ovaj frekvencijski opseg je da postoji manje sopstvenih modova tako da dolazi i do njihovog manjeg preklapanja. Zakrivljenost na niskim frekvencijama je posledica promenljivih vremena opadanja aksijalnih, tangencijalnih i bočnih (eng. *oblique*) modova [11]. Kako je vreme reverberacije veće kod aksijalnih modova, a mnogo manje kod tangencijalnih i bočnih modova [12], onda će se kao rezultat javiti zakrivljenost krivih opadanja. Praktično se krive opadanja svakog od modova kombinuju u krivu koja predstavlja globalno opadanje zvuka. Ova kriva onda nije prava linija, i izbor estimacije vremena opadanja (reverberacije) dobija još više na značaju.

Kada je mikrofon postavljen u ugao prostorije, izmereni

Dejan Ćirić – Elektronski fakultet u Nišu, Univerzitet u Nišu, Aleksandra Medvedeva 14, 18000 Niš, Serbia (e-mail: dejan.ciric@elfak.ni.ac.rs).

Kristian Jambrošić – Fakultet elektrotehnike i računarstva, Sveučilište u Zagrebu, Unska 3, HR-10000 Zagreb, Hrvatska (e-mail: Kristian.Jambrosic@fer.hr).

Nikola Stojković – Elektronski fakultet u Nišu, Univerzitet u Nišu, Aleksandra Medvedeva 14, 18000 Niš, Serbia (e-mail: stojkovicnikola@elfak.rs).

nivo zvučnog pritiska je veći u odnosu na srednju vrednost u prostoriji usled efekata interferencije. Ovo povećanje je 3, 6 i 9 dB za aksijalne, tangencijalne i bočne modove, respektivno [12]. Na sličan način se javljaju efekti interferencije i kada se zvučnik postavi u ugao. Ovakvo ponašanje ima jak uticaj na balans između modova.

Na srednjim i visokim frekvencijama situacija je nešto drugačija. Ovde neravnomerna raspodela apsorpcionih površina može dovesti do višestrukog (više-eksponencijalnog) opadanja [13], odnosno opadanja koje odstupa od Sabinovog zakona [14].

Značajno je istaći da zakrivljenost krive opadanja samo po sebi ne mora da znači da zvučno polje nije difuzno [8]. Međutim, zakrivljenost krivih opadanja može biti ozbiljan problem. Tako, pri merenjima koeficijenta apsorpcije u različitim laboratorijama, jedan od osnovnih uzroka razlika u rezultatima može biti različit pristup tretiranju višestrukih opadanja.

U literaturi je prezentovano da kod krivih sa višestrukim opadanjem početak krivih opadanja sadrži srednju vrednost svih modova u prostoriji [8]. Za razliku od toga, poslednji deo krivih opadanja sadrži modove koji sporije opadaju. U referenci 15 je predloženo da je moguće koristiti početni deo krive opadanja kako bi se izračunao koeficijent apsorpcije test uzorka. Eksperimenti u skaliranom modelu reverberacione komore su pokazali da se bolji rezultati za određivanje koeficijenta apsorpcije dobijaju kada se koristi početni deo opadanja umesto vremena reverberacije dobijenog na osnovu opadanja od 20 ili 30 dB [8]. Na ovaj način se dobijaju manje vrednosti vremena reverberacije nego što bi se po teoriji očekivalo, ali je to bolje rešenje nego koristiti opadanje sa manjom strminom. Prezentovani su i pristupi koji nisu favorizovali karakterizaciju opadanja zvuka u reverberacionoj komori koristeći samo jednu vrednost [16].

III. Granična frekvencija reverberacione komore

Kod prostorija malih dimenzija, dominantan uticaj na odziv ima modalno ponašanje, odnosno akustika malih prosorija se često karakteriše neregularnom raspodelom zvuka na niskim frekvencijama [12]. Reverberacione komore spadaju u prostorije specijalne namene, čija se konstrukcija razlikuje od običnih prostorija. Međutim, neregularna raspodela zvuka na niskim frekvencijama se može javiti i u ovim komorama.

Jedan od značajnih parametara kojim se opisuje reverberaciona komora je granična frekvencija koja pokazuje donju graničnu frekvenciju difuznosti zvučnog polja. Dve vrste definicija se koriste za određivanje donje granične frekvencije: jedna je bazirana na konceptu faktora modalnog preklapanja dok je druga bazirana na broju modova u određenom frekvencijskom opsegu [2]. Iz prvo pomenute defincije prositiče tzv. *Schroeder*-ova frekvencija koja odgovara faktoru modalnog preklapanja vrednosti 3 [9], koja je prilično restriktivna sa tačke gledišta primene [17]. *Schroeder*-ova frekvencija deli frekvencijski odziv prostorije na nisko frekventni (ispod *Schroeder*-ove frekvencije) gde dominiraju modovi prostorije, i visoko frekventni (iznad *Schroeder*-ove frekvencije) gde dominira gusto modalno preklapanje sa statističkim (Gausovim) svojstvima [10]. *Schroeder*-ova frekvencija je definisana izrazom

$$f_c = 2000 \cdot (T/V)^{0.5} \tag{1}$$

gde je T vreme reverberacije, a V zapremina prostorije. Za konkretnu reverberacionu komoru Elektronskog fakulteta u Nišu (u kojoj su izvršena merenja) zapremine 65.05 m^3, ukoliko se za vreme reverberacije uzme vrednost od 5 s, dobija se *Schroeder*-ova frekvencija 554 Hz. Međutim, u mnogim praktičnim merenjima nisu pronađeni dokazi da se nisko frekventni region prostirao na frekvencije veće od polovine *Schroeder*-ove frekvencije [10]. U skladu sa tim je predložena i modifikovana granična frekvencija koja je približno 0.45 vrednosti *Schroeder*-ove frekvencije [10]. U slučaju reverberacione komore Elektronskog fakulteta u Nišu, poslednji izraz bi dao graničnu frekvenciju od 250 Hz.

Drugo pomenuta definicija je statistički bazirana i često se koristi. Granična frekvencija dobijena na ovaj način odgovara modalnom broju (broju modova) 20 u bilo kom frekvencijskom opsegu. Za jedan tercni opseg, ova granična vrednost (f_c) se dobija pomoću izraza

$$f_c = \frac{343}{\sqrt[3]{V/4}} \tag{2}$$

U konkretnom slučaju komore zapremine 65.05 m^3, granična frekvencija iznosi oko 135 Hz. Za komore zapremine od 150 m^3, granična frekvencija prema (2) ima vrednost oko 102 Hz, dok za komore zapremine 200 m^3, granična frekvencija iznosi 93 Hz.

Stepen linearnosti krivih opadanja može biti dobar indikator difuznosti zvučnog polja [2]. Da bi se kvantifikovao stepen nelinearnosti krive opadanja ili drugim rečima njene zakrivljenosti, koristi se koeficijent korelacije (r) između krive opadanja i aproksimacione prave koja na najbolji način reprezentuje datu krivu opadanja [11]. Efektivna mera zakrivljenosti se može dobiti i pomoću odstupanja od idealne korelacije [11], što se predstavlja jednačinom

$$\kappa = 1000\left(1 - abs(r)\right) \tag{3}$$

IV. Merenja i obrada odziva

U okviru COST akcije 15125 realizuje se *round robin* eksperiment koji se bavi merenjem koeficijenta apsorpcije 3 unapred pripremljena test uzorka. Akcenat je na uticajima različitih reverberacionih komora, opreme, obrade i timova koji vrše merenja, sa posebnim osvrtom na rezultate na niskim frekvencijama. U tom kontekstu, izvršena su merenja koefcijenta apsorpcije 3 test uzorka u prethodno pomenutoj reveberacionoj komori Elektronskog fakulteta u Nišu. Prostorija je nepravilnog oblika, nema paralelnih zidova, najveća stranica osnove je 4.08 m, dok je najmanja stranica osnove 3.67 m. Najveća visina je 4.33 m, dok je najmanja

visina 3.87 cm. Svi zidovi su refleksioni, vrata su dvostruka, a unutrašnja površina vrata je prekrivena pločicama.

Za namenu povećanja difuznosti zvuka, mogu se koristiti difuzori koji se postavljaju da vise sa tavanice. Postoji 5 ovakvih difuzora površine od 0.8 do 2 m^2, videti Sl. 1, što je u skladu sa standardom ISO 354 [4]. Raspored difuzora je slučajan. Merenja u praznoj komori su obavljena sa i bez difuzora, dok su sva merenja sa test uzorcima obavljena kada su difuzori bili postavljeni.

Sl. 1. Reverberaciona komora sa difuzorima.

Izračunavanja koeficijenta apsorpcije u reverberacionoj komori su bazirana na izmerenim vrednostima vremena reverberacije prazne komore i kada je u nju postavljen test uzorak. Za ova merenja su primenjene dve tehnike, *swept sine* tehnika [18] i tehnika prekinutog šuma. Kod prvo pomenute tehnike je kao pobuda korišćen *swept sine* signal dužine 30 s, frekvencijskog opsega od 20 Hz do 11 kHz koji je ponovljen 2 puta sa pauzom od 30 s. U ovom radu će biti prikazani samo rezultati dobijeni *swept sine* tehnikom.

Pobudni signal je reprodukovan neusmerenim zvučnim izvorom u obliku sfere koji sadrži 12 pobudnih jedinica u rasporedu dodekedra, videti Sl. 2. Odzivi su snimani mernim mikrofonom Bruel & Kjaer, type 4144. Merna oprema je još sadržala pojačavač audio signala, eksternu zvučnu karticu, mikrofonsko napajanje i laptop računar sa koga je vršena reprodukcija pobude i snimanje odziva.

Sl. 2. Postavka za merenja sa prikazom zvučnog izvora i mikrofona sa test uzorkom u reverberacionoj komori.

U uputstvima za *round robin* test je već definisano da se za merenja koristi 12 regularnih kombinacija položaja zvučnog izvora i mikrofona i dodatna 2 položaja mikrofona u uglovima komore. Dakle, ukupno se koristi 14 kombinacija položaja izvora i mikrofona za svaki test uzorak. Pri tome, izabrane su 4 pozicije za zvučni izvor i za svaki od njih po 3 pozicije za merni mikrofon koje su zadovoljile uslove definisane standardom ISO 354. Za jedan položaj zvučnog izvora, definisane su i 2 dodatne pozicije mikrofona u uglovima komore. Za svaku od pozicija izvora i mikrofona je definisana visina izvora, odnosno mikrofona.

Isti položaji izvora i mikrofona se koriste i za merenja u praznoj komori i u komori sa test uzorcima. Za svaki test uzorak uključujući praznu komoru i komoru sa uzorkom, setovi merenja se vrše sa dva ponavljanja. Sa svim neophodnim pripremama, merenja su trajala nešto manje od 3 nedelje.

Na osnovu izmerenih odziva se najpre izdvajaju impulsni odzivi prostorije. Ovi odzivi se zatim filtriraju u opsezima terci, a zatim se primenom *Schoreder*-ovog integraljenja unazad dobijaju krive opadanja. Dalje sledi obrada radi izračunavanja koeficijenata apsorpcije koja nije predmet ovog rada. Obrada je obavljena u programskom paketu Matlab. Ovde će biti prikazani samo rezultati koji se odnose na dobijene krive opadanja.

V. Analiza krivih opadanja

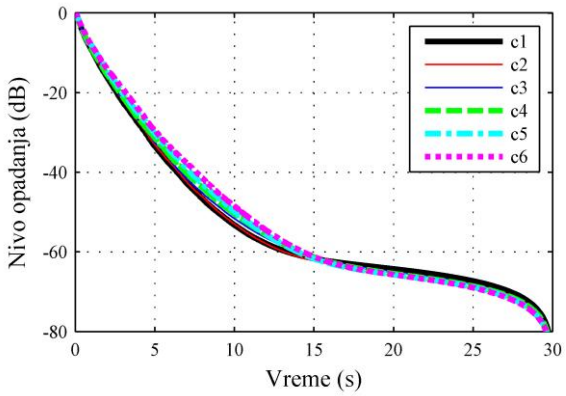
A. Uticaj difuzora

Najpre je anliziran uticaj difuzora na krive opadanja izmerene u praznoj reverberacionoj komori. Za tu namenu se porede krive opadanja dobijene sa i bez difuzora. Kao što je prethodno pomenuto, posebna pažnja se posvećuje krivama u opsezima terci na niskim i srednjim frekvencijama.

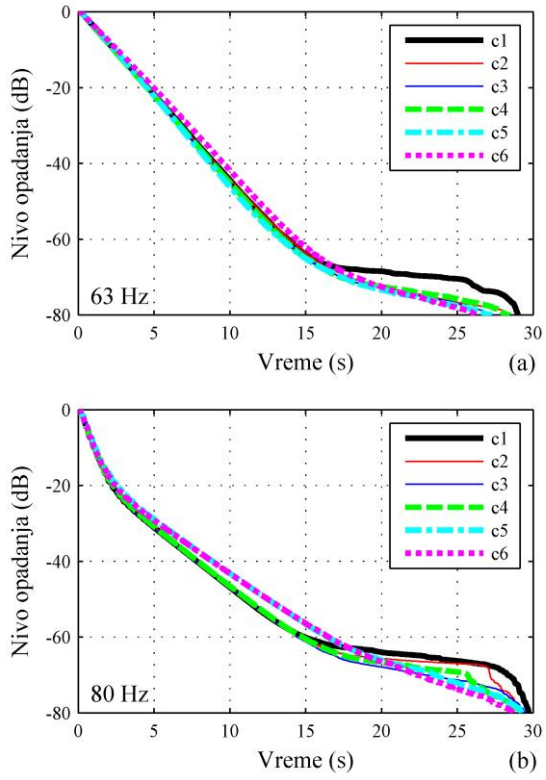
Krive opadanja dobijene *Schoreder*-ovim integraljenjem unazad širokopojasnih impulsnih odziva su prikazane na Sl. 3. Dato je 6 krivih opadanja koje su generisane na osnovu odziva izmerenih kada je u reverberacionoj komori bilo postavljeno svih 5 difuzora, kao i odziva izmerenih kada je u komori bilo 4 difuzora, zatim 3, 2 i 1 difuzor, kao i odziva izmerenih u praznoj komori bez difuzora. Uticaj difuzora je vidljiv kod prikazanih širokopojasnih krivih opadanja. Sve krive pokazuju određenu zakrivljenost gde je jasno vidljiv konkavni oblik. Strmine reverberacionog opadanja nisu potpuno identične kod ovih krivih. Prelaz od krive bez difuzora do krive sa svih 5 difuzora je postepen.

Krive opadanja dobijene na isti način kako je opisano za širokopojasne odzive ali za odzive filtrirane u opsezima terci na 63 Hz i 80 Hz su prikazane na Sl. 4(a) i (b), respektivno. Izabrana su dva tercna opsega koji ilustruju dve različite situacije prisutne na niskim frekvencijama. Sl 4(a) prikazuje slučaj kada je uticaj difuzora na krive opadanja manji, i gde gotovo da ne postoji zakrivljenost krivih opadanja, odnosno njihov konkavni oblik. Za razliku od toga, Sl. 4(b) prikazuje situaciju gde postoji određeni uticaj difuzora i gde je prisutno dvostruko opadanje kod krivih opadanja. Prvo opadanje ima veću striminu opadanja i manji dinamički opseg, dok drugo

opadanje ima manju strminu i veći dinamički opseg. Generalno se može reći da je uticaj difuzora najmanji na najnižim frekvencijama, i da se on povećava kako se povećava frekvencija. Pri tome, postoje tercni opsezi gde je uticaj difuzora veći, i oni gde je uticaj difuzora manji.

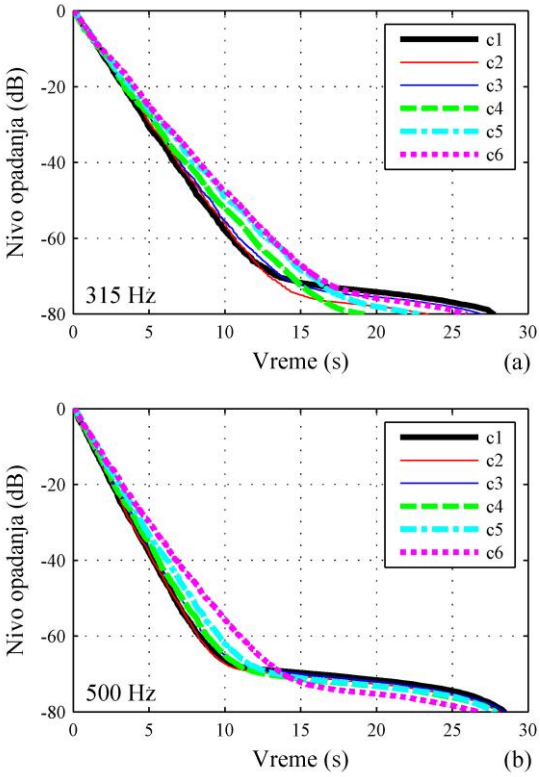


Sl. 3. Krive opadanja dobijene *Schroeder*-ovim integraljenjem unazad širokopojasnih impulsnih odziva izmerenih za jednu kombinaciju položaja zvučnog izvora i mikrofona: sa svih 5 difuzora (c1), sa 4 difuzora (c2), sa 3 difuzora (c3), sa 2 difuzora (c4), sa 1 difuzorom (c5) i bez difuzora (c6).



Sl. 4. Krive opadanja dobijene *Schroeder*-ovim integraljenjem unazad impulsnih odziva filtriranih u opsegu terci na 63 Hz (a) i na 80 Hz (b) izmerenih za jednu kombinaciju položaja zvučnog izvora i mikrofona: sa svih 5 difuzora (c1), sa 4 difuzora (c2), sa 3 difuzora (c3), sa 2 difuzora (c4), sa 1 difuzorom (c5) i bez difuzora (c6).

Može se reći da je uticaj difuzora najveći na srednjim frekvencijama, ili preciznije u tercnim opsezima na nekoliko stotina herca. Ilustracija ovakave situacije je prikazana na Sl. 5. U oba prikazana tercna opsega se može videti da se sa povećanjem broja difuzora prisutnih u reverberacionoj komori smanjuje zakrivljenost krivih opadanja. Drugim rečima rečeno, smanjuje se prisustvo dvostrukog opadanja tako što se strmina drugog (dela) opadanja povećava i ona postaje gotovo identična kao strmina prvog (dela) opadanja. Najveća razlika između krivih opadanja je ona koja se javlja u komori bez difuzora i u komori sa 3, 4 ili 5 difuzora. Pri tome, krive opadanja dobijene za prisustvo 3, 4 i 5 difuzora su veoma slične jedna drugoj.

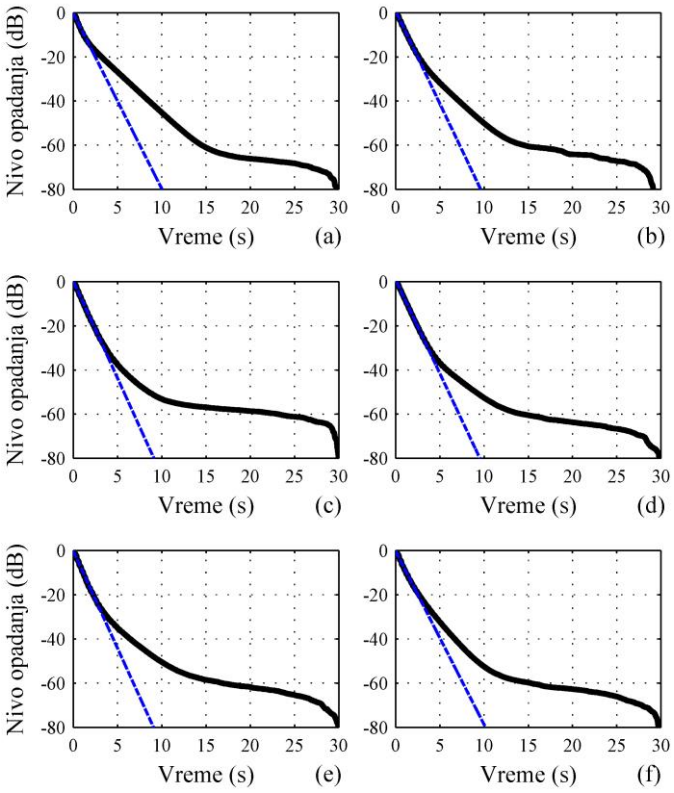


Sl. 5. Krive opadanja dobijene *Schroeder*-ovim integraljenjem unazad impulsnih odziva filtriranih u opsegu terci na 315 Hz (a) i na 500 Hz (b) izmerenih za jednu kombinaciju položaja zvučnog izvora i mikrofona: sa svih 5 difuzora (c1), sa 4 difuzora (c2), sa 3 difuzora (c3), sa 2 difuzora (c4), sa 1 difuzorom (c5) i bez difuzora (c6).

B. Krive opadanja prazne komore i sa test uzorkom

Rezultati prikazani u ovoj pod-sekciji se odnose na merenja sa svim difuzorima u komori. I ovde je posebna pažnja posvećena krivama opadanja na niskim i srednjim frekvencijama. Na niskim frekvencijama, postoje tercni opsezi gde krive opadanja imaju potpuno regularan (gotovo pravolinijski) oblik. Takvi slučajevi nisu analizirani ovde. Sa druge strane, postoje tercni opsezi gde krive opadanja pokazuju zakrivljenost, i karakteristični primeri su prikazani u nastavku. Jedan od njih se dobija u tercnom opsegu na 80 Hz kada se merenja vrše u praznoj reverberacionoj komori (bez test uzorka), Sl. 6. Na ovoj frekvenciji, za većinu kombinacija položaja izvora i mikrofona se dobija određena (manja ili veća) zakrivljenost krivih opadanja. Najčešće je to oblik dvostrukog (eksponencijalnog) opadanja poput onog na Sl.

6(b) ili 6(e). U određenim slučajevima, ovo dvosktruko opadanje nije očigledno, već kriva opadanja u delu reverberacionog opadanja ima konkavan oblik.

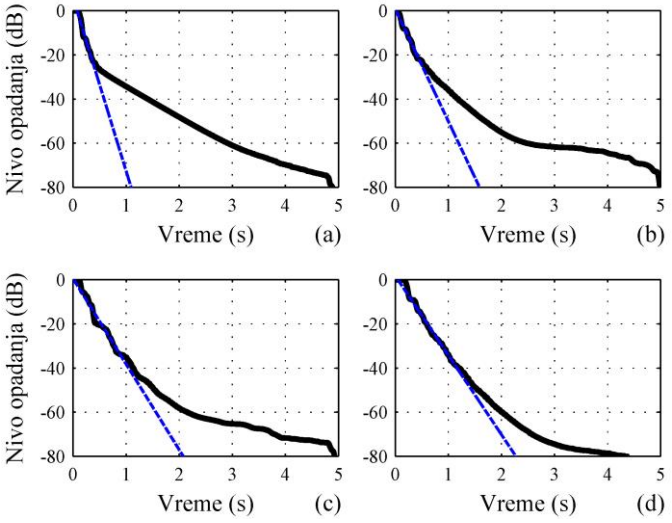


Sl. 6. Krive opadanja (—) dobijene *Schroeder*-ovim integraljenjem unazad 6 impulsnih odziva reverberacione komore bez test uzorka filtriranih u opsegu terce na 80 Hz za različite kombinacije položaja zvučnog izvora i mikrofona, kao i aproksimacione prave (- - -) dobijene linearnom regresijom početnog dela opadanja.

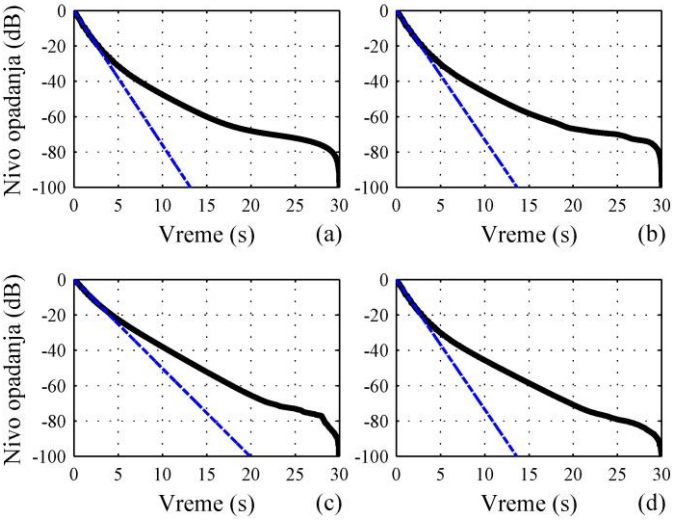
Situacija u ovom tercnom opsegu je nešto drugačija kada se bilo koji od merenih test uzoraka postavi u reverberacionu komoru. Krive opadanja tada su uglavnom regularne, imaju pravolinijski oblik. U jednom manjem broju slučajeva, javlja se oblik krive gde najpre dolazi do naglog opadanja nivoa zvuka, a zatim se uspostavlja relativno stabilan režim konstantne strmine opadanja, videti Sl. 7.

Pored karakterističnog dvostrukog opadanja dobijenog u praznoj reverberacionoj komori (Sl. 6), u ovakvim mernim uslovima se dobijaju i krive opadanja koje imaju dosta veliku zakrivljenost koja se ogleda u konkavnom obliku krive, ali bez vidljivog dvostrukog opadanja. Ovakva situacija se najčešće javlja u tercnom opsegu na 125 Hz, kao što je prikazano na Sl. 8. I u ovom tercnom opsegu postoje kombinacije položaja zvučnog izvora i mikrofona koje daju dvostruko opadanje, ali jedan manji broj kombinacija koji rezultira regularnim krivama opadanja.

Vredi istaći da se zakrivljenosti krivih opadanja prazne reverberacione komore ulgavnom javljaju do frekvencije 160 Hz. Međutim, u situacijama kada se merenja obavljaju sa test uzorkom u komori, onda se na srednjim frekvencijama (od 315 Hz do 630 Hz ili evenutalno do 800 Hz) može javiti blaga zakrivljenost krivih opadanja tako da kriva ima konstantno konkavan oblik u delu reverberacionog opadanja. Jaka zakrivljenost sa izraženim dvostrukim opadanjem na 400 Hz je prikazana na Sl. 9. Razlog zakrivljenosti na ovim frekvencijama je uglavnom neravnomerna raspodela apsorpcije. Naime, samo je pod u ovom slučaju apsorpciona površina, dok su sve ostale površine refleksione.



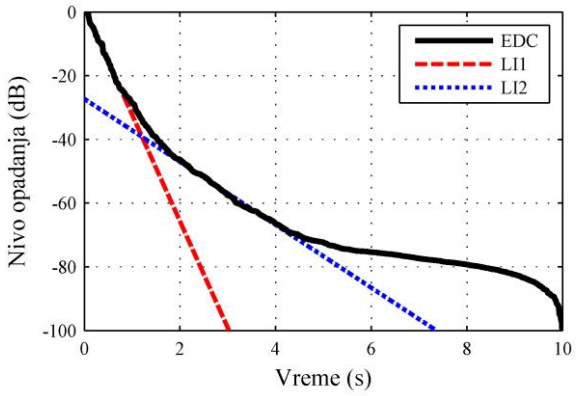
Sl. 7. Krive opadanja (—) dobijene *Schroeder*-ovim integraljenjem unazad 4 impulsna odziva reverberacione komore sa test uzorcima filtriranih u opsegu terce na 80 Hz za različite kombinacije položaja zvučnog izvora i mikrofona, kao i aproksimacione prave (- - -) dobijene linearnom regresijom početnog dela opadanja.



Sl. 8. Krive opadanja (—) dobijene *Schroeder*-ovim integraljenjem unazad 4 impulsna odziva reverberacione komore bez test uzorka filtriranih u opsegu terce na 125 Hz za različite kombinacije položaja zvučnog izvora i mikrofona, kao i aproksimacione prave (- - -) dobijene linearnom regresijom početnog dela opadanja.

Kada kriva opadanja pokazuje zakrivljenost poput one prikazane na Sl. 9, postavlja se pitanje na koji način izračunati vreme reverberacije. Da li je bolje koristiti početno opadanje (prikazano isprekidanom linijom na Sl. 9) ili kasno opadanje

(prikazano linijom sa tačkicama na Sl. 9).



Sl. 9. Kriva opadanja (EDC) dobijena *Schroeder*-ovim integraljenjem unazad impulsnog odziva reverberacione komore sa test uzorkom filtriranog u opsegu terce na 400 Hz, kao i aproksimaciona prava (LI1) dobijena linearnom regresijom početnog dela opadanja, kao i drugog dela opadanja (LI2).

VI. Zaključak

Krive opadanja zvuka dobijene na osnovu izmerenih impulsnih odziva prostorije mogu imati regularan pravolinijski oblik na logaritamskoj skali u decibelima. Međutim, odstupanja od ovakvog ponašanja se mogu javiti pre svega u manjim prostorijama. Ovakva odstupanja su karakteristična za niže i eventualno srednje frekvencije. Na niskim frekvencijama, dominantan uzrok mogu biti različite brzine opadanja zvuka aksijalnih, tangencijalnih i bočnih modova, dok dominantan uzrok na srednjim frekvencijama može biti neravnomerna raspodela apsorpcije. Kao posledica pomenutog ponašanja, javljaju se zakrivljenosti krivih opadanja, odnosno višestruka (eksponencijalna) opadanja.

Zakrivljenosti krivih opadanja na niskim i srednjim frekvencijama u reverberacionoj komori relativno malih dimenzija je analizirano u ovom radu. Pomenute neregularnosti (zakrivljenosti) se mogu delimično korigovati u reverberacionoj komori postavljanjem difuzora. Pri tome, efekat je izraženiji na srednjim nego na niskim frekvencijama.

I pored primene difuzora, u konkretnoj reverberacionoj komori se dobijaju krive opadanja sa dvostrukim opadanjem i konkavnim oblikom na niskim frekvencijama u praznoj reverberacionoj komori, kao i na srednjim frekvencijama kada se u komori nalazi test uzorak. Ostaje otvoreno pitanje na koji način vršiti izračunavanje vremena reverberacije kada krive opadanja pokazuju pomenute zakrivljenosti.

Zahvalnica

Ovo istraživanje je podržano od strane Ministarstva prosvete, nauke i tehnološkog razvoja Republike Srbije kroz projekat 36026.

Abstract

One of classical approaches for measurements of absorption coefficient of test sample is based on measurements of reverberation time of empty reverberation room and reverberation time of the same room when the test sample is in the room. Dimensions and important characteristics of a reverberation room are defined in the relevant standards. When certain conditions are fulfilled, especially when the reverberation room volume is smaller than recommended values, some disturbing effects of room modes can appear at lower frequencies. Influence of these effects in measurements of absorption coefficient of test samples on energy decay curves is analysed in the paper. Impulse response measurements are carried out in the reverberation room of volume of about 65 m^3. In third-octave bans below 160 Hz, specific multi-exponential (often double) sound decays yielding concave shape of decay curves are present. In such cases, there is a question how to estimate the reverberation time.

Energy Decay Curves Obtained in Reverberation Chamber During Measurements of Absorption Coefficient

Upotreba različitih obeležja za prepoznavanje drvenih duvačkih instrumenata korišćenjem neuralnih mreža

Tatjana Miljković, Miloš Bjelić, Dragana Šumarac Pavlović, Goran Kvaščev

***Apstrakt*— U procesima automatskog prepoznavanja instrumenata koriste se različita obeležja zasnovana na analizi spektralnog sadržaja audio zapisa. U ovom radu prikazan je hroma profil tonova kao novo obeležje, izdvojeno iz audio zapisa muzičkog sadržaja, na osnovu kojeg se vrši prepoznavanje duvačkih instrumenata pomoću neuralne mreže. Kako bi hroma profil predstavljao validno obeležje izvršena je komparativna analiza sa MFCC koeficijentima. Duvački instrumenti koji su bili od interesa u ovom istraživanju su: klarinet, flauta i oboa. Metodologija karakterizacije duvačkih instrumenata bazirana na hroma profilu tonova pokazala je očuvanje osnovnih razlika u karakteristikama instrumenata. Hroma profil predstavlja prikaz relativnih odnosa energije na pojedinim tonovima unutar oktave. Posmatrani su hroma profili tonova računati nad celim signalom i po prozorima signala. Isti principi računanja obeležja primenjena su i na MFCC koeficijente. Korišćenjem hroma profila tonova i MFCC koeficijenata kao ulaznih parametara neuralne mreže ostvareni su visoki procenti prepoznavanja instrumenata.**

***Ključne reči*— audio obeležja; hroma profil; MFCC; muzički instrumenti; neuralna mreža; prepoznavanje.**

I. Uvod

Digitalna revolucija u distribuciji muzike podstakla je ogroman interes za pronalaženje različitih načina na koje se informacione tehnologije mogu primeniti na ovakvu vrstu sadržaja. Stoga, sve veća količina audio i muzičkih signala ukazuje na potrebu za inteligentnim pretraživanjem, prikupljanjem i obradom muzičkog sadržaja pomoću automatizovanih metoda [1]. Takođe, razvitkom tehnologije javila se potreba za različitim multimedijalnim aplikacijama koje su imale za cilj da izvršavaju automatsku transkripciju nota, klasifikaciju muzičkih žanrova, identifikaciju pevača kao i prepoznavanje muzičkih instrumenata. Stečena znanja o osobinama i građi zvuka stvorila su osnov za dalja istraživanja audio zapisa muzičkog sadržaja, ali takođe i za određivanje atributa zvuka muzičkih instrumenata, pomoću savremenih softverskih alata. Kao reference pri istraživanju muzičkih signala najčešće se uzimaju u obzir nekoliko osnovnih parametara koji ih opisuju i to: visina tona, melodija, harmonija i ritam [2].

Iako postoje raznovrsni muzički sadržaji njihova osnova je ista i čine je tonovi. Ton predstavlja zvuk koji ima izraženu tonsku visinu. Spektar tona je diskretan i sastavljen od harmonijskog niza frekvencija koji se u muzičkoj literaturi naziva alikvotni niz [2]. Harmonijski niz frekvencija kao takav se prema osnovnom tonu odnosi kao 1:2:3:4:*n*, gde je *n* određena granična frekvencija. Iako je intervalski odnos harmonika prema osnovnom tonu uvek jednak, kod različitih muzičkih instrumenata razlikuje se relativna jačina pojedinih alikvota. Razlike u relativnoj jačini pojedinih alikvota formiraju anvelopu spektra tona koja predstavlja jedan od faktora kojim se definiše boja tona.

Proces percepcije tonske visine kod čoveka formira se na logaritamskoj frekvencijskoj osi. Proces koji se odvija u čulu sluha dovodi do preslikavanja harmonijskog niza frekvencija na logaritamsku frekvencijsku osu. Pri preslikavanju spektralnih komponenti tona na hroma krug pozicije nekih komponenti odgovaraju određenim tonovima unutar jedne oktave. Analizom pozicija harmonika određenog tona na hroma krugu nakon preslikavanja pokazano je da se ukupna energija tona dominantno nalazi na osnovnoj frekvenciji tona i na frekvencijama koje odgovaraju intervalima velike terce i čiste kvinte [3]. Raspodela energije jednog tona unutar hroma kruga predstavlja pogodan podatak za prepoznavanje različitih karakteristika kojima se mogu opisati muzički signali. Takođe, zbog izražene harmonijske strukture muzički ton se može jednostavno matematički modelovati. U literaturi je pokazano da takav model predstavlja jedan od glavnih ulaznih parametara algoritama za automatsko prepoznavanje atributa muzičkih instrumenata [4].

U cilju automatskog prepoznavanja muzičkih instrumenata razvijen je veliki broj algoritama. Iako je broj algoritama značajan, velika većina se zasniva na izdvajanju karakterističnih obeležja. Prvobitna istraživanja u pravcu izdvajanja obeležja muzičkih audio zapisa zasnivala su se na tehnikama izdvajanja govornih obeležja kao što su: LPC (*Linear Prediction Coefficients*) i MFCC (*Mel-Frequency Cepstral Coefficients*) koeficijenti [5]. Marques i Moreno su pomoću ovih obeležja uspeli da ostvare klasifikaciju od oko 70% muzičkih audio zapisa [6]. Eronen i Klapuri, razvili su sistem u kojem izdvajaju preko 20 različitih obeležja [7]. Koristili su kako spektralna tako i vremenska obeležja, među

Tatjana Miljković – Elektrotehnički fakultet, Univerzitet u Beogradu, Bulevar kralja Aleksandra 73, 11020 Beograd, Srbija (e-mail: tm@etf.rs).

Miloš Bjelić – Elektrotehnički fakultet, Univerzitet u Beogradu, Bulevar kralja Aleksandra 73, 11020 Beograd, Srbija (e-mail: bjelic@etf.rs).

Dragana Šumarac Pavlović – Elektrotehnički fakultet, Univerzitet u Beogradu, Bulevar kralja Aleksandra 73, 11020 Beograd, Srbija (e-mail: dsumarac@etf.rs).

Goran Kvaščev – Elektrotehnički fakultet, Univerzitet u Beogradu, Bulevar kralja Aleksandra 73, 11020 Beograd, Srbija (e-mail: kvascev@etf.rs).

kojima su različite varijacije MFCC koeficijenata, spektralni centroid, "udarna"(*attack*) i "opadajuća"(*decay*) faza tona i druge. Uprkos većem broju kako vremenskih tako i spektralnih obeležja rezultati klasifikacije instrumenata iznosili su oko 80% uspešnosti [8].

Kako bi se povećao procenat uspešnog prepoznavanja instrumenata izvršeno je istraživanje sa ciljem pronalaska novih obeležja muzičkih signala koji bi se koristili kao ulazni parametri veštačkih neuralnih mreža. U ovom radu prikazana je metodologija za analizu audio sadržaja muzičkih signala koja se naziva hromatogram. Kada se govori o hromatogramu kao alatu za analizu muzičkih signala podrazumeva se da je na osnovu hromatograma moguće izvršiti analizu raspodele energije u vremenu datog audio zapisa, kao i ustanovljavanje energetskog bilansa na očekivanim parcijalama analiziranih tonova. Na osnovu hromatograma muzičkih signala dobijeni su hroma profili datih signala, gde hroma profil predstavlja prikaz raspodele energije signala u vremenu. Analizom hroma profila pomenutih instrumenata uočeni su različiti bilansi enegrije za različite instrumente. Na osnovu uočenih razlika u hroma profilima instrumenata pokazano je da hroma profil predstavlja adekvatno obeležje jednog instrumenta, kao i povoljan ulazni parametar veštačke neuralne mreže. Kako bi se verifikovala tvrdnja da hroma profil predstavlja adekvatno obeležje jednog instrumenta, u ovom radu izvršena je komparativna analiza prepoznavanja drvenih duvačkih instrumenata pomoću neuralnih mreža upotrebom kako hroma profila, tako i MFCC koeficijenata. Cilj ovog rada je da pokaže da hroma profil predstavlja adekvatno obeležje, poput MFCC koeficijenata, na osnovu kog se može izvršiti prepoznavanje drvenih duvačkih instrumenata pomoću veštačke neuralne mreže.

Rad je organizovan kako sledi. U drugom poglavlju prikazani su hromatogram, hroma profil i kepstralna obeležja kao metodologije za analizu audio signala. U narednom poglavlju prikazani su eksperimentalni rezultati i diskusija dobijenih rezultata. Na kraju dat je zaključak o mogućnosti korišćenja hroma profila i MFCC koeficijenata kao ulaznih parametara neuralnih mreža na osnovu kojih se dobijaju visoki procenti prepoznavanja drvenih duvačkih instrumenata.

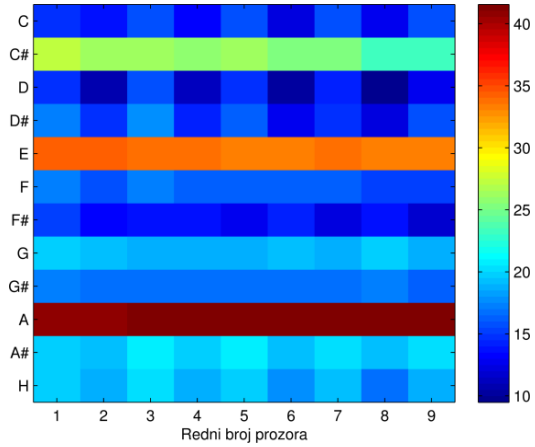
II. METODOLOGIJA

A. Hromatogram i Hroma profil

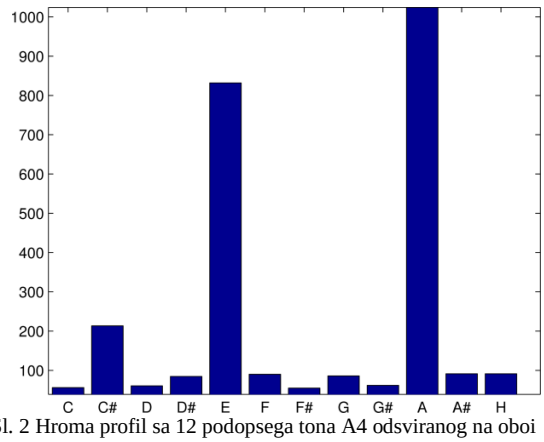
Pri automatskom prepoznavanju sadržaja audio signala koriste se različita obeležja zasnovana na analizi spektralnog sadržaja. Jedan od alata na osnovu kojeg se izdvajaju obeležja spektralnog sadržaja signala je hromatogram. Hromatogram predstavlja vremensko-frekvencijski prikaz signala gde je kompletan spektar signala transponovan na jednu izabranu oktavu koja je izdeljena na proizvoljan broj podopsega.

Izračunavanje hroma karakteristika jednog muzičkog signala se svodi na množenje hroma matrice i spektrograma datog signala, čime se dobija nova matrica koja se naziva hromatogram [8]. Spektrogram signala predstavlja matricu $\boldsymbol{S}$ dimenzija NxM dobijenu pomoću kratkovremene Furijeove transformacije (*STFT*). Redovi matrice $\boldsymbol{S}$ odgovaraju svakoj od N frekvencija i imaju indekse k, $k\epsilon[0, N\text{-}1]$. Broj kolona matrice $\boldsymbol{S}$ odgovara broju prozora u vremenu M. Hroma matrica $\boldsymbol{C}$ je dimenzija KxN, gde K predstavlja broj opsega u okviru jedne oktave [9]. Vrednost parametra K je proizvoljna, ali se uglavnom uzima vrednost 12, gde 12 predstavlja broj polutonova koji čine temperovanu skalu. Na Slici 1 prikazan je izgled hromatograma sa 12 podopsega za ton A4 odsviran na oboi.

Pored hromatograma, na osnovu kog se može posmatrati raspodela energije signala unutar oktave, postoji još jedan alat za analizu raspodele energije i naziva se hroma profil. Hroma profil predstavlja jedan vid hromatograma. Sumiranjem hromatograma za sve vremenske prozore audio signala dobija se hroma profil datog audio signala. Računanjem hroma profila na ovaj način ne dolazi do značajnijeg gubitka informacija o raspodeli energije posmatranog signala. Potreba za pojavom hroma profila audio signala javila se usled želje za preglednijim prikazom relativnih odnosa energije na pojedinim tonovima unutar oktave. Na Slici 2 prikazan je hroma profil sa 12 podopsega tona A4 odsviranog na oboi.



Sl. 1. Izgled hromatograma za ton A4 odsviran na oboi sa 12 podopsega



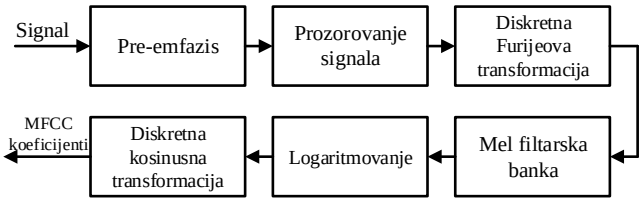
Sl. 2 Hroma profil sa 12 podopsega tona A4 odsviranog na oboi

B. Kepstralna obeležja

U domenu audio signala, kepstralna obeležja su prvobitno korišćena za analizu govora. Danas se kepstralna obeležja primenjuju u svim poljima pretraživanja audio signala kao što su govor, muzika i analiza zvukova okoline [10-12]. Kepstralna obeležja predstavljaju frekvencijski prikaz logaritmovanog amplitudskog spektra signala. Takođe,

omogućavaju primenu euklidske metrike, kao meru distanci zbog njihove ortogonalne prirode koja olakšava poređenje na osnovu sličnosti [13].

Na Slici 3 prikazana je blok šema postupka za određivanje MFCC (*Mel-frequency Cepstral Coefficients*) koeficijenata. Pre izdvajanja segmenata signala, odnosno prozorovanja, vrši se korekcija signala upotrebom pre-emfazisa. Zatim se vrši prozorovanje signala nekim od prozora, kao što su Hanov i Hammingov. Dužina prozora, odnosno trajanje segmenta signala koji se analizira zavisi od konkretne aplikacije i obično iznosi do 100 ms. Nakon toga se za svaki prozor izračunava DFT. Spektar signala u svakom prozoru se propušta kroz mel filtarsku banku koja se sastoji od filtara trouganog oblika [14]. Broj filtara zavisi od broja MFCC koeficijenata koji se želi odrediti. Zatim se na signale na izlazu iz svakog filtra primenjuje logaritmovanje i izračunavanje DFT. Na taj način se za svaki prozor dobija niz koeficijenata. Broj koeficijenata zavisi od tipa signala i vrste analize, ali se uglavnom uzima prvih 12 koeficijenata.



Sl. 3. Blok šema procedure za određivanje kepstralnih koeficijenata

C. Neuralna mreža

Veštačke neuralne mreže (*Artificial Neural Networks*) predstavljaju grupu računarskih modela. Izvorno, neuralne mreže inspirisane su biološkim strukturama, posebno strukturom mozga zbog njegove sposobnosti da rešava kompleksne probleme [15]. Veštačke neuralne mreže dobile su ime zahvaljujući njihovoj strukturi koju čini pregršt procesorskih jedinica, koje su poznate kao neuroni organizovani po slojevima. Svaki od slojeva povezan je sa prethodnim i sledećim slojem i na taj način formira se mreža sačinjena od povezanih neurona. Postoje tri tipa slojeva neuralne mreže: ulazni, skriveni i izlazni. Ulazni sloj predstavlja vezu sa polaznim parametrima neuralne mreže. Skriveni slojevi su zaduženi za transformaciju ulaznih podataka u prihvatljive informacije za izlazni sloj. U zavisnosti od broja skrivenih slojeva može se meriti sofisticiranost informacija koje su predviđene za izlazni sloj [16].

III. EKSPERIMENTALNI REZULTATI I DISKUSIJA

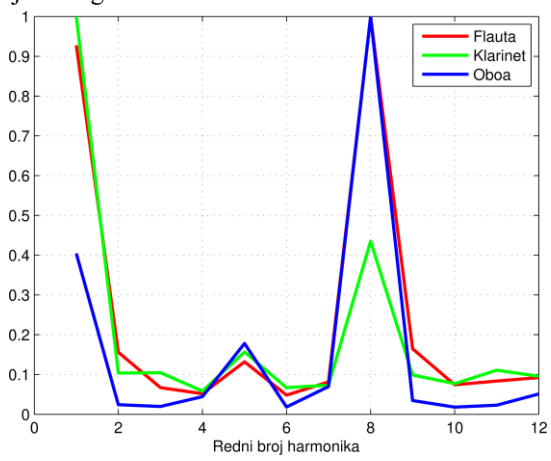
A. Baza snimaka

Problemi koji se rešavaju pomoću veštačkih neuralnih mreža zahtevaju podatke na kojima će se vršiti testiranje i verifikacija same mreže. U ovom radu korišćena je baza snimaka preuzeta sa internet stranice Britanske filharmonije [17]. Audio snimci koji čine bazu odsvirani su na: klarinetu, flauti i oboi. Snimke po sadržaju čine tonovi hromatske lestvice celokupnog registra posmatranih instrumenata. Bazu čini ukupno 2047 snimaka, od toga je 763 snimaka tonova flaute, 746 tonova klarineta i 538 tonova oboe. Snimci koji se nalaze u bazi su izolovani, tj. spadaju u monofone audio zapise, te tako predstavljaju idealan slučaj za prepoznavanje i izdvajanje obeležja audio zapisa muzičkog sadržaja. Takođe, odlikuju se različitim trajanjem: 1, 0.5 i 0.25 sekundi. Pored toga, audio zapisi su odsvirani u četiri različita dinamička manira: pianissimo, piano, mezzo-forte i forte.

B. Hroma profil i MFCC koeficijenti drvenih duvačkih instrumenata

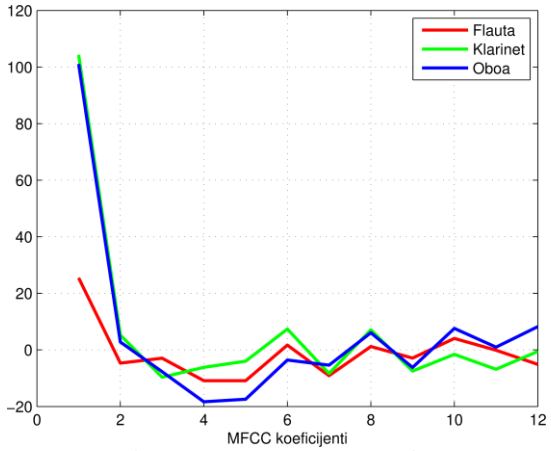
Kako se neuralnoj mreži prosleđuju ulazni parametri potrebno je izvršiti pretprocesiranje podataka, odnosno izdvojiti obeležja iz audio signala. U ovom radu kao obeležja drvenih duvačkih instrumenata od interesa izabrani su: MFCC koeficijenti i hroma profil.

Kako bi se izračunao hroma profil za pojedine tonove potrebno je prvo odrediti hromatogram datih tonova. Za izračunavanje spektrograma tonova instrumenata korišćen je Hammingov prozor dužine 2048 odbiraka sa 50% preklapanja. Zatim je množenjem spektrograma sa hroma matricom, spektrogram signala transponovan na oktavu izdeljenu na 12 podopsega i time je dobijen hromatogram. Sumiranjem hromatograma za sve vremenske prozore signala dobijen je hroma profil. Ovako opisan proračun podrazumeva da je sa 12 vrednosti koje odgovaraju hroma profilu opisan ceo signal, odnosno posmatrani ton. Te u tom slučaju ulazni parametri neuralne mreže predstavljaju 12 vrednosti hroma profila tona. Na Slici 4 prikazani su hroma profili sa 12 podopsega za ton A4 odsviran na flauti, klarinetu i oboi. Sa slike se može uočiti da za sva tri instrumenta postoji nagomilavanje energije na prvom harmoniku, koji odgovara osnovnom tonu i na petom i osmom harmoniku, koji odgovaraju intervalima velike terce i čiste kvinte. Takva raspodela energije se objašnjava prirodom tona, jer je spektar tona sačinjen od harmonijskog niza frekvencija. Takođe, na osnovu slike se može zaključiti da postoje vidljive razlike u raspodeli energije za posmatrana tri instrumenta, što predstavlja dobar preduslov da hroma profil predstavlja obeležje nekog instrumenta.



Sl. 4. Hroma profili sa 12 podopsega tona A4 odsviranog na flauti, klarinetu i oboi

Radi komparativne analize broj koeficijenata koji su korišćeni je 12. Za izračunavanje koeficijenata korišćen je Hammingov prozor sa 50% preklapanja. Vrednost pre-emfazis koeficijenta iznosi 0.97. Korišćen je frekvencijski opseg od 200 Hz do 20 kHz, kako bi se pokrile sve frekvencije koje posmatrani instrumenti mogu da proizvedu i 30 filtara u mel frekvencijskoj banci. Takođe, kao i u slučaju računanja hroma profila, ovaj slučaj proračuna podrazumeva da je ceo signal opisan samo sa prvih 12 MFCC koeficijenata. Na Slici 5 prikazano je 12 MFCC koeficijenata za ton A4 odsviran na flauti, klarinetu i oboi. Sa slike se može uočiti da postoje izvesne razlike u vrednostima MFCC koeficijenata za posmatrane instrumente. Varijacije u vrednostima MFCC koeficijenata ukazuju da se na osnovu njih mogu okarakterisati instrumenti.

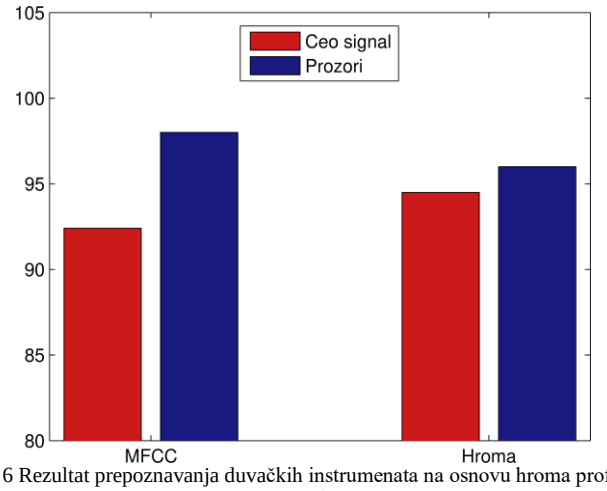


Sl. 5. 12 MFCC koeficijenata za ton A4 odsviran na flauti, klarinetu i oboi

Kada se govori o obeležjima koja predstavljaju signal uglavnom se ona izračunavaju na manjim delovima signala, odnosno prozorima. Kako bi se uočio uticaj različitog broja obeležja jednog signala, izvršeno je računanje kako hroma profila tako i MFCC koeficijenata za svaki prozor posmatranog signala. Da bi se uspešno sprovela komparativna analiza hroma profila i MFCC koeficijenata kao obeležja signala, potrebno je izvršiti prozorovanje signala ili na prozore jednake dužine trajanja ili na jednaki broj prozora. Kako bazu snimaka čine snimci različite dužine trajanja nije bilo moguće prozorovati signale tako da svi prozori budu jednake dužine trajanja. Zbog toga je u daljem toku analize uzeto u obzir prozorovanje signala na jednak broj prozora. Svaki signal iz baze snimaka podeljen je na 19 prozora, te se za svaki prozor računa po 12 vrednosti koje predstavljaju hroma profil datog segmenta i 12 MFCC koeficijenata. Što dalje implicira, da se jedan signal opisuje sa ukupno 228 vrednosti u oba slučaja. Te tada ulaz neuralne mreže čini 228 vrednosti koje predstavljaju obeležja celog signala računata po prozorima.

C. *Rezultati prepoznavanja*

Kao klasifikator instrumenata korišćena je MLP (*Multilayer Perceptron*) *feed forward* neuralna mreža sa propagacijom unazad. Struktura mreže se sastoji od ulaznog sloja, koji je povezan sa početnim parametrima neuralne mreže, odnosno sa hroma profilima instrumenata i MFCC koeficijentima. U zavisnosti od toga da li su kao ulazni parametri korišćeni hroma profili tonova ili MFCC koeficijenti računati nad celim signalnom ili po prozorima, broj ulaznih parametara neuralne mreže bio je 12, odnosno 228. Broj neurona koji je korišćen u skrivenom sloju je 40. Izlaz neuralne mreže predstavlja sloj od tri neurona. Takođe, neuralna mreža je potpuno povezana, odnosno svaki neuron je povezan sa svakim neuronom iz sledećeg sloja bilo direktno ili indirektno. Skup podataka koji se koristi za prepoznavanje podeljen je na podskupove za trening, validaciju i test. Podskup za trening čini 70% skupa podataka, dok su podskupovi za validaciju i test jednaki i iznose 15% skupa podataka. U procesu treniranja neuralne mreže korišćen je skalirani konjugovani gradijentni algoritam (*Scaled Conjugate Gradient Algorithm*). Kao aktivaciona funkcija neurona korišćena je tangent sigmoid funkcija (*Tansig function*) [18]. Pri treniranju mreže nije korišćena regularizacija.

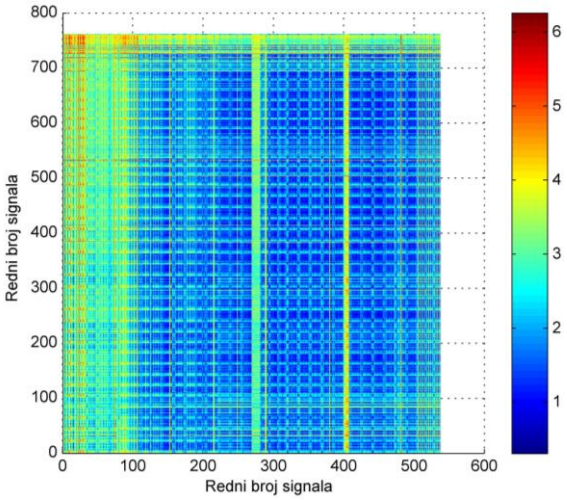


Sl. 6 Rezultat prepoznavanja duvačkih instrumenata na osnovu hroma profila i MFCC koeficijenata

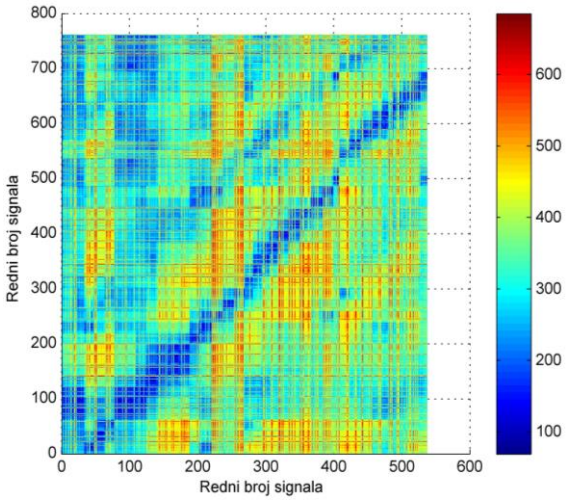
Na Slici 6 prikazan je rezultat prepoznavanja duvačkih instrumenata na osnovu hroma profila i MFCC koeficijenata koji su predstavljali ulazne parametre neuralne mreže. Pri prepoznavanju uzeta su u obzir dva slučaja i to: kada je ceo signal predstavljen sa 12 koeficijenata i kada su izračunati koeficijenti za svaki prozor signala. Kada su kao ulazni parametri neuralne mreže uzeti MFCC koeficijenti, tačnije njih 12, procenat uspešnog prepoznavanja instrumenta iznosi 92%. Dok za slučaj kada su ulazni parametri neuralne mreže predstavljali hroma profili tonova sa 12 podopsega procenat uspešnog prepoznavanja iznosio je 95%. Ako su obeležja signala računata po prozorima, odnosno ukoliko je broj ulaznih parametara neuralne mreže bio 228, procenat prepoznavanja u slučaju hroma profila iznosi 96%. Ukoliko je ulaz neuralne mreže bio niz od 228 vrednosti, koje predstavljaju MFCC koeficijente računate za svaki prozor signala, procenat prepoznavanja instrumenata iznosi 98%.

Kako bi se utvrdio razlog za ostvarene veće procente uspešnog prepoznavanja instrumenata za slučaj kada su

korišćena obeležja računata po prozorima signala formirane su matrice sličnosti. Prikazane su matrice sličnosti, gde se jedna dimenzija matrice odnosi na ukupan broj snimaka flaute, a druga na ukupan broj snimaka oboe. Pri računanju matrice snimci su sortirani onim redosledom koji zauzimaju i u hromatskoj lestvici. Takođe, sortiranje snimaka je izvršeno i prema oktavi kojoj snimci pripadaju i to u rastućem poretku, od treće do šeste oktave. Na Slici 7 prikazana je matrica sličnosti flauta-oboa, koja je računata na osnovu hroma profila tonova flaute i oboe. Na osnovu slike se može zaključiti da postoje izvesne razlike medju tonovima instrumenata flaute i oboe, naročito u nižim oktavama. Upravo zbog postojećih razlika ostvareni su visoki procenti prepoznavanja neuralne mreže. Na Slici 8 prikazana je matrica sličnosti flauta-oboa, koja je računata na osnovu MFCC koeficijenata tonova flaute i oboe. Takođe, sa slike se uočava da postoje razlike među tonovima posmatranih instrumenata. Činjenica da su razlike prikazane matricom sličnosti za slučaj MFCC koeficijenata za dva reda veličine veće u odnosu na razlike za slučaj hroma profila, potvrđuje rezultat gde su ostvareni veći procenti prepoznavanja za slučaj kada su ulazni parametri neuralne mreže bili MFCC koeficijenti signala računati po prozorima.



Sl. 7. Matrica sličnosti flauta-oboa hroma



Sl. 8. Matrica sličnosti flauta-oboa MFCC

Iako je procenat prepoznavanja instrumenata za slučaj kada su ulazni parametri predstavljali obeležja računata po prozorima signala veći u odnosu kada su ulaz činila obeležja koja su karakterisala ceo signal, takvi parametri zahtevaju više vremena za obradu. Stoga, u pogledu vremenske kompleksnosti neuralna mreža kod koje su ulazni parametri predstavljali 12 koeficijenata ima prednost za korišćenje u aplikacijama koje rade u realnom vremenu. Time se postiže ušteda u vremenu na štetu nešto nižem ostvarenom procentu uspešnog prepoznavanja instrumenata.

IV. ZAKLJUČAK

U ovom radu prikazana je upotreba različitih obeležja za prepoznavanje drvenih duvačkih instrumenata korišćenjem neuralnih mreža. Obeležja koja su uzeta u razmatranje su: hroma profil i MFCC koeficijenti. Pomenuta dva obeležja su uzeta u razmatranje, kako bi se hroma profil prikazao kao novo obeležje audio zapisa, čija bi se verifikacija utvrdila poređenjem sa u literaturi poznatim MFCC koeficijentima. Duvački instrumenti koji su prepoznavani su: klarinet, flauta i oboa. Ovi instrumenti odabrani su tako da pokrivaju širok opseg varijacija u pogledu načina pobuđivanja, oblika cevi i strukture rezonantnih modova. Prikazane razlike između instrumenata pružaju dobru osnovu za upotrebu hroma profila kao obeležja na osnovu kojih neuralna mreža vrši prepoznavanje instrumenta. Ostvareni su visoki procenti prepoznavanja instrumenata za slučaj kada su kao ulazni parametri neuralne mreže uzeti hroma profili i MFCC koeficijenti, računati kako za ceo signal tako i po prozorima signala. Iako prikazana neuralna mreža ostvaruje bolji učinak u prepoznavanju instrumenata za slučaj kada su ulazni parametri predstavljali obeležja računata po prozorima signala, uočeno je da takvi parametri zahtevaju više vremena za njihovu obradu. Te u smislu vremenske kompleksnosti rada neuralne mreže, kao i pretprocesiranja samih signala, povoljnije je kao ulazne parametre korsititi obeležja računata za ceo signal, odnosno uzeti u obzir samo 12 vrednosti. U tom slučaju procenti prepoznavanja instrumenata na osnovu hroma profila iznosi 95%, dok na osnovu MFCC koeficijenata prepoznato je 92% instrumenata. Cilj rada bio je ispitati mogućnost upotrebe hroma profila tonova duvačkih instrumenata kao obeležja audio zapisa muzičkog sadržaja na osnovu kog je moguće izvršiti prepoznavanje instrumenta. Pokazano je kako kroz ostvarene visoke procente prepoznavanja duvačkih instrumenata, tako i kroz komparativnu analizu sa već verifikovanim obeležjem da je hroma profil tonova adekvatno obeležje koje se može koristiti u daljim istraživanjima. Tako bi se u nekim od budućih istraživanja uzeli u obzir hroma profili ne samo monofonih nego i polifonih audio zapisa.

ABSTRACT

In the processes of automatic recognition of the content of audio signals, various features based on the analysis of spectral content are used. In this paper are presented the chroma tones profile as a new feature separated from music content on the basis of which recognition of wind instruments by neural network is performed. In order to represent chroma profile as valid feature comparative analysis with MFCC coefficients has been done. Wind instruments that were of interest to this research are: clarinet, flute and oboe. The methodology for the characterization of wind instruments based on chroma tone profiles has shown the preservation of the basic differences in the characteristics of the instruments. The chroma profile represents relative energy ratios on individual tones within octave. Chroma profile of tones were been observed, which were calculated over complete signal and per windows of signal. The same principles of calculating the features were applied to the MFCC coefficients. Using chroma profile of tones and MFCC coefficients as the input parameters of the neural network, high percentages of instrument recognition were achieved.

Use of different features for recognizing wooden wind instruments using neural networks

Akustički prenos podataka baziran na OFDM tehnici

Tatjana Miljković, Miloš Bjelić, Miljko Erić

***Apstrakt*— Prenos podataka korišćenjem audio signala (*data over sound*) u poslednjih nekoliko godina se koristi sve više. Iako koncept nije nov, njegov rast podstaknut je velikim brojem IoT uređaja i naprednih tehnika za obradu signala. Ova tehnologija može biti alternativa drugim tehnologijama za prenos podataka na malom rastojanju. Prednosti akustičkog (zvučnog) prenosa podataka u odnosu na radio tehnologije je mogućnost upotrebe na mestima na kojima je prenos radio talasa onemogućen. Prednost je i to što većina uređaja poseduje zvučnik i mikrofon i ne zahteva se upotreba dodatnih hardverskih komponenti. Ograničenje akustičkog prenosa podataka može biti manji protok u odnosu na druge tehnologije. U ovom radu prikazana je upotreba akustičkog signala za prenos podataka u vazduhu u čujnom delu audio opsega. Akustički prenos podataka realizovan je korišćenjem OFDM tehnike prenosa akustičkog signala. Mogućnost prenosa je ilustrovana rezultatima simulacije i realnih eksperimenata, bez tehnika zaštitnog kodovanja. Uvedena je tehnika za kompenzaciju vremenskog kašnjenja za necelobrojne vrednosti u broju odbiraka. Za uvedene parametre predajnika ostvaren je bitski protok od 3.2 Kbit/s. Dobijeni rezultati pokazali su mogućnost upotrebe ovakvog sistema za prenos informacija na malim rastojanjima u realnim uslovima.**

***Ključne reči*— akustički prenos, akustički OFDM, OFDM, prenos podataka, QAM.**

I. Uvod

Prenos podataka bežičnim putem koristi se jedan vek i kroz istoriju je doživeo velike promene. Današnji sistemi za bežični prenos podataka koristeći radio tehnologije mogu postići velike protoke u gotovo svakoj tački na planeti. Personalni uređaji koji se svakodnevno koriste poseduju mogućnosti za prenos podataka na velikom rastojanju korišćenjem javnih mobilnih mreža. Međutim, u poslednjih nekoliko decenija trend je da uređaji međusobno komuniciraju na manjim rastojanjima, formirajući lokalne mreže, uz vrlo malu potrošnju energije. Takvi uređaji predstavljaju osnovu za Internet of Things - IoT platforme. Na malim rastojanjima između predajnika i prijemnika mogu se koristiti i akustički signali za prenos informacija [1]. Prenos podataka korišćenjem akustičkog (zvučnog) signala kao nosioca poznat je već dugo u literaturi [2]. Pri akustičkom prenosu podataka zbog malog frekvencijskog opsega uređaja za reprodukciju i prijem signala ostvaruju se značajno manji protoci podataka u odnosu na radio prenos (reda nekoliko kb/s). Akustički prenos podataka se tradicionalno koristi za podvodne komunikacije [3]. U ovoj komunikaciji uslovi propagacije su vrlo nepovoljni za akustički signal pa se koriste razne vrste ekvalizacije kanala [4, 5]. Zbog ograničenog frekvencijskog opsega akustičkog kanala upotrebljavaju se tehnike za efikasnije korišćenje spektra [6]. Tokom prethodnih godina u ovu svrhu dominantno je korišćena OFDM (*Orthogonal Frequency-Division Multiplex*) tehnika [7]. OFDM predstavlja poznatu tehniku prenosa sa više podnosilaca [8]. Najveća prednost OFDM sistema u odnosu na sisteme sa jednim nosiocem je mogućnost za prilagođavanje lošim uslovima za prenos kroz kanal, kao što su slabljenje, uskopojasne smetnje i frekvencijski selektivni feding [9]. Upotrebom MIMO (*Multiple Input Multiple Output*) sistema u akustičkoj komunikaciji može se ostvariti dodatno povećanje protoka [10, 11]. Korišćenjem ovih tehnika uz OFDM ostvareni su protoci od par desetina Kbit/s, uz relativno malu verovatnoću greške.

U ovom radu analizirana je mogućnost upotrebe akustičkog signala za prenos podataka u vazduhu. Za prenos podataka korišćena je OFDM tehnika, odnosno akustički ekvivalent OFDM signala. Akustički prenos podataka realizovan je u čujnom audio opsegu (do 4.096 kHz). Kao podaci za prenos korišćena je *grayscale* slika. Realizovano je nekoliko simulacija i eksperimenata sa ciljem da se ispita kvalitet prenosa podataka kroz akustički kanal bez korišćenja tehnika zaštitnog kodovanja i bez korišćenja cikličnog prefiksa (CP). Pre slanja akustičkog signala u kom su kodovani podaci vršeno je slanje preambule sa sekvencom koju karakteriše ravan spektar. Preambula je korišćena na prijemnoj strani za određivanje početka korisnog signala metodom kroskorelacije. Preambula je korišćena i za ekvalizaciju kanala u eksperimentima sa realnim prenosom. U radu je prikazana i tehnika pomoću koje se vrši kompenzacija kašnjenja primljenog signala koje u opštem slučaju ne mora biti jednako celom broju odbiraka. Metoda je verifikovana u simulacijama akustičkog prenosa između zvučnika i mikrofonskog niza. U realizovanim eksperimentima zvučnik i mikrofon nalazili su se na rastojanju oko 2 metra u anehoičnim uslovima, što u literaturi predstavlja relativno veliko rastojanje između predajnika i prijemnika. Primenom ekvalizacije kanala postignut je relativno dobar kvalitet rekonstruisane slike. Ovaj rad predstavlja uvodno istraživanje čiji je cilj bio ispitivanje mogućnosti realizacije sistema za prenos podataka kroz akustički kanal u realnim uslovima u vazduhu.

Rad je organizovan kako sledi. U drugom poglavlju prikazan je postupak generisanja akustičkog OFDM signala. U trećem poglavlju prikazana je postavka realizovanih eksperimenata i simulacija. U četvrtom poglavlju prikazani su najvažniji rezultati u ovom istraživanju, kao i njihova

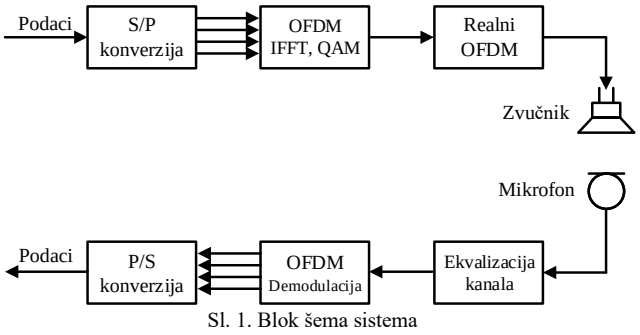
diskusija. U petom poglavlju izneti su zaključci.

II. METODOLOGIJA

U ovom poglavlju prikazan je način generisanja akustičkog OFDM signala na osnovu korisničkih podataka koje je potrebno preneti. Prikazani su parametri sistema na predajnoj strani kao i način kvantifikacije kvaliteta prenosa podataka. Na Slici 1 prikazana je principijelna blok šema sistema za prenos podataka korišćenjem akustičkog signala.



Sl. 1. Blok šema sistema

Kao informacija koja se prenosi pomoću prikazanog sistema u ovom radu korišćena je fotografija (slika). Slika je odabrana zbog toga što se nakon prenosa i demodulacije akustičkog signala na prijemnoj strani pored objektivne mere može i vizuelno izvršiti procena kvaliteta prenosa informacije.

Slika koju je potrebno preneti akustičkim signalom mapirana je sa 512 OFDM podnosioca. Polovina podnosilaca, odnosno 256 podnosioca, predstavljaju realan deo spektra, a ostalih 256 podnosioca predstavljaju konjugovano kompleksne parove realnog dela spektra. Odabrano je da frekvencija odabiranja iznosi 8192 Hz, pa se na širini spektra od 4096 Hz nalazi 256 OFDM podnosilaca. Širina svakog podkanala iznosi 16 Hz. Prvih 32 podnosioca (koji se nalaze u spektru na frekvencijama od 0 do 512 Hz), kao i poslednjih 24 podnosioca (koji se nalaze u spektru na frekvencijama od 3712 do 4096 Hz) se ne koriste. Prvih 32 podnosilaca se ne koriste zbog mogućih ograničenja zvučnika za reprodukciju niskih frekvencija. Na 20-om podnosiocu, što odgovara frekvenciji od 320 Hz, nalazi se prostoperiodični signal. Ovaj signal će se u daljim istraživanjima koristiti za rešenje problema razdešenosti takta na prijemnoj i predajnoj strani. Preostalih 200 podnosioca korišćeni su za mapiranje slike. Mapiranje slike je izvršeno 256 QAM modulacijom podnosilaca. OFDM signal je kompleksan i kao takav ne može se direktno reprodukovati preko zvučnika. Zbog toga je potrebno oformiti realni OFDM signal. Signalu sa prethodno generisanim podnosiocima potrebno je odrediti simetrične konjugovano kompleksne parove, a zatim izvršiti inverznu Furijeovu transformaciju. Dobijeni signal je realan i moguće ga je reprodukovati direktno preko zvučnika.

Zbog slabljenja prilikom prenosa akustičkog signala, na prijemnoj strani pre demodulacije primljenih OFDM simbola potrebno je izvršiti ekvalizaciju kanala. Zbog toga se pre slanja OFDM simbola koji prenosi informaciju šalje preambula od 3 OFDM simbola sa poznatom sekvencom sa ravnim amplitudskim spektrom [12], ukupne dužine 1536 odbiraka. Preambula se koristi i za vremensku sinhronizaciju, odnosno za detekciju početka OFDM simbola sa rezolucijom od 1 perioda samplovanja signala.

Kako bi se kvantifikovao kvalitet prenosa podataka pomoću akustičkog signala potrebno je uvesti objektivnu meru sličnosti poslate i primljene informacije. Pošto je slika informacija koja se prenosi kao mera razlike korišćena je kumulativna vrednost greške koja se računa na sledeći način:

$$greška = \sum_{i=1}^{m}\sum_{j=1}^{n}\left|I_{Tx,i,j} - I_{Rx,i,j}\right|, \quad (1)$$

gde su I_{Tx} i I_{Rx} poslati i rekonstruisani pikseli slike, respektivno. Broj vrsta piksela u slici iznosi *m*, a broj kolona piksela slike iznosi *n*. Na osnovu prethodnog izraza zaključuje se da kumulativna funkcija greške predstavlja sumu razlike svih piksela i da nema jedinicu.

III. POSTAVKA EKSPERIMENATA I SIMULACIJA

U ovom poglavlju biće prikazana postavka simulacije akustičkog prenosa, kao i eksperimenata koji su realizovani. Na Slici 2 prikazana je *grayscale* fotografija koja je korišćena kao informacija koja se prenosi akustičkim signalom u realizovanim simulacijama i eksperimentima. Broj bita za kodovanje vrednosti piksela je 8, pa se vrednosti piksela nalaze se u opsegu 0 do 255.

Sl. 2. Slika koja se koristi za prenos

Kao polazna tačka u ovom istraživanju korišćene su simulacije akustičkog prenosa informacije između dve tačke u prostoru. Na osnovu slike koju je potrebno preneti generisan je realni OFDM signal koji se reprodukuje sa zvučnika. Simulacija prostiranja akustičkih talasa zasniva se na množenju svake spektralne komponente signala sa odgovarajućim *steering* vektorom.

Takođe, važno je definisati temperaturu ambijenta zbog zavisnosti brzine prostiranja zvuka od temperature. Kao prijemna tačka u prostoru uzeta je pozicija jednog od mikrofona iz mikrofonskog niza [13]. Izabrano je da talasni front nailazi na mikrofonski niz pod uglom određenim azimutnim uglom 5° i elevacionim uglom 90°.

Nakon simulacije izvršeni su i realni eksperimenti. Eksperimenti su realizovani u Laboratoriji za Akustiku Elektrotehničkog fakulteta u Beogradu. Na Slici 3 prikazana je postavka eksperimenta. Kao prijemnik akustičkog signala korišćen je jedan od mikrofona iz mikrofonskog niza, kao i u simulacijama. Za akviziciju signala sa mikrofona korišćen je *Pulse* sistem [14]. Akustički OFDM signal reprodukovan je sa monitorskog zvučnika [15]. Rastojanje između

mikrofona i zvučnika iznosilo je oko 2 metra. Početak signala na prijemu detektovan je korišćenjem autokorelacije preambule koja se šalje pre OFDM signala.

Sl. 3. Eksperimentalna postavka

IV. REZULTATI I DISKUSIJA

U ovom poglavlju prikazani su rezultati simulacija i eksperimenata prenosa informacija korišćenjem akustičkog OFDM signala. Parametri simulacije odabrani su tako da odgovaraju eksperimentalnoj postavci prikazanoj na Slici 3. Prikazani rezultati predstavljaju izgled prenete fotografije nakon demodulacije i obrade signala na prijemnoj strani.

A. Rezultati dobijeni na osnovu simulacija

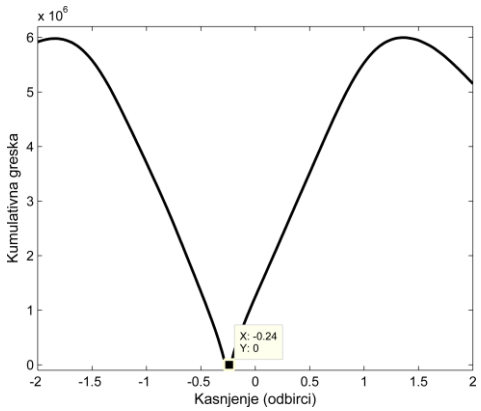
Množenjem spektralnih komponenti generisanog akustičkog OFDM signala sa *steering* vektorom dobijeni su signali na mikrofonskom nizu. Za potrebe ovog rada koristi se primljeni signal sa jednog mikrofona. Korišćenjem kroskorelacije određen je početak korisnog signala sa tačnošću od jednog vremenskog odbirka, a zatim izvršen postupak demodulacije primljenog OFDM signala i rekonstrukcija slike. Na Slici 4 prikazana je rekonstruisana slika dobijena na osnovu simulacije akustičkog prenosa.

Sl. 4. Primljena slika

Poredeći rezultat sa Slike 4 sa originalnom fotografijom (prikazanoj na Slici 2) evidentno je da postoje razlike. Na osnovu Slike 4 se prepoznaje sadržaj prenete fotografije, ali je oštrina fotografije narušena. Razlike se najlakše uočavaju na svetlijim delovima slike. Vrednost kumulativne greške, izračunate na osnovu izraza (1), iznosi 1245514. Prosečna vrednost razlika piksela poslate i primljene slike iznosi 10. Prosečna vrednost razlika piksela poslate i primljene slike računa se kao količnik kumulativne greške i ukupnog broja piksela.

U realizovanoj simulaciji nije modelovan realan akustički kanal, već samo kašnjenje usled prostiranja, pa je za očekivati da je rekonstruisana fotografija identična kao poslata. Korišćenjem kroskorelacije kao metode za detekciju početka korisnog dela signala može se postići vremenska tačnost do nivoa jednog odbirka. U realizovanoj simulaciji zbog izabranih pozicija zvučnika i mikrofona i zadate frekvencije odabiranja može se dogoditi da vremenski trenutak u kom počinje korisni signal ne odgovara celobrojnom broju odbiraka. Zbog toga se može desiti da je narušena fazna karakteristika primljenog signala. OFDM prenos je osetljiv na promenu faznog stava, pa je pretpostavljeno da se zbog toga javlja razlika između primljene i poslate slike.

Kako bi se ispitala navedena pretpostavka izvršena je izmena u simulaciji akustičkog prenosa. Nakon detekcije početnog vremenskog trenutka korisnog signala metodom kroskorelacije, izvršeno je dodatno vremensko kašnjenje. Pošto je potrebno zakasniti signal za necelobrojnu vrednost odbiraka τ, kašnjenje je izvršeno u frekvencijskom domenu. Za zadatu poziciju mikrofona u prostoru potrebno je odrediti vrednost τ koja će dovesti do idealne rekonstrukcije prenete fotografije. Vrednost τ određena je iterativnim postupkom tako što su pretpostavljane vrednosti vremenskog kašnjenja u opsegu [-2/fs 2/fs], a nakon toga izvršeno kašnjenje signala i demodulacija tako dobijenog OFDM signala. Za svaku vrednost pretpostavljenog vremenskog kašnjenja računata je vrednost kumulativne greške. Korak „pretrage“ iznosio je $f_s/100$. Nakon izračunavanja vrednosti greške za sve vrednosti vremenskog kašnjenja dobijena je zavisnost prikazana na Slici 5.



Sl. 5. Zavisnost vrednosti greške od vrednosti vremenskog kašnjenja

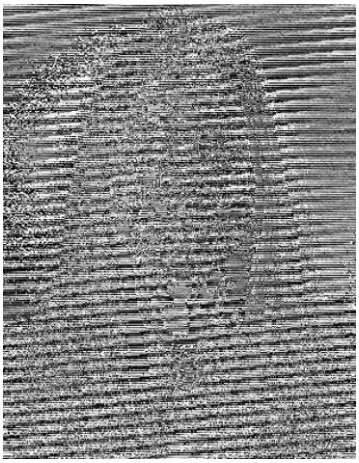
Sl. 6. Rekonstruisana fotografija sa unetim kašnjenjenjem

Na Slici 5 se vidi da je minimalna vrednost greške postignuta za vrednost vremenskog kašnjenja τ=0.24 odbirka. Vrednost greške u ovom slučaju iznosi 0, što znači da je rekonstruisana slika identična kao poslata. U simulacijama nije dodavan šum. Na Slici 6 prikazana je rekonstruisana slika za pronađenu vrednost necelobrojnog vremenskog kašnjenja u odbircima.

Dodatni postupak vremenskog kašnjenja ponovljen je i za ostale mikrofone iz mikrofonskog niza. Za svaki mikrofon je pronađena optimalna vrednost dodatnog kašnjenja i u svim slučajevima dobijena je idealno rekonstruisana fotografija. Na osnovu prethodno prikazanih rezultata zaključuje se da je za idealnu rekonstrukciju signala potrebno izvršiti dodatno vremensko kašnjenje, kako bi se očuvao početni fazni stav primljenog akustičkog OFDM signala. Ova procedura primenjena je u realizovanim eksperimentima, prikazanim u nastavku ovog poglavlja.

B. Rezultati dobijeni na osnovu eksperimenata

Na Slici 7 prikazana je fotografija dobijena demodulacijom akustičkog OFDM signala sa jednog mikrofona iz mikrofonskog niza u eksperimentu čija je eksperimentalna postavka prikazana na Slici 3. Na osnovu rekonstruisane slike ne može se zaključiti šta je njen sadržaj. Vrednost kumulativne greške iznosi 4831274. Prosečna razlika po pikselu između poslate i primljene slike iznosi 40. Akustički kanal kroz koji je vršen prenos nije idealan, odnosno postoji odstupanje od ravne amplitudske i linearne fazne karakteristike. Da bi se uspešno rekonstruisala informacija preneta kroz akustički kanal potrebno je izvršiti ekvalizaciju kanala. Ekvalizacija kanala izvršena je korišćenjem preambule koja se šalje pre generisanog OFDM signala. Preambula se sastoji od tri OFDM simbola sa poznatom sekvencom koje imaju ravan amplitudski spektar.



Sl. 7. Rekonstruisana fotografija bez korišćenja ekvalizacije kanala

Nakon primenjene ekvalizacije kanala izvršeno je određivanje početka korisnog dela signala, vremensko necelobrojno kašnjenje i demodulacija signala. Na Slici 8 prikazana je rekonstruisana slika. Sadržaj slike se za razliku od situacije bez ekvalizacije sada može prepoznati. Postoje izvesne razlike u odnosu na originalnu sliku koje se pre svega odnose na oštrinu slike. Vrednost kumulativne greške u ovom slučaju iznosi 1300189. Prosečna vrednost greške po pikselu je 10.

Sl. 8. Rekonstruisana fotografija sa korišćenom ekvalizacijom kanala

Fotografija preneta kroz realan akustički kanal korišćenjem OFDM signala u ovom eksperimentu nije identična kao poslata fotografija. Eksperiment je realizovan u anehoičnoj prostoriji pa je bilo za očekivati idealnu rekonstrukciju poslate fotografije. Jedan od razloga koji je mogao uticati da ne dođe do idealne rekonstrukcije je razlika u radnim frekvencijama odabiranja hardverskih sistema na predaji i prijemu. Svođenje na istu frekvenciju odabiranja izvršeno je decimacijom [16]. Početni rezultati dobijeni u ovom radu mogu biti unapređeni pre svega korišćenjem sistema koji rade sa istim taktom. Dalja unapređenja sistema za akustički prenos podataka baziran na OFDM tehnici mogu biti i uvođenje zaštitnih vremenskih intervala i cikličnog prefiksa kod OFDM simbola. Takođe, uvođenjem tehnika zaštitnog kodovanja signala generisanog na predajnoj strani može dovesti do smanjivanja kumulativne vrenosti greške. Bitski protok ostvaren pri ovakvom prenosu iznosi 3.2 kbit/s. Vrednost protoka bi se značajno uvećala korišćenjem veće frekvencije odabiranja, odnosno veće širine kanala za prenos. U ovom radu širina kanala iznosila je 4096 Hz. Dodatno povećanje protoka moglo bi se postići i povećavanjem reda QAM modulacije koja se korisiti za generisanje OFDM signala.

V. ZAKLJUČAK

U ovom radu prikazan je postupak akustičkog prenosa podataka korišćenjem OFDM tehnike. Prikazan je način generisanja akustičkog OFDM signala koji se može reprodukovati u akustičkom domenu. Realizovani eksperimenti i simulacije pokazali su da je moguće izvršiti prenos podataka korišćenjem ove tehnike, pri čemu je ostvaren protok od 3.2 kbit/s. Simulacijom akustičkog prenosa pokazano je da je neophodno izvršiti kompenzaciju vremenskog kašnjenja signala na prijemu, pre nego što se izrvši demodulacija OFDM signala. Vrednost kašnjenja ne mora biti jednaka celom broju odbiraka, pa je zbog toga kašnjenje signala izvršeno u frekvencijskom domenu. Vrednost kašnjenja određena je iterativnim postupkom. Pokazano je da se nakon ovog postupka preneti podaci mogu idealno rekonstruisati. Postupak određivanja tačne vrednosti kašnjenja potrebno je odrediti samo jednom za trenutnu poziciju mikrofona u prostoru. To znači da bi se pre slanja korisnih podataka mogla poslati referentna slika, koju bi unapred znao prijemnik, kako bi se odredila vrednost kašnjenja potrebna za idealnu rekonsturukciju. Realizovani

eksperimenti pokazali su neophodnost upotrebe ekvalizacije kanala kako bi se podaci mogli uspešno rekonstruisati. Rekonstruisani podaci na prijemnoj strani nisu identični kao poslati, ali pokazuju da je ovakav način prenosa moguć. Da bi se ovakav prenos mogao koristiti u realnim aplikacijama potrebno je koristiti još neka predprocesiranja signala. Korišćenjem cikličnog prefiksa i zaštitnog intervala kod OFDM simbola, kao i tehnika zaštitnog kodovanja mogla bi se smanjiti verovatnoća greške u prenosu. Buduća istraživanja ići će u pravcu uvođenja navedenih predobrada ali i varijacije širine kanala za prenos i reda QAM modulacije, sa ciljem da se ostvari što veći protok i da se smanji verovatnoća greške pri prenosu.

ZAHVALNICA

Ovaj rad je realizovan u okviru projekta TR 36026 koga finansira Ministarstvo prosvete, nauke i tehnološkog razvoja Republike Srbije. Autori se zahvaljuju profesorki Jeleni Ćertić na korisnim savetima i sugestijama.

ABSTRACT

Over the past few years data transfer using audio is more used. While the concept is not new, its current growth is being fuelled by the rise of smartphones, IoT devices and improved signal-processing technology. This technology can be an alternative to other data transmission. Advantages of acoustic (sound) data transmission in relation to radio technologies is the possibility of use in places where radio transmission is disabled. The advantage is that most devices have a speaker and a microphone and no additional hardware components are required. The limitation of acoustic data transmission may be a smaller flow than other technologies. This paper presents the use of an acoustic signal for data transmission in the air in the audio band. Acoustic data transmission is realized using an acoustic OFDM signal. The transmission was realized in simulations and real experiments without encoding techniques. A time delay compensation technique has been introduced that can take non-integer values in the number of samples. For the introduced transmission parameters, a bit rate of 3.2 kbit/s has been achieved. The results obtained showed the possibility of using such a system for the information transmission at small distances in realistic terms.

Data transmission based on acoustic OFDM technique

***Abstract*— In this paper, we present microwave components and sensors based on surface plasmon polariton-like (SPP-like) propagation induced by structural dispersion of substrate integrated waveguide (SIW). We develop a theoretical framework upon which the novel microwave diplexer, dual-band filters, and sensor are designed and fabricated. Basic building block is a multilayer SIW, where layers represent sub-SIWs with different dielectric filling materials and/or different geometric parameters. The layers are designed to have effective permittivities of opposite signs in certain frequency ranges, which enables SPP-like propagation to occur at their interfaces. A detailed theoretical and numerical analysis together with numerical optimization has been performed to design the novel components, which were afterwards fabricated using different techniques. Excellent filtering operation has been confirmed with the designed diplexer and dual-band bandpass filters, while extreme sensitivity has been demonstrated with the proposed sensor. These results show the great potential of SPP-like phenomenon for design of microwave components and sensors.**

***Index Terms*— Dual-band bandpass filter, surface plasmon polariton (SPP), diplexer, sensor**

I. Introduction

The coupling between free electrons and photons at the interface of metal and dielectric medium enables a peculiar phenomenon – surface plasmon polaritons (SPP) [1] that is characterized by a strong field confinement, which has been widely applied in optical communications, imaging, and sensors [2-4]. Due to the advantageous properties of SPPs and the fact that SPPs naturally occur at optical frequencies, there have been proposed different concepts to engineer SPP phenomenon in the frequency ranges other than optical, including microwaves and terahertz. One of the concepts that effectively mimics SPPs are spoof or designer surface plasmon polaritons, which have been widely used in different microwave circuits including transmission lines, filters, antennas, couplers, splitters, absorbers, and circulators [5-21]. Unlike genuine SPPs, spoof SPPs are supported by specifically designed structures, predominantly by grooved strips whose geometrical properties are used to tailor the behavior of spoof SPPs.

Recently, a novel "natural" SPP-like concept in microwave regime has been proposed, which is based on the exploitation of the well-known structural dispersion of the electromagnetic modes in parallel-plate waveguide structure filled only with materials with positive permittivity [22]. Namely, if two waveguides with different cut-off frequencies are coupled, then the two exhibit effective permittivities of opposite signs in a certain frequency range, which opens up a possibility for SPP-like behavior to occur at their interface.

In this paper, we demonstrate how this promising concept can be employed to design novel circuits and sensors that operate at microwave frequencies [23-26]. Namely, it is well-known that the rapid growth of communication systems imposes the requirements for high-performance, low-cost, low-profile components that operate at two or more non-harmonically related frequencies. On the other hand, microwave sensors have attracted a considerable attention since they can provide non-invasive, label-free, as well as real-time detection and thus they have been utilized in various applications including dielectric constant sensing [27-36], food quality control, and concentration measurements of liquid solutions. Nevertheless, microwave sensors very often suffer from low resolution and sensitivity, which limits their applicability when a minute change has to be detected, which is the case in engine oil quality and fuel blends detection [37-41], or vegetable oils quality analysis and adulteration detection [41-43].

To address these requirements, we design SPP-like propagation using substrate integrated waveguide (SIW) that is comprised of several layers, i.e. sub-SIW structures, each having particular width and dielectric filling material, and consequently particular cut-off frequency. Since the layers are designed to have effective permittivities of opposite signs in certain frequency ranges, SPP-like propagation occurs at their interface. Besides slow-wave behavior and field confinement, SPP-like propagation also provides a transmission zero in the spectral response, and enables a clear separation of a passband and stopband in the spectrum paving a way towards good filtering operation. On the other hand, strong field enhancement at the interface and sensitivity of the transmission zero to the surrounding dielectric environment

represents a promising sensing scheme.

This concept is the underlying idea of the operating principle of the circuits and sensor that will be presented here – diplexer consisting of two SPP-based filters, three dual-band filters, and a dielectric constant sensor. In the following, we will present a theoretical background of the SPP-like phenomenon, its realization in SIW structure, as well as filter and sensor operation principles. The numerical analysis and results will be provided together with fabrication procedure and measurement results.

II. Theoretical Background

To present the underlying idea of the circuits and sensor, we first consider the basic building block - SIW consisting of two sub-SIW sections, whose layout and corresponding geometric and material parameters are shown in Fig. 1. In general case, the widths and dielectric filling materials are different for each sub-SIW.

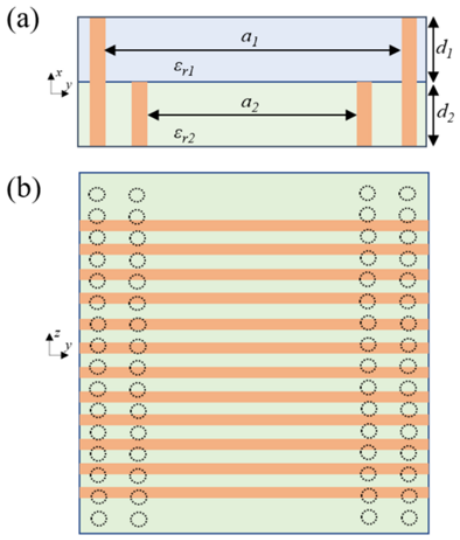

Fig. 1. (a) Cross section of a SIW composed of two sub-SIW sections, (b) top view of the interface of two sub-SIW sections.

Substrate integrated waveguide (SIW) represents a guiding structure whose dominant propagating mode is TE_{10}, whilst TM modes are not supported. The cut-off frequency of the TE_{10} mode is given as:

$$f_{cTE10} = \frac{c}{2a\sqrt{\varepsilon_r}}, \tag{1}$$

where ω is angular frequency, c is speed of light, a is SIW's width, and ε_r is the dielectric constant of the filling material. In other terms, we can say that SIW is characterized by the effective permittivity:

$$\varepsilon_e = \varepsilon_r - \left(\frac{c}{2af}\right)^2, \tag{2}$$

where f is frequency, and it can be seen that the effective permittivity is negative below and positive above the cut-off frequency.

SPP-like propagation can be achieved if two SIWs with different cut-off frequencies, i.e. with different effective permittivities in a certain frequency range, are coupled. This can be realized using the configuration shown in Fig. 1, so that the two SIWs represents sub-SIWs comprising the major SIW. Since each sub-SIW is bounded by the top and bottom metal plates, the interface metal plate is replaced by an array of wires, which provides coupling of the fields in the sub-SIWs, as well as accumulation of electric charges and consequently the condition that the normal components of the electric field at the interface are opposite to each other.

To further analyze the properties of the proposed structure, the dispersion relation is derived under approximation that a structure is a 2D partially-filled waveguide [25]:

$$\sqrt{\beta^2 + \frac{1}{4a_2^2} - \varepsilon_{r2}k_o^2}\left(\varepsilon_{r1} - \frac{1}{4a_1^2k_o^2}\right) \tanh\left(d_2\sqrt{\beta^2 + \frac{1}{4a_2^2} - \varepsilon_{r2}k_o^2}\right) = -\sqrt{\beta^2 + \frac{1}{4a_1^2} - \varepsilon_{r1}k_o^2}\left(\varepsilon_{r2} - \frac{1}{4a_2^2k_o^2}\right) \tanh\left(d_1\sqrt{\beta^2 + \frac{1}{4a_1^2} - \varepsilon_{r1}k_o^2}\right), \tag{3}$$

where β is the propagation constant in the z direction, k_o is the wavenumber in vacuum, a_i is the width and d_i is the height of the SIWs as shown in Fig 1 (a), where i takes values 1 and 2.

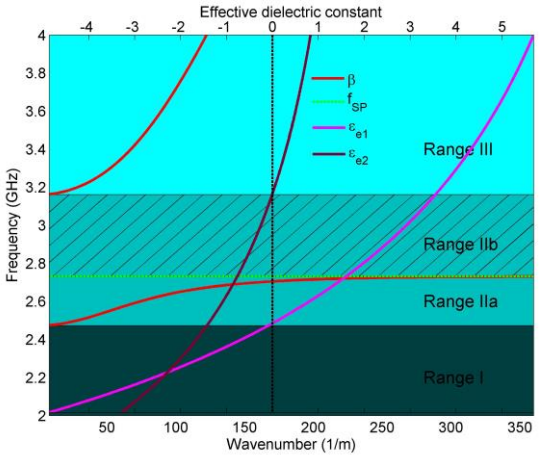

Fig. 2. Dispersion relation and effective permittivities of the sub-SIWs. The geometrical parameters of the structure are the following: a1 = 34.8 mm, a2 = 21.7 mm, ε1 = 2.2 and ε2 = 9.2.

Fig. 2 show the dispersion relation and characteristic frequency ranges for the two-layer SIW, for arbitrarily chosen values of the characteristic parameters – dielectric constants and sub-SIW's width. However, we consider that the characteristic values are such that the cut-off frequency of the upper layer is lower than that of the bottom layer. One can note three frequency ranges – in the first one both effective permittivities are negative, in the second one they are of opposite signs, whilst in the third frequency range both effective permittivities are positive. It is clear that the first range entirely suppresses propagation, whilst in the third one the conventional propagation occurs.

For the SPP-like propagation, the second frequency range is of major importance and it can be divided into two sub-regions, IIa and IIb, as shown in Fig. 2. Namely, in the region IIa, the absolute value of the negative effective permittivity is greater than that of the positive effective permittivity, causing SPP-like propagation, which is confirmed by the corresponding dispersion curve. The same curve goes to the infinity at the frequency at which the permittivities have the same values but opposite signs, causing a transmission zero to occur in the spectrum. In the region IIb, the negative permittivity has lower absolute value in comparison to the positive permittivity, and thus no propagation can occur, which is confirmed by the fact that dispersion curve does not exist in that region. In summary, owing to the nature of the SPP-like phenomenon, the two-layer structure provides stopbands in the I and IIb regions, and consequently the passband in the frequency range IIa. Since the widths and dielectric filling materials are different in general case, this indicates that transmission zero and consequently passband can be positioned arbitrarily.

The previous analysis represents the underlying idea of the formation of SPP-like propagation, and it can be further expanded to three-layer structure or adjusted to the case of half-mode SIW. As such, the analysis is the initial step in design of the microwave circuits and sensors, as it will be demonstrated.

III. MICROWAVE SINGLE-BAND FILTERS AND DIPLEXER

The SPP-like behavior in two-layer SIW can be used to realize single-band bandpass filters, since the two-layer structure can provide a passband owing to the transmission zero that stems from the SPP-like propagation. A single-band filter can be realized as a microstrip tapered two-layer SIW structure where two sub-SIWs have different filling dielectric materials and widths, Fig. 3 (a) and (b). To demonstrate this possibility, we have designed two single-band filters that operate at 2.4 and 2.6 GHz, respectively.

They have been designed according to the theoretical analysis in the previous section and in that sense, opposite signs of effective permittivity have been achieved relying on both different sub-SIWs' width and their filling materials. Dielectric materials that are used are Rogers RT 5800 (ε_{r1}=2.2, $tan\delta_1$=0.0009, d_1=0.51 mm) and TMM 10 (ε_{r2}=9.2, $tan\delta_2$=0.002, d_2=1.27 mm). The dimensions have been optimized using CST software package and their final values in millimeters are: a_{11}=34.8, a_{12}=21.7, a_{21}=32, a_{22}=20, L=40, L_T=5, W_{T1}=5.22, W_{T2}=4.8, w_{50}=3.4, w_w=0.4, d_w=0.4, n_w=31, d_{via}=0.5, p_{via}=0.25, where a_{11}/a_{21} and a_{12}/a_{22} are the widths of the upper and lower sub-SIW structures for bandpass filter operating at 2.4 and 2.6 GHz, respectively. The filters are fed by the tapered microstrip lines, which have also been optimized to achieve good impedance matching.

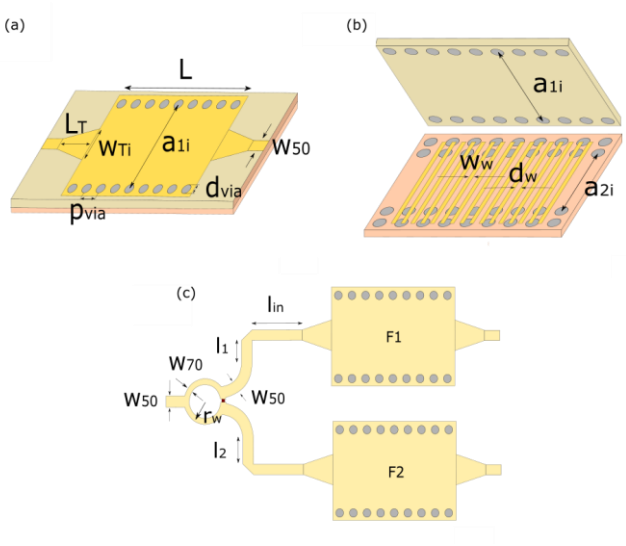

Fig. 3. (a) Two layer SIW with a microstrip transition (b) SPP interface (c) Final layout of the diplexer.

Furthermore, the single-band filters can be used to design a diplexer and to that end, we have designed a diplexer operating at 2.4/2.6 GHz that consists of the two single-band bandpass filters incorporated into diplexer using a convectional Wilkinson power divider, Fig. 3 (c) [26].

It should be noted that for the SIW bandpass filter that operates at 2.4 GHz, it is important not only to position the central frequency at 2.4 GHz, but also to position the transmission zero at 2.6 GHz, i.e. at the higher operating frequency of the diplexer, to achieve high selectivity as well as stopband suppression. To that end, the cut-off frequency of the upper sub-SIW structure is chosen to be at 2.35 GHz, whilst the cut-off frequency of the bottom sub-SIW structure should be placed above 2.8 GHz. Thus, the transmission zero and the stopband is positioned in the frequency range 2.5-2.65 GHz, which coincides with the higher operating band. As for the filter with the central frequency of 2.6 GHz, the cut-off frequency of the upper sub-SIW structure is placed at 2.55 GHz, whilst the cut-off frequency of the bottom sub-SIW structure is placed above 3 GHz, so its transmission zero is placed at 2.8 GHz, i.e. closely to the passband.

The simulated responses of the individual filters are shown in Fig 4 and they have the following characteristics - their 3-dB bandwidths are 8.3 and 7.69%, the insertion losses -0.735 and -0.78 dB, and the return losses are below -35 and -30 dB, respectively. The passbands are characterized by the excellent selectivity which is primarily due to transmission zeros that

occur at 2.59 GHz and 2.78 GHz.

The final response of the diplexer is also shown in Fig. 4 (b) and (c) and it is in a good agreement with the responses of the individual filters. The central operating frequencies are positioned at 2.4 and 2.63 GHz, and their 3-dB bandwidths are 10.4 and 7.98%, respectively. The insertion loss is -3.21 dB and 3.41 dB, whilst the return losses are 12 and 26 dB, respectively. The passbands are characterized by the excellent selectivity which is primarily due to transmission zeros that occur at surface-plasmon frequencies at 2.6 GHz and 2.8 GHz respectively. The isolation between outputs ports is below -20dB in the frequency range of interest. Transmission zero of the filter at 2.4 GHz is located at 2.6 GHz and ensures high stopband suppression below -26 dB.

IV. Multi-Band Microwave Filters

The concept of microwave filters based on SPP-like propagation can be further extended to multi-band filters using multilayer SIW structures. Introduction of multiple sub-SIWs with different cut-off frequencies leads to the introduction of multiple transmission zeros and passbands in the spectrum. We note that the position of transmission zeros, and consequently passbands and stopbands can be chosen arbitrarily, since they depend on geometrical and material parameters of the individual sub-SIW structures. This property, together with SIW wave guiding capabilities, meets the requirement for high performance, low-cost, multiband microwave filters with non-harmonically related passbands.

To demonstrate this potential, we have designed two dual-band bandpass filters that are based on three-layer SIW structure, where each layer represents a sub-SIW structure with specific width and filling material, Fig 5. Since the sub-SIWs' width and dielectric constants are mechanisms for independent control of the passbands, theoretically there are six degrees of freedom in filter design. However, it should be noted that the top sub-SIW should have the lowest cut-of frequency and the bottom one the highest cut-of frequency or vice versa, to achieve dual-band operation. Otherwise, the two SPP-like propagation would overlap and only one passband would be formed. Also, to further simplify the procedure and simultaneously keep the design freedom it is judicious to use either the same width or the same dielectric constant for the three sub-SIWs.

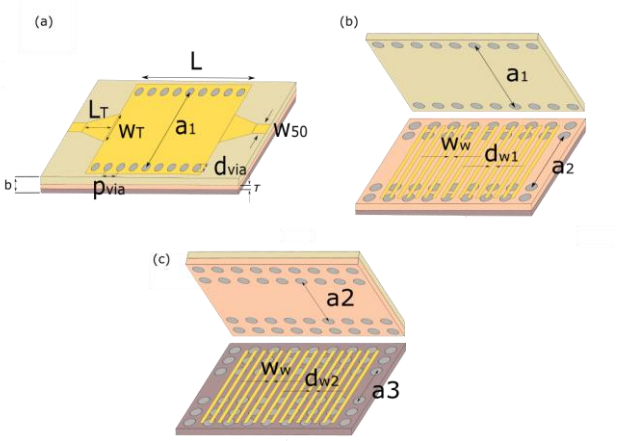

Fig. 5. (a) Layout of the proposed multi-band filters (a) top view (b) first SPP interface (c) second SPP interface

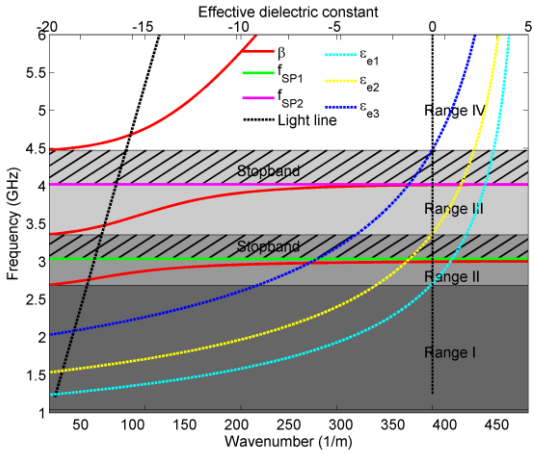

Fig. 6. (a) Dispersion relation of the multiband filter (b) effective permittivities of the three sub-SIWs. The geometrical parameters of the structure are the following: a_1=25 mm, a_2=20 mm, a_3=15 mm, ε_1=9.8, ε_2=4.5, ε_3=2.2, d=τ=1 mm and b=3 mm.

To demonstrate the operating principle, we extend the theoretical analysis given in the Section II, to the three-layer structure and obtain the following dispersion relation:

$$\frac{k_{y3}}{\varepsilon_{e3}}\tanh\left(k_{y3}d\right)=-\frac{k_{y2}}{\varepsilon_{e2}}\coth\left(k_{y2}\frac{\tau}{2}+\psi\right),$$
$$-\frac{k_{y1}}{\varepsilon_{e1}}\tanh\left(k_{y1}(b-d-\tau)\right)=-\frac{k_{y2}}{\varepsilon_{e2}}\coth\left(k_{y2}\frac{\tau}{2}-\psi\right), \quad (4)$$
$$k_{yi}=\sqrt{\beta^2-k_o^2\varepsilon_{e3}},$$

where β is the propagation constant in the z direction, k_0 is the wavenumber in vacuum, k_{yi} is the wavenumber in the y

direction, ε_{ei} effective dielectric constant, whilst i take the values 1, 2, and 3, denoting the top, middle, and bottom layer, respectively, and where d, τ, and b are the geometrical parameters of the structure as shown in Fig. 5(a).

Figure 6 shows the dispersion relations along with effective permittivities of each sub-SIW, where sub-SIWs have the same geometrical parameters and different dielectric constants. Similar to Figure 2 which shows a specific spectral region that enables passband in the spectrum, here we have two such spectral regions that enable the existence of the separate SPPs and consequently two passbands.

Following this analysis, we first propose a filter that comprises three sub-SIWs of the same width filled with different dielectric materials [23]. The dielectric constant of the middle layer and its width have been chosen to position its cut-off frequency in the range 2.7–3.2 GHz to be able to position the passbands around 2.4 and 3.5 GHz. Afterwards, the dielectric constants of the top and bottom sub-SIWs have been chosen to obtain the passbands at the desired frequencies.

The three layers are realized using the following dielectric substrates: Rogers TMM10i with relative permittivity ε_{r1}=9.8, dielectric loss $tan\delta_1$=0.002, and thickness $t_1=b-d-\tau$=1.27mm, Neltec NH9450 with relative permittivity ε_{r2}=4.5, dielectric loss $tan\delta_2$=0.0027, and thickness τ=0.768mm, and Rogers RT5880 with relative permittivity ε_r=2.2, dielectric loss $tan\delta$=0.0009, and thickness d=0.51mm.

The final geometrical parameters of the filter in millimeters are the following: a=22, L=40, L_T=12.5, W_{in}=4.5, W_t=5, w_w=0.2, d_{w1}=1, n_{w1}=33, d_{w2}=0.4, n_{w2}=65, d_{via}=0.8, p_{via}=1.1, where dvia represents the diameter of the via, pvia the spacing between the vias, whilst n_{w1} and n_{w2} represent the number of wires at the interface between neighboring materials.

To demonstrate the second tuning mechanism, we proposed a filter that comprises three sub-SIWs with different widths and same dielectric filling materials. To that end, the dielectric substrate Neltec NH9450 with relative permittivity ε_{r2}=4.5, dielectric loss $tan\delta_2$=0.0027, and thickness τ=0.768 mm, has been used. The widths a_1, a_2, and a_3 have been determined to achieve the passbands around the frequencies 4.7 and 5.5 GHz. The final geometrical parameters in millimeters of the filter are following: a_1=16, a_2=13.8, a_3=12.4, L=25, L_T=5, W_{in}=4.5, W_T=9, w_w=0.25, d_{w1}=0.25, n_{w1}=45, d_{w2}=0.375, n_{w2}=30, d_{via}=0.5, p_{via}=0.8.

In both filters, sub-SIWs are coupled through the array of wires, and the arrays together with microstrip feeding lines have been optimized to achieve good impedance matching. More detail on this can be found in [23].

The fabricated filters are shown in Fig. 7, while Fig 8. shows the simulated and measured response of the filters.

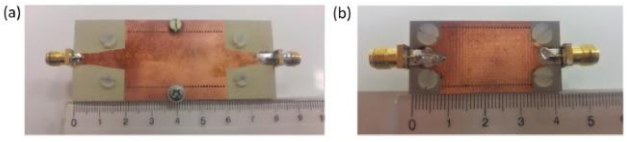

Fig. 7. Fabricated dual-band filters (a) First dual-band filter (b) Second dual-band.

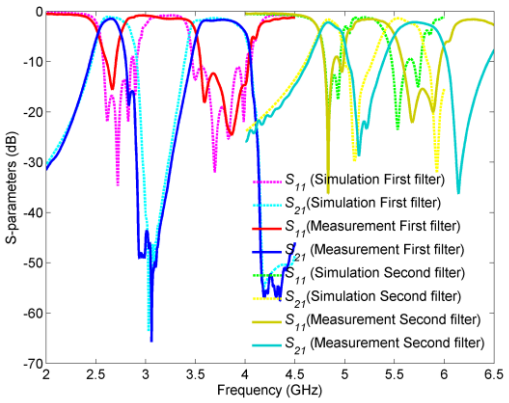

Fig. 8. Comparison of simulated and measured response for First- and Second dual-band filter.

The first filter exhibit two passbands at 2.65 and 3.75 GHz, with insertion loss of 1.47 and 1.69 dB, and the 3-dB bandwidths of 8.7% and 13.3%, respectively. The central frequencies of the second filter are 4.8 and 5.7 GHz, their insertion losses 2.22 and 2.17 dB, and the 3-dB bandwidths 5.2% and 8.2%, respectively. Both filters are characterized by good in-band and out-of-band performance as well as by excellent selectivity owing to the transmission zeros. The difference in the insertion losses between the first and the second filter can be attributed to the fact that the first filter comprises three different substrates whose dielectric losses are $tan\delta_1$=0.002, $tan\delta_2$=0.0027, and $tan\delta_3$=0.0009, respectively, whilst in the second proposed filter only the substrate with $tan\delta_2$=0.0027 has been used. Therefore, the losses in dielectric are more pronounced in the second proposed filter, which results in higher insertion losses.

The proposed filters were fabricated using standard printed circuit board (PCB) technology and each layer was fabricated separately and afterwards assembled into the final structure using screws, which inevitably causes small air gaps between the layers. Since SPP-like propagation is confined to the interface between layers, air gaps could influence the response introducing a small shift in the frequency spectrum. Their thickness cannot be measured precisely, but can be approximated by the thickness of the wires, i.e. copper thickness. In addition, imperfections in soldering of the connectors and employed three port measuring method could be a reason for higher return losses in the fabricated structure.

In order to overcome technology related limitations, we also proposed LTCC dual-band microwave filter based on “natural” SPP concept. LTCC enables accurate, robust, and low-cost production of multilayer circuits that can be easily integrated. In other words, employment of LTCC technology prevents occurrence of air gaps and misalignment in the structure, which provides very reliable fabrication of demanding multilayer structures. Since the filter is fabricated using LTCC technology, all layers have the same filling dielectric material, and the cut-off frequencies of the sub-SIWs are controlled exclusively by their widths.

The green tapes that are used in the LTCC process as the

dielectric material, have the relative permittivity 5.6, dielectric loss 0.001, and thickness 0.24 mm. The final geometrical parameters of the filter in millimeters are the following: a_1=16, a_2=13.8, a_3=12.5, L=40, L_T=5, W_{in}=4.5, W_T=5, w_w=0.2, d_{w1}=1, n_{w1}=33, d_{w2}=0.4, n_{w2}=65, d_{via}=0.8, p_{via}=1.1, where dvia represents the diameter of the via, pvia the spacing between the vias, whilst n_{w1} and n_{w2} represent the number of wires at the interface between neighboring materials.

During the lamination and co-firing process of LTCC process, slight shrinking of the structure has arisen due to inhomogeneity of the proposed structure, which is investigated using computed tomography, Fig. 9 (b).

The simulated and measured results are shown in Fig. 10. The simulated and measured responses show the same trend and *a* slight discrepancy is due to the difference in the simulated and fabricated dimension of a_1, and manufacturer tolerance in terms of dielectric constant.

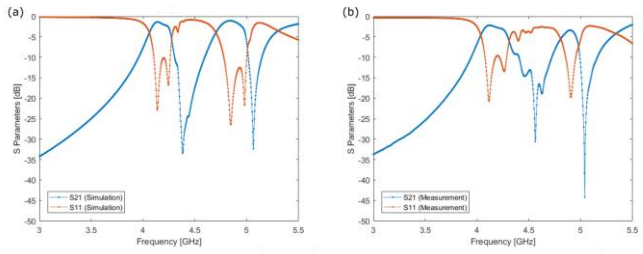

Fig. 10. (a) Simulated and (b) measured S parameters of the proposed dual-band bandpass filter.

V. MICROWAVE SINGLE-BAND FILTERS AND DIPLEXER

Relying on the previous discussions, we have proposed a microwave dielectric constant sensor [25], which is however based on half-mode (HM) SIW structure. Although SIW can provide lower radiation losses in comparison to HMSIW, HMSIW has comparable performance in the frequency range of interest, sufficiently good to support propagation and the proposed sensing concept. However, unlike the cumbersome structures in conventional SIW, HMSIW provides significantly smaller structure.

The layout of the proposed sensor is shown in Fig. 11. The HMSIW is comprised of two parts filled with a dielectric substrate material, where the bottom part also features a reservoir that hosts the sensed liquid analyte. The two parts are coupled through an array of wires, and since they differ in the dielectric constant, SPP occurs causing a sharp transmission zero in HMSIW response, which is very sensitive to small changes of the dielectric constant of the analyte. In that manner, minute changes in dielectric constant can be detected, which is not the case with the majority of the microwave dielectric constant sensors.

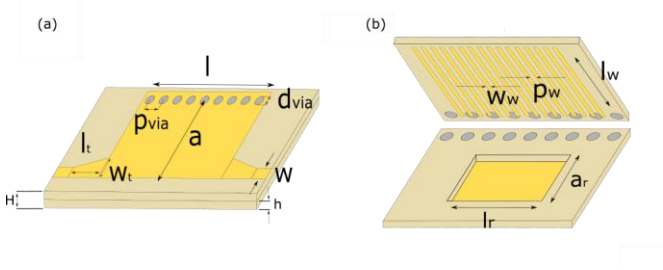

Fig. 11. Layout of the sensor based on HMSIW.

Fig. 12 shows HMSIW numerical transmission response for different materials in the reservoir, whose real part of the dielectric constant ranges from 2.4 to 3.8. The responses have been obtained using finite element method in CST solver, and the geometrical parameters are chosen to provide the response of interest in the range from 2 to 3 GHz. Obtained geometrical parameters in millimeters are: a=15, a_r=12.1, l=40, l_r=20, H=1.27, h=0.635, w=1.9, w_t=5, l_t=30, l_w=12.7, w_w=0.1, p_w=0.5, d_{via}=0.8, p_{via}=1.1. The dielectric substrate was Rogers TMM6 with relative permittivity ε_r=6, dielectric loss $tan\delta$=0.0023, and thickness t=0.635 mm, Also, the width of the microstrip lines that feed HMSIW have been optimized to achieve good impedance matching and low-loss response.

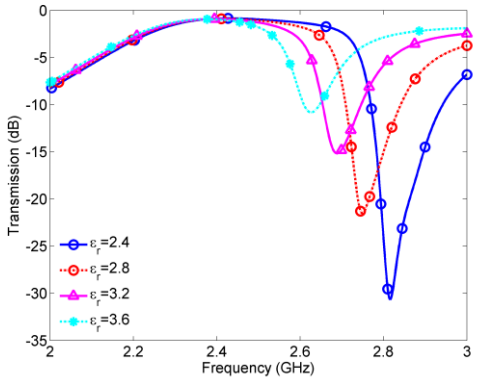

Fig. 12. HMSIW numerical transmission response for different materials in the reservoir.

One can notice that a cut-off frequency of the overall structure is the same for all responses – 2.2 GHz. However, the responses differ in the position of the sharp transmission zero. Namely, when the absolute values of the two dielectric constants are equal, propagation is not allowed and a sharp transmission zero occurs in HMSIW response. Using the calculation method proposed in [6], both real and imaginary parts of the unknown dielectric constant can be calculated:

$$\mathrm{Re}(\varepsilon_{e2}) = -\mathrm{Re}(\varepsilon_{e1}),$$
$$\mathrm{Im}(\varepsilon_{e2}) = \mathrm{Im}\left(\varepsilon_{r2}\left(1-\frac{\omega_2^2}{\omega(\omega+i\omega\gamma_2)}\right)\right) = \left|\mathrm{Re}(\varepsilon_{e2})\right|, \quad (5)$$

where ε_{ei} and ε_{ri} represent complex effective permittivities and real parts of the dielectric constant, ω_{pi} and γ_i are the plasma frequency and the damping rate of the plasma oscillations, where index i denotes the substrate (1) and sensing analyte (2). Q_d is the Q-factor of the plasma resonance and Υ is a derived parameter. A more detailed derivation can be found in [6].

To confirm the predicted sensor operation, we have fabricated the sensor using standard PCB technology, Fig. 13, and tested for different binary toluene/methanol mixtures. In the pure toluene whose dielectric constant is equal to 2.4-i*0.11, different amounts of methanol were added using micropipette to achieve the real parts of the dielectric constant values in the range from 2.4 to 3.8. Consequently, due to the losses in methanol, the range of the imaginary part of the dielectric constant in the mixtures was from 0.1 to 0.5. The exact value of the dielectric constant of the mixtures have been determined using Kraszewski formula.

Fig. 14 show the measured responses of the sensor for different binary toluene/methanol mixtures and they exhibit the same trend as the simulated ones. The dielectric constants of the analytes have been determined using the spectral positions of the transmission zeros in the measured responses and above mentioned calculation method. The obtained values have been compared to those calculated using Kraszewski formula and this is shown in Fig. 15.

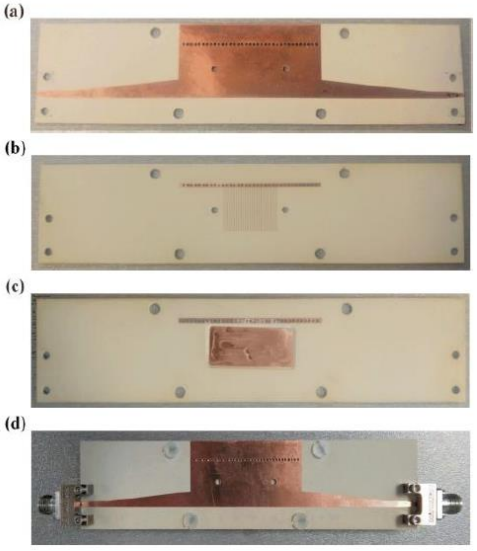

Fig. 13. Photographs of the fabricated sensor (a) top layer (b) bottom face of the top layer with wires (c) drilled tank in the bottom layer (d) assembled sensor.

One can note an excellent agreement between the two sets of the values for both real and imaginary part of the dielectric constant - the relative error is lower than 4% and 9%, respectively, for the whole set of measurement

The proposed sensor exhibits excellent sensitivity, which is significantly higher than the sensitivity of other recently proposed sensors [25]. Also, it should be noted that a particular strength of the proposed sensor is the detection of the real part of the dielectric constant in a very small range, whilst the majority of the published sensor are aimed at the detection of a wide range of the dielectric constant. We note here that the range of the real part of the dielectric constant values detectable by the proposed sensor can be widened using substrate with higher dielectric constant of HMSIW.

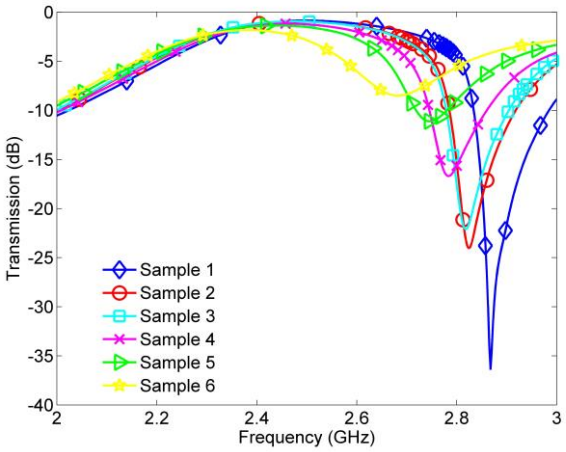

Fig. 14. Measured response of the fabricated sensor

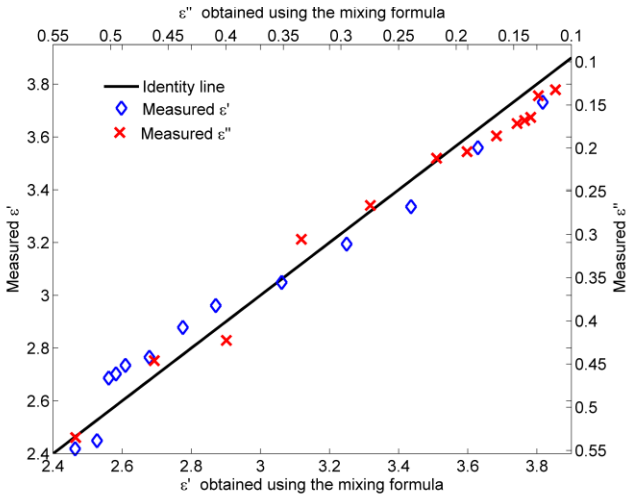

Fig. 15. Comparison of dielectric constants obtained using the mixing formula and spectral positions of the transmission zeros in the measured responses: real part and imaginary part.

These results confirm that the proposed sensor has a great potential for highly sensitive dielectric constant detection in liquid analytes in microwave regime, which can be applied in quality analysis of engine and edible oils. Moreover, the sensor represents a compact and low-cost solution since it is fabricated in low-profile configuration using PCB technology.

VI. Conclusions

In this paper, we have demonstrated the concept of "natural" SPP-like propagation and its applicability for

microwave components and sensors. We shown how SPP-like propagation can be realized in SIW structure and afterwards be applied to design single-band and dual-band filters, diplexer and dielectric constant sensor. Basic building block is a multilayer SIW, where layers represent sub-SIWs with different dielectric filling materials and/or different geometric parameters. The layers are designed to have effective permittivities of opposite signs in certain frequency ranges, which enables SPP-like propagation to occur at their interfaces. A detailed theoretical and numerical analysis together with numerical optimization was shown and afterwards used to design the novel components. Excellent filtering operation has been confirmed with the designed diplexer and dual-band bandpass filters, while extreme sensitivity has been demonstrated with the proposed sensor.

Comparison of Various Geometries of Nonuniform Helical Antennas

Jelena Dinkić, Dragan Olćan, *Member*, *IEEE*, and Antonije Đorđević

***Abstract*—We present comparison of nonuniform helical antennas with linear, exponential, and piecewise-linear variations of the turn radius and the pitch angle. Parameters that define the geometry of these antennas are optimized at a single frequency and in a frequency range in order to maximize the gain. The obtained optimal designs are compared and some practical aspects are commented.**

***Index Terms*—Nonuniform helical antennas, numerical modeling, optimization.**

I. Introduction

HELICAL antennas have been known for more than 70 years [1]. During that period, different types of geometry were investigated and published in the open literature. Uniform helical antennas [1], [2] have the simplest geometry. Further, nonuniform helical antennas were investigated in order to improve the antenna performances [3]–[8].

In this paper we consider three geometry types of nonuniform helical antennas, with linear, exponential, and piecewise-linear variations of the turn radius and the pitch angle. For each geometry and different axial antenna lengths, we perform sets of optimization at a single frequency and in a frequency range. From the optimization results, the optimal antennas for all considered geometries are identified. These optimal antennas are further compared by considering various practical aspects.

The rest of the paper is organized as follows. Section II defines the considered geometries, simulation models, and optimization setups. Section III presents results of the single-frequency optimization. Section IV compares antennas obtained by the optimization in a frequency range. Finally, section V concludes the paper.

II. Geometries, Simulation Models, and Optimization Setup

The typical geometry of nonuniform helical antennas is shown in Fig. 1. The geometry of the helical antenna is defined by the turn radius, *r*, the pitch angle, φ (or pitch, *p*), and the overall axial antenna length, *L*. The conductor is considered to be a wire with a circular cross-section of the radius r_{w}, which is uniform along the conductor.

In this paper we consider three classes of geometries of nonuniform helical antennas.

The first class are helical antennas with linearly varying geometrical parameters (LG). The turn radius and the pitch angle are linear functions of the axial coordinate ($0 \le z_k \le L_k$):

$$r = (r_{k+1} - r_k)\frac{z_k}{L_k} + r_k\,,\ \varphi = (\varphi_{k+1} - \varphi_k)\frac{z_k}{L_k} + \varphi_k\,, \qquad (1)$$

where $k = 1$ and $L_1 = L$. Parameters r_1 and r_2 are the radii of the first and the last turn, and φ_1 and φ_2 are the pitch angles of the first and the last turn, respectively. During the optimization, the parameters r_1, r_2, φ_1, and φ_2 serve as the optimization variables.

The second class are helical antennas whose geometrical parameters have piecewise-linear variations (PWLG). We primarily focus on antennas that consist of three linear segments. Each segment is defined in a similar way as in (1). Hence, the radius and the pitch angle of each turn can be calculated from (1), where *k* is the index of the segment, $k \in \{1,2,3\}$. The optimization variables are r_j and φ_j, $j \in \{1,2,3,4\}$. In addition, we optimize the axial length of the two lower linear segments, whereas the length of the third segment is $L_3 = L - L_1 - L_2$, where L_1, L_2, and L_3 are the axial lengths of segments (Fig. 1).

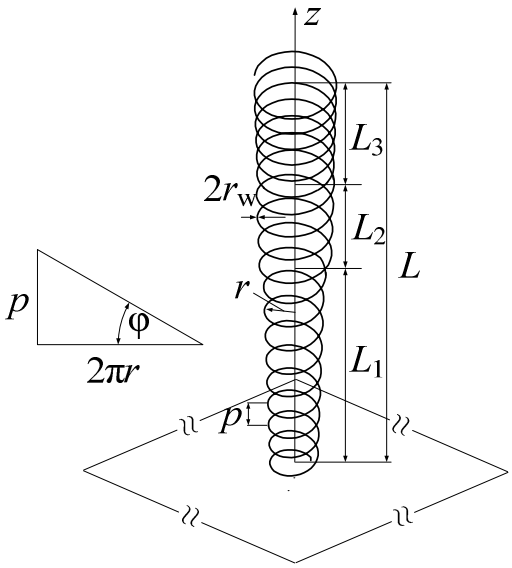

Fig. 1. Sketch of nonuniform helical antenna.

The third considered class of helical antennas are those with exponential variation of geometrical parameters (EG). The turn radius and the pitch angle are exponential functions of the axial coordinate (*z*):

$$r = A_{\mathrm{r}} + B_{\mathrm{r}}\mathrm{e}^{C_{\mathrm{r}}z}\,,\ \varphi = A_{\varphi} + B_{\varphi}\mathrm{e}^{C_{\varphi}z}\,, \qquad (2)$$

where $A_{\mathrm{r}} = r_1 - B_r$, $B_{\mathrm{r}} = (r_2 - r_1)/\left(\mathrm{e}^{C_{\mathrm{r}}L} - 1\right)$,

Jelena Dinkić, Dragan Olćan, and Antonije Đorđević are with the School of Electrical Engineering, University of Belgrade, 73 Bulevar kralja Aleksandra, P.O. Box 35-54, 11120 Belgrade, Serbia (e-mail: jdinkic@etf.bg.ac.rs, olcan@etf.bg.ac.rs, and edjordja@etf.bg.ac.rs).

$A_\varphi = \varphi_1 - B_\varphi$, and $B_\varphi = (\varphi_2 - \varphi_1)/\left(\mathrm{e}^{C_\varphi L} - 1\right)$. In this case, the optimization variables are r_1, r_2, φ_1, φ_2 (the same variables as defined for LG antennas), with additional variables C_r and C_φ.

All simulations are performed in software WIPL-D [9]. Since WIPL-D can analyze only straight-line wire segments, in order to reduce the computation time, we approximate perfectly circular turns with square turns as described in [10]. Since the focus of this paper is on the design of the helical conductor, and not on the design of the ground plane, all considered antennas are located above an infinite perfectly conducting ground plane. All antennas are fed by a generator located on a short vertical wire segment between the ground plane and the helical conductor.

Parameters for the three antenna geometries are optimized in order to maximize the partial gain [11] for the circular polarization at a single frequency or in a frequency range.

A two-step optimization is performed. The reliable choice for this optimization is PSO [12]–[13] followed by Nelder-Mead simplex [14], as indicated in [15]. For the linearly and the exponentially varying geometrical parameters, we implement PSO with 2000 iterations, followed by Nelder-Mead simplex with 200 iterations launched form the best found PSO solution. For the antenna with piecewise-linear variations of the geometrical parameters, 5000 PSO iterations are followed by 200 Nelder-Mead simplex iterations.

For the optimization in the frequency range, the same combinations of optimization algorithms are utilized, but they are repeated five times. The best solution of those five independent optimizations is taken to be the optimal solution.

Simulations and optimizations are performed on a PC (Intel Core i5-4690 processor). Typically, the single-frequency simulation lasts around 0.3 s, whereas the simulation in the considered frequency range lasts around 1 s. The results presented in this paper are obtained from the optimizations that contain around 500000 electromagnetic (EM) solver calls.

III. Single-Frequency Optimization

Firstly, the optimization for each geometry is performed at a single frequency, 300 MHz. The overall axial antenna length is $L = 3\lambda$, where λ is the wavelength at the operating frequency ($\lambda \approx 1\,\mathrm{m}$), and the conductivity of the wire conductor is $\sigma = 58\,\mathrm{MS/m}$ (copper). The models of the optimal antennas are shown in Fig. 2. Although the optimization is performed at a single frequency, in Fig. 3 the gain of the optimal antennas is presented in a frequency range in order to illustrate the frequency response. The gain of the LG and EG antennas at 300 MHz is 0.5 dB lower than the gain of the PWLG antenna. However, the PWGL antenna has a sharp maximum of the gain at 300 MHz, while the gain of the LG and EG antennas is a smooth function of frequency. In practice, this can be critical due to the tolerances in manufacturing because the frequency response of PWGL antenna may shift.

From the practical point of view, an important characteristic is the overall length of the wire conductor, which was not taken into the account during the optimization because it is of a secondary interest. With respect to this criterion, the PWLG antenna has the shortest conductor length (27.63 λ), whereas the LG and the EG antennas require longer conductors (39.02 λ and 33.50 λ, respectively). Note from Fig. 2 that the optimal LG antenna has significantly more turns at the lower end of the antenna compared to the PWLG and EG antennas.

However, the bandwidth of the PWLG antenna is significantly narrower than for the LG and EG antennas, which makes this comparison somewhat unfair.

For those reasons, we perform optimization in a frequency range with the aim to obtain as high as possible gain in a reasonable frequency range. Since the discrepancies of the gain are significant at higher frequencies, instead of the frequency range symmetrically positioned around the operating frequency, the frequency range considered during the optimization is slightly shifted towards higher frequencies.

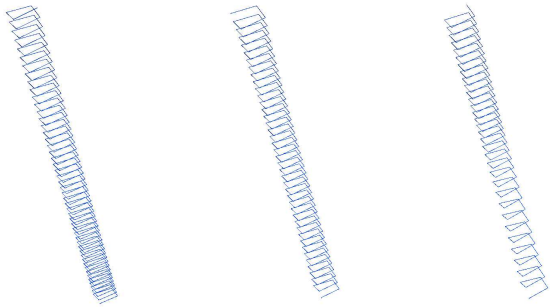

Fig. 2. Models of the optimal antennas (single-frequency optimization) whose geometrical parameters are (a) linear, (b) exponential, and (c) piecewise-linear functions of axial coordinate.

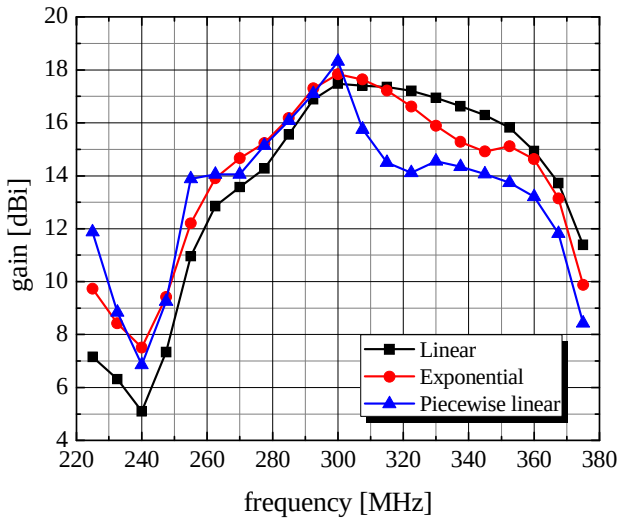

Fig. 3. Gain of the optimal antennas (single-frequency optimization).

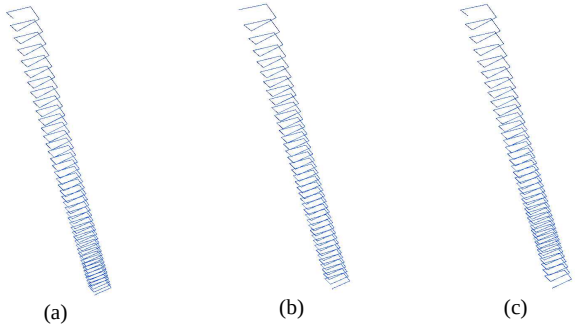
IV. Optimization in Frequency Range

For the optimization in a frequency range, we consider seven equidistantly spaced frequencies within the range from 280 MHz to 340 MHz. For each frequency, we calculate the partial gain for the circular polarization. The cost function is the arithmetic mean of the cost functions

calculated at each considered frequency in the same way as for the optimization at a single frequency.

We perform optimization in the frequency range for the same antenna axial length as in the previous section ($L = 3\lambda$, where λ is the wavelength at 300 MHz), and the wire conductivity is $\sigma = 58\,\mathrm{MS/m}$.

The optimal antennas for all considered geometries are shown in Fig. 4. The gain and the axial ratio of those antennas are presented in Fig. 5. Small differences between the antennas shown in Fig. 2 and Fig. 4 can be noticed. The conductor lengths of the antennas shown in Fig. 4a, b, and c are 34.88 λ, 31.79 λ, and 32.97 λ, respectively. These total wire lengths differ for less than 10 % among each other. It can be seen from Fig. 4 that all considered geometries have more densely spaced turns and smaller turn radii near the feeding point, compared to the end of antenna.



(a) (b) (c)

Fig. 4. Models of the optimal antennas (optimization in frequency range) whose geometrical parameters are (a) linear, (b) exponential, and (c) piecewise-linear functions of axial coordinate.

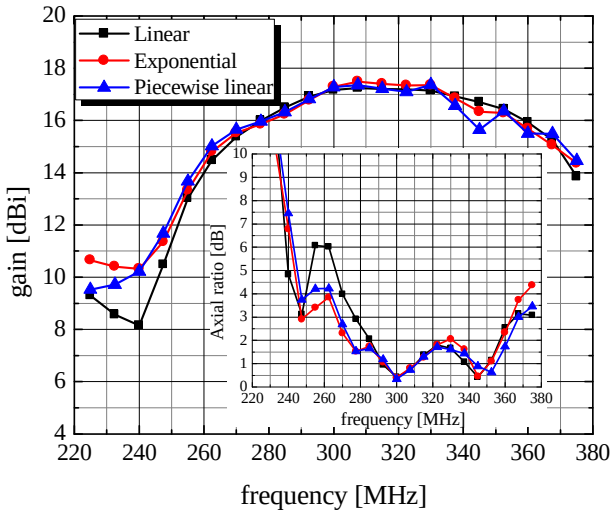


Fig. 5. Gain and axial ratio of the optimal antennas (optimization in frequency range).

Obviously, the optimization performed in a frequency range resulted in a wider bandwidth. However, this improvement is accompanied in some cases with degradation of other characteristics. The optimal antennas achieve practically the same gain from 260 MHz to 330 MHz, regardless of the geometry (the gain differs for less than 0.5 dB in the whole considered frequency range and for all considered antennas). Further, from Fig. 6 it can be noticed that the PWLG antenna optimized in a frequency range achieves around 1 dB lower gain at 300 MHz then the PWLG antenna optimized at a single frequency, and its wire conductor is around 20% longer. For the EG antenna the decrease of the gain at 300 MHz is around 0.5 dB, but the wire conductor is slightly shorter and the bandwidth is wider. In case of the LG antenna, the optimization in a frequency range results in a slightly wider bandwidth and shorter conductor, accompanied with a small decrease of the gain at 300 MHz (0.3 dB).

The high gain at 300 MHz and short conductor are the main advantages of the PWLG antennas optimized at a single frequency. However, those advantages are not present in case of the PWLG antennas optimized in a frequency range.

Hence, the following investigation for various antenna axial lengths will be performed only for LG and EG antennas because their geometry is simpler. Hence, they require fewer optimization parameters and allow easier fabrication.

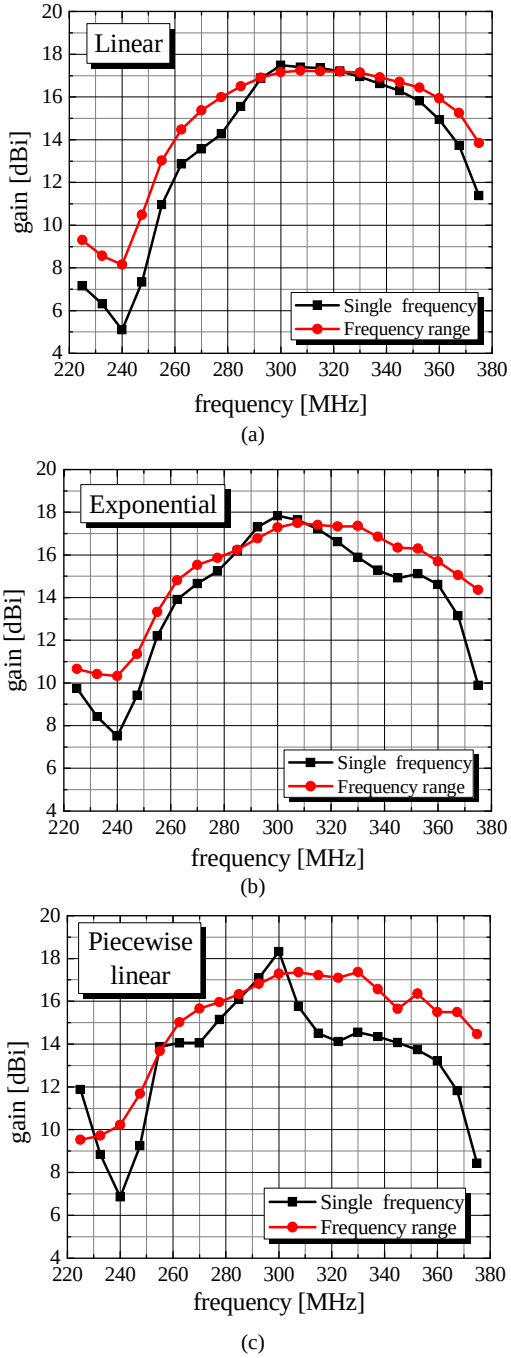

Fig. 6. Gain of the optimal (a) LG, (b) EG, and (c) PWLG antenna optimized at single frequency and in frequency range.

Optimization in a frequency range for the LG and the EG antennas is performed for different axial antenna lengths (2 λ, 2.5 λ, 4 λ, and 5 λ). Fig. 7 compares the gain of those antennas for each axial length, whereas Table I lists the lengths of the wire conductors for the considered antennas. The optimal EG antennas achieve a slightly higher gain at the operating frequency (300 MHz), especially for longer antennas (around 0.15 dB). For shorter antennas ($L \leq 3\lambda$) the optimal EG antennas also require shorter wire conductors than the optimal LG antennas. However, for longer antennas the situation is reversed.

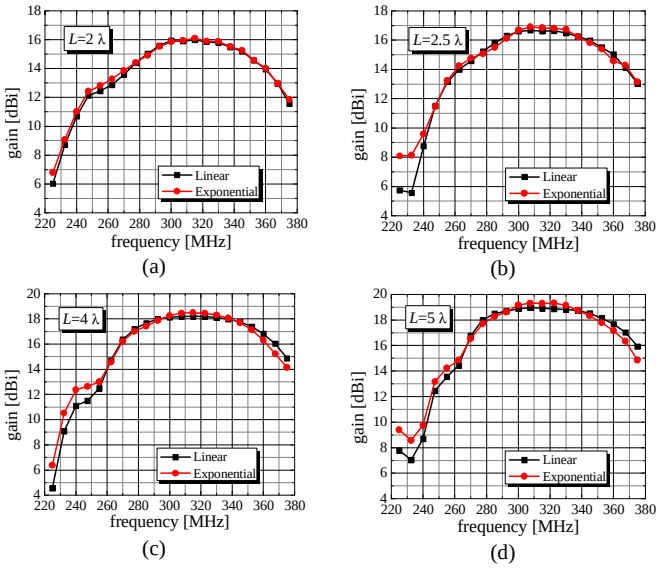

Fig. 7. Gain of the optimal antennas optimized in frequency range: (a) L=2 λ, (b) L=2.5 λ, (c) L=4 λ, and (d) L=5 λ.

TABLE I
CONDUCTOR LENGTHS AND MAXIMAL GAIN OF OPTIMAL ANTENNAS

L	LG antennas		EG antennas	
	conductor length	max gain [dBi]	conductor length	max gain [dBi]
2 λ	26.7 λ	16.0	26.7 λ	16.1
2.5 λ	31.8 λ	16.7	31.2 λ	16.9
3 λ	34.9 λ	17.2	31.8 λ	17.5
4 λ	44.0 λ	18.2	45.8 λ	18.5
5 λ	53.2 λ	19.0	54.9 λ	19.3

V. CONCLUSION

In this paper various geometries of nonuniform helical antennas are investigated and compared. It is shown that the optimization at a single frequency yields antennas with linearly-varying geometrical (LG) parameters that are reasonably broadband. The bandwidth of antennas whose geometrical parameters have exponential (EG) and piecewise-linear (PWLG) variations is narrower, although the gain is slightly higher. The optimization in a frequency range broadens the bandwidth, but the gain of all antennas is almost equal. Further, electrically shorter EG antennas require shorter conductors than LG antennas. However, for electrically longer antennas the situation is reversed. The results presented in this paper impose the conclusion that the optimization in a frequency range aimed at maximizing the partial gain should also include the conductor length into the cost function, with an appropriate weight, in order to increase the gain, but also to keep the required conductor length as short as possible, which is of practical interest. That optimization will be the scope of our future work.

Two-dimensional Green's function for the Truncated Wedge in Terms of an Improper Integral

Dragan Filipović, Tatijana Dlabač

***Abstract*—In this paper two-dimensional Green's function for the truncated wedge is derived by separation of variables in Laplace's equation in cylindrical coordinates. The sign of the separation constant is chosen so as to exclude periodical particular solutions (harmonics). Hence, Green's function is sought in the form of an improper integral (which is essentially a summation of continual harmonics). An unknown function in the integral is found from the boundary conditions, and the integral itself, although rather complex, is found in a closed form. This method is in contrast with the conventional one, where Green's function involves an infinite summation of discrete harmonics.**

***Index Terms*—Green's function, truncated wedge, improper integral.**

I. Introduction

SEPARATION of variables in Laplace's equation is a standard way for determining two-dimensional Green's function for various cylindrical domains [1] – [3]. Usually, the sign of the separation constant is chosen so as to make some of the particular solutions (harmonics) periodic and Green's function is obtained in the form of an infinite summation of discrete harmonics.

However, it is quite legitimate to choose the separation constant with the opposite sign which gives rise to nonperiodical harmonics. In this case it is not possible to find Green's function in the form of an infinite summation and a representation in the form of an improper integral (essentially an infinite summation of continual harmonics) is used instead.

As an example of the latter, less conventional approach, two-dimensional Green's function for the truncated wedge is derived in the present paper. The involved integral is found in a closed form yielding Green's function in the same closed form, as obtained in [4] by the conventional way.

II. Two possible ways of separating variables in two-dimensional Laplace's equation in cylindrical coordinates

Separation of variables in two-dimensional Laplace's equation in cylindrical coordinates leads to two equations

$$\frac{r}{R}\frac{\partial}{\partial r}\left(r\frac{\partial R}{\partial r}\right)=\lambda \tag{1}$$

$$\frac{1}{\Theta}\frac{\partial^2\Theta}{\partial\theta^2}=-\lambda\,, \tag{2}$$

where λ is the separation constant, and $R(r)$ and $\Theta(\theta)$ constitute the potential, i.e.

$$V(r,\theta)=R(r)\cdot\Theta(\theta)\,.$$

Let $\lambda=k^2$ be positive. Then, the particular solutions of (1)–(2) are $r^{\pm k}$ (radial harmonics) and cos$k\theta$, sin$k\theta$ (angular harmonics), and the potential is sought in the form of an infinite summation of these (discrete) harmonics

$$V(r,\theta)=\sum_k\left(A_k r^k+B_k r^{-k}\right)\left(C_k\cos k\theta+D_k\sin k\theta\right),$$

where the unknown coefficients are determined from boundary conditions.

It is instructive to see how the potential looks quite different if the separation constant is chosen to be negative $(\lambda=-k^2)$ The particular solutions of (1) - (2) in this case are sin(k·ln$r$), cos(k·ln$r$) (radial harmonics) and sh$k\theta$, ch$k\theta$ (angular harmonics) (see Appendix A for a derivation of the radial harmonics). Neither of these harmonics is a periodical function, hence it is impossible to find the potential in the form of an infinite summation. Instead, we seek for a solution in the form of an improper integral, which is essentially an infinite summation of continual (in $k\in(0,\infty)$) harmonics, defined above. Thus, the potential should have the form

$$V(r,\theta)=\int_0^\infty\left[A(k)\,\mathrm{sh}k\theta+B(k)\,\mathrm{ch}k\theta\right]$$
$$\cdot\left[C(k)\cos(k\ln r)+D(k)\sin(k\ln r)\right]dk\,.$$

Note that the unknown coefficients with the harmonics are now functions to be determined from boundary conditions.

III. Two-dimensional Green's function for the truncated wedge in the form of an improper integral

Let there be given a cylindrical domain whose cross-section is a truncated wedge of radius R and angle α. By definition, Green's function is the potential at the point (r, θ), produced by the unit line charge running parallel and passing through the point (r', θ'), provided the boundary is kept at zero potential. The wedge is partitioned into two

Dragan Filipović is with the Faculty of Electrical Engineering, University of Montenegro, Dzordza Vasingtona bb, 81000 Podgorica, Montenegro (e-mail: draganf@ucg.ac.me).

Tatijana Dlabač is with the Faculty of Maritime Studies, University of Montenegro, Dobrota 36, 85330 Kotor, Montenegro (e-mail: tanjav@ucg.ac.me).

subdomains by the surface $\theta = \theta'$ (Fig. 1).

As stated in the previous section, the potentials in subdomains 1 and 2 can be sought in the forms

$$V_1(r,\theta) = \int_0^\infty A(k)\,\mathrm{sh}k\theta \sin\left(k\ln\frac{r}{R}\right)dk\,,\ \theta \le \theta'\,, \qquad (3)$$

$$V_2(r,\theta) = \int_0^\infty B(k)\,\mathrm{sh}\,k(\alpha-\theta)\sin\left(k\ln\frac{r}{R}\right)dk,\ \theta \ge \theta'\,, \qquad (4)$$

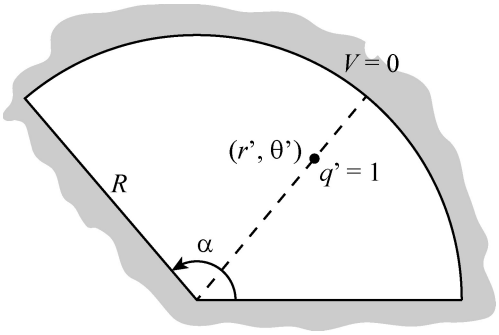

Fig. 1. Truncated wedge with unit line charge partitioned into two subdomains

which ensure that the boundary conditions are met (V_1=0 for θ=0 and r=R, V_2=0 for θ=α and r=R). In (3) – (4) $A(k)$ and $B(k)$ are unknown functions that should be determined.

Continuity of the potential requires V_1=V_2 for $\theta = \theta'$, whence

$$B(k) = A(k)\frac{\mathrm{sh}k\theta'}{\mathrm{sh}k(\alpha-\theta')},$$

and

$$V_2(r,\theta) = \int_0^\infty A(k)\frac{\mathrm{sh}k\theta'}{\mathrm{sh}k(\alpha-\theta')}\mathrm{sh}k(\alpha-\theta)\sin\left(k\ln\frac{r}{R}\right)dk\,. \quad (5)$$

The unknown function $A(k)$ in (3) and (5) can be determined from the boundary condition for the normal components of the electric field at the interface $\theta = \theta'$

$$\frac{1}{r}\left(\frac{\partial V_1}{\partial\theta} - \frac{\partial V_2}{\partial\theta}\right)_{\theta=\theta'} = \frac{1}{\varepsilon_o}\cdot\delta(r-r')\,, \qquad (6)$$

where the δ - function accounts for the presence of the unit line charge at the point (r', θ'). Some properties of the δ – function used below are listed in Appendix B. By using (3) and (5), after some elementary manipulations (6) becomes

$$\frac{1}{r}\int_0^\infty kA(k)\frac{\mathrm{sh}k\alpha}{\mathrm{sh}k(\alpha-\theta')}\sin\left(k\cdot\ln\frac{r}{R}\right)dk = \frac{1}{\varepsilon_o}\cdot\delta(r-r')\,. \quad (7)$$

Next, we multiply (7) by $\sin(m\ln\frac{r}{R})$, m>0 and integrate with respect to r from 0 to R. Then, after interchanging the order of integration (7) is transformed into

$$\int_0^\infty kA(k)\frac{\mathrm{sh}\,k\alpha}{\mathrm{sh}\,k(\alpha-\theta')}\left(\int_0^R \frac{\sin(k\ln\frac{r}{R})\sin(m\ln\frac{r}{R})}{r}dr\right)dk = \quad (8)$$
$$= \frac{1}{\varepsilon_0}\sin(m\ln\frac{r'}{R})\,.$$

The inner integral in (8) can be expressed in terms of the δ function by the change of variables $\ln\frac{r}{R} = u$

$$\int_0^R \frac{\sin\left(k\ln\frac{r}{R}\right)\sin\left(m\ln\frac{r}{R}\right)}{r}dr = \int_{-\infty}^0 \sin ku\sin mu\ du =$$
$$= \frac{1}{2}\int_{-\infty}^\infty \sin ku\sin mu\ du = \quad (9)$$
$$= \frac{1}{4}\int_{-\infty}^\infty\left[\cos(k-m)u - \cos(k+m)u\right]du =$$
$$= \frac{1}{2}\pi\left[\delta(k-m) - \delta(k+m)\right].$$

When (9) is substituted into (8), we obtain

$$m\cdot A(m)\frac{\mathrm{sh}\,m\alpha}{\mathrm{sh}\,m(\alpha-\theta')}\frac{\pi}{2} = \frac{1}{\varepsilon_o}\cdot\sin\left(m\cdot\ln\frac{r'}{R}\right),$$

whence

$$A(k) = \frac{2}{\pi\varepsilon_0}\cdot\frac{\mathrm{sh}\,k(\alpha-\theta')}{k\cdot\mathrm{sh}k\alpha}\cdot\sin\left(k\cdot\ln\frac{r'}{R}\right), \qquad (10)$$

and the potentials (3) and (5) become

$$V_1(r,\theta) = V_1(r,r',\theta,\theta') =$$
$$= \frac{2}{\pi\varepsilon_0}\int_0^\infty \frac{\mathrm{sh}\,k(\alpha-\theta')}{k\ \mathrm{sh}\,k\alpha}\sin(k\ln\frac{r'}{R})\mathrm{sh}\,k\theta\,\sin(k\ln\frac{r}{R})dk\,, \quad (11)$$
$$V_2(r,\theta) = V_2(r,r',\theta,\theta') =$$
$$= \frac{2}{\pi\varepsilon_0}\int_0^\infty \frac{\mathrm{sh}\,k\theta'}{k\ \mathrm{sh}\,k\alpha}\sin(k\ln\frac{r'}{R})\mathrm{sh}\,k(\alpha-\theta)\sin(k\ln\frac{r}{R})dk\,. \quad (12)$$

Equations (11) – (12) constitute Green's function for the considered domain

$$G(r,r';\theta,\theta') = \begin{cases} V_1(r,r',\theta,\theta'), & \theta \le \theta' \\ V_2(r,r',\theta,\theta'), & \theta \ge \theta' \end{cases}$$

It can be observed from (11) – (12) that V_2 is obtained from V_1 by interchanging θ and θ', so that V_1 suffices to describe Green's function

$$G(r,r';\theta,\theta') = \begin{cases} V_1(r,r',\theta,\theta'), & \theta \le \theta' \\ V_1(r,r',\theta',\theta), & \theta \ge \theta' \end{cases} \quad (13)$$

IV. Green's function in an explicit closed form

The integral in (11) can be found in a closed form. This is done in Appendix C; here we state the result

$$\int_0^\infty \frac{\operatorname{sh} k(\alpha-\theta')}{k \operatorname{sh} k\alpha} \sin\left(k \ln\frac{r'}{R}\right) \operatorname{sh} k\theta \sin\left(k \ln\frac{r}{R}\right) dk = \\ = \frac{1}{8} \ln\left[\frac{\operatorname{ch}\left(\frac{\pi}{\alpha}\ln\frac{r}{r'}\right) - \cos\left(\frac{\pi}{\alpha}(\theta+\theta')\right)}{\operatorname{ch}\left(\frac{\pi}{\alpha}\ln\frac{r}{r'}\right) - \cos\left(\frac{\pi}{\alpha}(\theta-\theta')\right)} \cdot \right. \\ \left. \cdot \frac{\operatorname{ch}\left(\frac{\pi}{\alpha}\ln\frac{r\cdot r'}{R^2}\right) - \cos\frac{\pi}{\alpha}(\theta-\theta')}{\operatorname{ch}\left(\frac{\pi}{\alpha}\ln\frac{r\cdot r'}{R^2}\right) - \cos\frac{\pi}{\alpha}(\theta+\theta')} \right]. \quad (14)$$

Interchanging θ and θ' does not affect (14), hence $V_2(r,r',\theta,\theta') = V_1(r,r',\theta',\theta) = V_1(r,r',\theta,\theta')$ and from (11), (13) – (14), Green's function is

$$G(r,r',\theta,\theta') = \frac{1}{4\pi\varepsilon_0} \ln\left[\frac{\operatorname{ch}\left(\frac{\pi}{\alpha}\ln\frac{r}{r'}\right) - \cos\left(\frac{\pi}{\alpha}(\theta+\theta')\right)}{\operatorname{ch}\left(\frac{\pi}{\alpha}\ln\frac{r}{r'}\right) - \cos\left(\frac{\pi}{\alpha}(\theta-\theta')\right)} \cdot \right. \\ \left. \cdot \frac{\operatorname{ch}\left(\frac{\pi}{\alpha}\ln\frac{r\cdot r'}{R^2}\right) - \cos\frac{\pi}{\alpha}(\theta-\theta')}{\operatorname{ch}\left(\frac{\pi}{\alpha}\ln\frac{r\cdot r'}{R^2}\right) - \cos\frac{\pi}{\alpha}(\theta+\theta')} \right].$$

This result is identical to the one obtained in [4] by summing an infinite series in a closed form.

V. Conclusion

This paper presents a derivation of two-dimensional Green's function for the truncated wedge. Two-dimensional Laplace's equation is solved by separating variables in cylindrical coordinates. The sign of the separation constant is chosen so that no periodical harmonics exist which makes an improper integral a suitable form for Green's function, contrary to the conventional summation form. The integral which determines Green's function is found in a closed form

Appendix A

For $\lambda = k^2$ (1) becomes

$$r^2 \cdot R_r'' + r \cdot R_r' + k^2 R = 0 . \quad (A1)$$

The change of variables $r = e^t$ transforms (A1) into

$$R_t'' + k^2 R = 0 ,$$

with particular solutions cos(*kt*) and sin(*kt*). Therefore, the radial harmonics, i.e. the solutions of (A1) are cos(*k*·ln*r*) and sin(*k*·ln*r*).

Appendix B

In deriving (8) – (10) we used the following properties of the δ - function [5]

$$\int_a^b f(x)\,\delta(x-x')dx = \begin{cases} f(x'), x' \in (a,b) \\ 0, x' \in (-\infty,a) \cup (b,+\infty) \end{cases}$$

and

$$\delta(x) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} \cos xt\, dt = \frac{1}{\pi}\int_{-\infty}^{0} \cos xt\, dt = \frac{1}{\pi}\int_0^{+\infty} \cos xt\, dt .$$

Appendix C

To evaluate the integral in (11), we start from [6]

$$F(A,B,C) = \int_0^\infty \frac{\operatorname{sh} Ax \cdot \operatorname{sh} Bx}{x \operatorname{sh} Cx} dx = \frac{1}{2} \ln \frac{\cos\frac{\pi}{2C}(A-B)}{\cos\frac{\pi}{2C}(A+B)}, \quad (C1)$$

where

$$A + B < C .$$

The next step is evaluation of

$$G(A,B,C,D) = \int_0^\infty \frac{\operatorname{sh} Ax \cdot \operatorname{sh} Bx}{x \cdot \operatorname{sh} Cx} \cos Dx\, dx = \\ = \operatorname{Re} \int_0^\infty \frac{\operatorname{sh} Ax \cdot \operatorname{sh}(B + jD)}{x \cdot \operatorname{sh} Cx} dx = \operatorname{Re} F(A, B + jD, C) .$$

By using (C1) we readily find

$$G(A,B,C,D) = \frac{1}{4} \ln \frac{\operatorname{ch}\frac{\pi D}{C} + \cos\frac{\pi}{C}(A-B)}{\operatorname{ch}\frac{\pi D}{C} + \cos\frac{\pi}{C}(A+B)} . \quad (C2)$$

Finally, the integral in (11)

$$I(A,B,C,D,F) = \int_0^\infty \frac{\operatorname{sh} Ax \cdot \operatorname{sh} Bx}{x \cdot \operatorname{sh} Cx} \sin Dx \cdot \sin Fx \cdot dx ,$$

with $A = \alpha - \theta'$, $B = \theta$, $C = \alpha$, $D = \ln\frac{r}{R}$ and $F = \ln\frac{r'}{R}$ is evaluated by using the identity $\sin Dx \cdot \sin Fx = \\ = \frac{1}{2}\left[\cos(D-F)x - \cos(D+F)x\right]$ and (C2)

$$I(A,B,C,D,F)=\frac{1}{2}\left[G(A,B,C,D-F)-G(A,B,C,D+F)\right]=$$

$$=\frac{1}{8}\ln\left[\frac{\mathrm{ch}\left(\frac{\pi}{\alpha}\ln\frac{r}{r'}\right)+\cos\left(\frac{\pi}{\alpha}(\theta+\theta')\right)}{\mathrm{ch}\left(\frac{\pi}{\alpha}\ln\frac{r}{r'}\right)+\cos\left(\frac{\pi}{\alpha}(\theta-\theta')\right)}\cdot\right.$$

$$\left.\cdot\frac{\mathrm{ch}\left(\frac{\pi}{\alpha}\ln\frac{r\cdot r'}{R^2}\right)+\cos\frac{\pi}{\alpha}(\theta-\theta')}{\mathrm{ch}\left(\frac{\pi}{\alpha}\ln\frac{r\cdot r'}{R^2}\right)+\cos\frac{\pi}{\alpha}(\theta+\theta')}\right].$$

On Efficient Evaluation of Pole-Free Sommerfeld Integrals

Nikola Basta and Branko Kolundžija, *Fellow, IEEE*

***Abstract*—An approach to computation of pole-free Sommerfeld integrals is proposed using the example of free-space Green function in lossless media. Besides the cancellation of the branch-point singularity based on a change of variables, the proposed approach includes optimal choice of the lower endpoint of the tail subdomain and definition of thresholds that improve accuracy and efficiency of tail-integral evaluation. Additionally, formulas for estimation of the required number of integration points for given accuracy are given. The presented techniques are verified through numerical examples with large range of source-observer distances.**

***Index Terms*—Sommerfeld integral; free space; Green's function;**

I. Introduction

THE increasing demand for accurate solving of large-scale electromagnetic scenarios, e.g. in [1]–[2] calls for further investigation of strategies that address computation of the Sommerfeld integrals (SIs) [3]–[5] for a wide range of source-observer distances. Sommerfeld integrals are important tool for computation of the electromagnetic field in the presence two or more layered materials.

The associated integrands are singular, oscillatory and slow decaying, which makes the evaluation of the SIs demanding. In this work, we focus on numerical computation of SIs [6]–[13] for a large range of source-observer distances, from 10^{-3} to 10^{3} free-space wavelengths. Typically, the singularities, i.e. poles and branch points, are circumvented by integrating over a deformed path [6]–[10], [14], [15]. In this study, integration over the real-axis is applied [6], [16] due to its simplicity, robustness and resistance to the problem of high-valued Bessel function of complex argument [13]. Since the numerical treatment of the poles close to the integration path is well covered in the literature [6], [7], [13], our intention here is to consider thoroughly the branch-point singularities [16], [17]–[19], the effect of which has shown to be significant in numerous cases of interest, e.g. low-loss materials in the form of microwave dielectric laminates or weakly conductive earth. The proposed technique for cancellation of the branch-point singularity relies on a square-root change of variables.

Once the integrand is freed of singularities, the question of calculation of the semi-infinite integral tail remains. The position of the tail beginning can be important for the efficiency of the evaluation and related to the treatment of branch points, yet we were unable to find precise guidelines for its choice [9]–[12]. Therefore, expressions for optimal choice of the lower endpoint of the tail subdomain and of the threshold for tail truncation are proposed.

Not much work has been dedicated to construction of formulas that predict minimum number of integration points for requested accuracy, which is important for efficient evaluation of SIs, particularly for large source-observer distances. We propose simple formulas for estimation of required number of integration points for given accuracy.

Since the key numerical properties of the SIs remain the same regardless of the field component they represent, the techniques established here for the free-space SI can be transferred to other pole-free SIs.

Branko Kolundzija is with the School of Electrical Engineering, University of Belgrade, 73 Bulevar kralja Aleksandra, 11020 Belgrade, Serbia (e-mail: kol@etf.rs).

II. Properties of the Proposed Approach

The particularities of pole-free SIs can be observed fairly through the integral associated to the scalar spherical wave in homogenous free space. Its solution is the well-known free-space Green's function [1], thus the relative error of the numerical evaluation can be calculated precisely. Therefore, we will illustrate our approach by computing integrals of general form

$$I(k_{\rho 1}, k_{\rho 2}; \rho, z) = \int_{k_{\rho 1}}^{k_{\rho 2}} \frac{k_\rho}{\sqrt{k_\rho^{\,2} - k^2}} \mathrm{e}^{-\sqrt{k_\rho^{\,2}-k^2}\,|z|} J_0(k_\rho \rho) \mathrm{d}k_\rho \qquad (1)$$

so that the SI associated to free-space GF can be expressed as

$$I(0, \infty) = \frac{\mathrm{e}^{-\mathrm{j}kr}}{r} = g(r), \qquad (2)$$

where J_0 is the Bessel function of zeroth order, $k = \omega\sqrt{\varepsilon_0 \mu_0} = 2\pi/\lambda$ is the free-space wave number, $r = \sqrt{\rho^2 + z^2}$ and ρ and z are the horizontal and vertical coordinate of the observation point, respectively, as shown in inset of Fig. 1. For purpose of brevity, we have omitted dependence of the integral on ρ and z in (2) and in all further references of (1).

In this work, we apply the Gauss-Legendre (GL) quadrature formula for numerical evaluation of the integral. There are several challenges in numerical evaluation of (2). Besides the singularity at the branch point, $k_\rho = k$, there is also the oscillatory nature of the integrand, due to the Bessel function factor for any k_ρ, and the exponential factor for $k_\rho < k$. The oscillatory nature of the integrand and the fact

that the domain of integration is semi-infinite raise the question of the computation efficiency. To overcome these difficulties, the integral (2) is divided into three parts, i.e., $I(0,\infty) = I_1 + I_2 + T$, where $I_1 = I(0,k)$, $I_2 = I(k,b)$, $T = I(b,\infty)$, and b designates the lower endpoint of the tail. An example of the integrand plot is illustrated for $\rho = 3\lambda$ and $z = 0.05\lambda$ in Fig. 1.

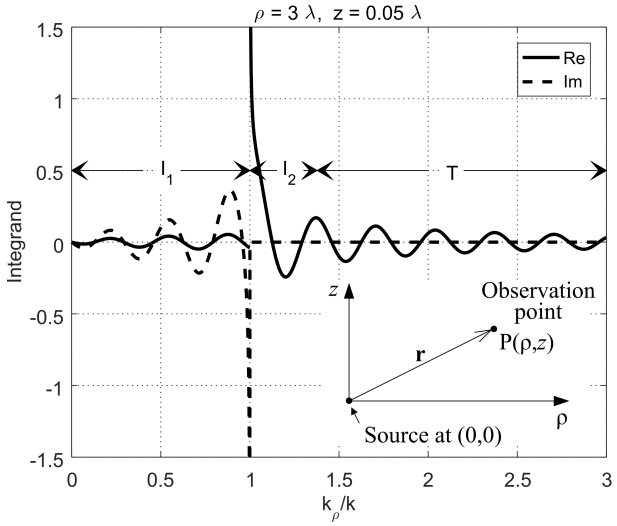

Fig. 1. Example of the integrand function in (1) with decomposition of the problem to three integrals, I_1, I_2 and T, over respective subdomains.

A. Cancellation of branch-point singularity

The integrals over finite subdomains, I_1 and I_2, have a common singular endpoint at $k_\rho = k$, where the integrand is unbounded. For overcoming this branch-point singularity, several techniques can be found in published literature, e.g. [16], [17]–[19]. However, most of these techniques are either too cumbersome or are not robust enough for the large range of source-observer distances that is of interest here.

For an efficient evaluation of I_1 and I_2 we propose a singularity cancellation technique by square-root change of variables $s = \sqrt{k_\rho^2 - k^2}$. If applied to (1), we obtain

$$I(k_{\rho 1}, k_{\rho 2}) = \int_{s_1}^{s_2} \mathrm{e}^{-s|z|} J_0(\rho\sqrt{s^2 + k^2})\mathrm{d}s, \tag{3}$$

where $s_{1,2} = \sqrt{k_{\rho 1,2}^2 - k^2}$. Note that the integrand in (3) is now nonsingular. This enables increase of accuracy and savings of integration points, and therefore of computation time. We notice that in the first subdomain, s is purely imaginary, whereas in the second subdomain, it is purely real. The integration paths before and after the change of variables are presented in the corresponding complex planes in Fig. 2. The singularity $k_\rho = k$ in the k_ρ-plane is mapped to the nonsingular point at the origin, $s = 0$, in the s-plane. It is worth noting that both integrand in (3) and its first derivative are bounded, despite the fact that the argument of the Bessel function, $\rho\sqrt{s^2 + k^2}$, suffers from the first-derivative discontinuity at $s = \mathrm{j}k$.

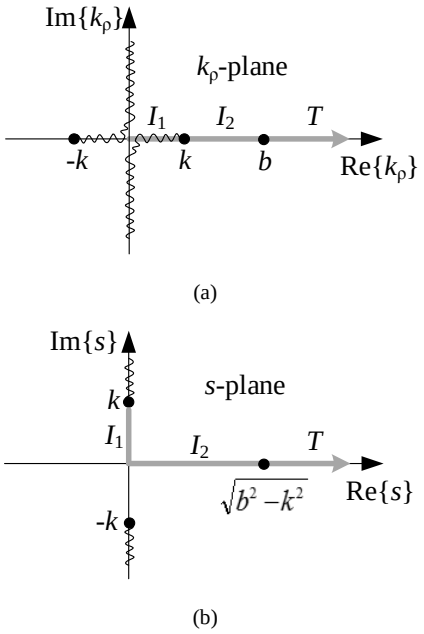

Fig. 2. Integration paths (grey line) and branch cuts (wavy line) for corresponding subdomain integrals in lossless media: (a) In k_ρ-plane, before the change of variables. (b) In s-plane, after the change of variables.

B. Lower endpoint of the tail subdomain

Among the methods for numerical integration of the tail, one can basically distinguish two approaches. The first one is the *integrate-and-sum* approach [11], [12], which proposes dividing the tail domain into equal segments. The partial integrals over these segments represent a series of numbers, the sum of which is to be evaluated. The second approach would be to evaluate the tail integral over the entire semi-infinite subdomain by means of a dedicated quadrature formula, which usually incorporates a variable transformation [6], [16]. In this paper, we adopt the former approach without using any change of variables for the tail. Integral T is approximated as a sequence of partial sums

$$\begin{aligned} T &\approx T_n = \sum_{i=1}^{n} t_i, \\ t_i &= I(b + i\Delta k_\rho, b + (i-1)\Delta k_\rho), \end{aligned} \tag{4}$$

where b is the tail beginning, Δk_ρ is the size of the segments and n is the number of segments. Partial integrals t_i in (4) can be evaluated using the GL quadrature. Depending on the segments' breakpoints, series t_i can be monotonous or alternating, and sequence T_n can converge slower or faster. In an extensive analysis we have considered several series-acceleration techniques: Shanks' transformation, Aitkin's Δ^2 process, Cesàro means [19]–[21] and weighted averages (WA) [11],[23]. The analysis has confirmed, as indicated in [11], [22], [23] that the combination of (i) *half-period* long segments, (ii) placement of breakpoints at the extrema [22], and (iii) application of WA acceleration algorithm is the optimal choice regarding complexity, convergence rate, computational cost and

robustness for a wide range of parameters ρ and z. The WA algorithm is based on a repeated (recursive) linear transformation of the sequence

$$T_n^{(l)} = \frac{T_n^{(l-1)} + \eta_n^{(l-1)} T_{n+1}^{(l-1)}}{1+\eta_n^{(l-1)}}, \qquad \begin{matrix} 1 \le n \le N \\ l = 1,2,...,n-1 \end{matrix} \tag{5}$$

where l is the level of the transformation, coefficient η_n is derived from the asymptotic expansion of the sequence [11] as

$$\eta_n^{(l)} \approx e^{z\pi/\rho}\left(1+\frac{2l}{b\rho/\pi+n}\right) \tag{6}$$

and N is the maximal reached number of segments, n, resulting from a certain accuracy criterion. Thus, the best estimate of the tail integral is $\hat{T} = T_1^{(N-1)}$.

Now, we propose setting b to the *first extremum after the second zero*, exceeding $k_\rho = k$. Note that, with such framework, b depends on ρ, which produces a *floating* endpoint of the tail subdomain. One important advantage of this framework is that the complexity of the integrand over the second subdomain $0 < k_\rho < b$ is kept low, with maximally one full oscillation occurring within. This implies that for given accuracy, small and rather constant number of integration points with respect to ρ will be required for the second subdomain. Additionally, in our experiments such choice of b has proven to be far enough from the branch-point singularity, which leaves the tail convergence unaffected. The extrema of Bessel function can be found approximately in different ways, e.g. through Newton-Raphson's rule or as mean of two neighboring zeros. In our study, we have used the extrema of the large-argument approximation

$$J_0(u) \approx \sqrt{\frac{2}{\pi u}}\cos\left(u-\frac{\pi}{4}\right), \tag{7}$$

thus, obtaining their positions at

$$k_{\rho,ex}(n) \approx b + n\frac{\pi}{\rho}. \tag{8}$$

Finally, the tail beginning is defined as

$$b = \left(\left(\left\lfloor \frac{k\rho}{2\pi} \right\rfloor + 2\right)\pi + \frac{\pi}{4}\right)\frac{1}{\rho}, \tag{9}$$

where $\lfloor \cdot \rfloor$ denotes the *floor* function.

C. Thresholds for truncation of tail integral

With purpose of control and savings in computing resources, we propose placing certain thresholds in the part of the algorithm, which is responsible for the calculation of the tail.

For large ratios z/ρ the coefficient η_n of the WA approach in (6) can reach arbitrarily high values. We, therefore, limit the maximum value of η_n to 10^{10}, thus avoiding working with extremely large numerical dynamic range.

If the ratio z/ρ is moderate or small, a cut-off number of required tail segments needs to be introduced. We use relative error for determination of the cut-off number. This criterion is introduced in a *while loop*, which halts further integration when the desired error level is reached.

However, for large *z*, the exponential factor of the integrand in (1) can be rather small, which allows us to discard the tail segments, the contribution of which is below certain threshold. We have set the threshold for the value of the exponential factor to 10^{-30} and obtained the limit for the tail subdomain

$$k_{\rho,\mathrm{th}} = \sqrt{k^2 + \left(\frac{-30}{|z|\log_{10}\mathrm{e}}\right)^2}. \tag{10}$$

We stress that value $k_{\rho,\mathrm{th}}$ can be smaller or larger than b, which, in former case, allows us to completely discard the tail, thus affecting only the integral of the second part, I_2. That way we save computational resources, which would be otherwise used for summing series of rather small numbers. The integral of the second part changes its limits and is then redefined as $I_2 = I(k, k_{\rho,\mathrm{th}})$.

D. Relative error

If an evaluation of our SI is denoted by A, then the relative error of that evaluation is defined as

$$RF = \frac{|A - A_{\mathrm{ref}}|}{|A_{\mathrm{ref}}|}, \tag{11}$$

where A_{ref} is some reference value. Additionally, we define the number of significant digits with which the evaluation is performed as $\chi = -\log_{10}(RF)$.

We point out that for the error analysis we choose the reference value always to be the total value of the GF, $A_{\mathrm{ref}} = g(r)$, regardless of the subdomain that is being analyzed. This is very important when analyzing the convergence of the tail integral, where very small cut-off number of required segments can be achieved, if the tail turns out to be numerically much less significant than the finite subdomains with respect to $g(r)$.

However, in the computation algorithm itself, the tail truncation is achieved using the relative error with respect to the preceding iteration as criterion function. In that case, the relative error is computed using $A = T_1^{(n)}$ and $A_{\mathrm{ref}} = T_1^{(n-1)}$, where index n designates the number of half-period segments included in the evaluation of the SI, according to (4) and (5).

III. Analysis of Subdomain Partial Integrals

In this section we provide a short overview of qualitative and quantitative properties of the SI in terms of relative error, using GL quadrature formula. For each of the three parts we propose formulas that estimate the required number of integration points for a given accuracy. The space of interest is a 2-D set of distance coordinates, given by $(\rho, z) \in [10^{-3}\lambda, 10^{3}\lambda] \times [10^{-3}\lambda, 10^{3}\lambda] = D$.

A. First subdomain integral

In the first subdomain, where $k_\rho \in [0, k]$, the oscillations occur due to the imaginary nature of the exponent and due to the Bessel function factor in (3). According to (11), the relative error for the first subdomain can be determined for the observable $A(n_{g1}) = \hat{I}_1(n_{g1}) + \tilde{I}_2 + \tilde{T}$, where $\hat{I}_1$ is the evaluation of the integral over the first subdomain, n_{g1} is the number of integration points used and $\tilde{I}_2$ and $\tilde{T}$ are the second subdomain and tail integral evaluations, respectively. Integrals $\tilde{I}_2$ and $\tilde{T}$ are computed with the maximum possible accuracy using enough GL integration points and tail half-periods. In Fig. 3, we show the relative error for the first subdomain with respect to the number of integration points in a subset of D, defined by the line $\rho = z$. In general, we can distinguish three characteristic parts of the relative-error curve: (i) the initial part, where the relative error is larger than one, (ii) the steep (decreasing) part and (iii) the saturation part where some minimal error level ($10^{-16} \div 10^{-10}$) is reached. The slope of the steep part is changing moderately with distance, while the threshold, after which the error starts decreasing abruptly, depends strongly on ρ and z.

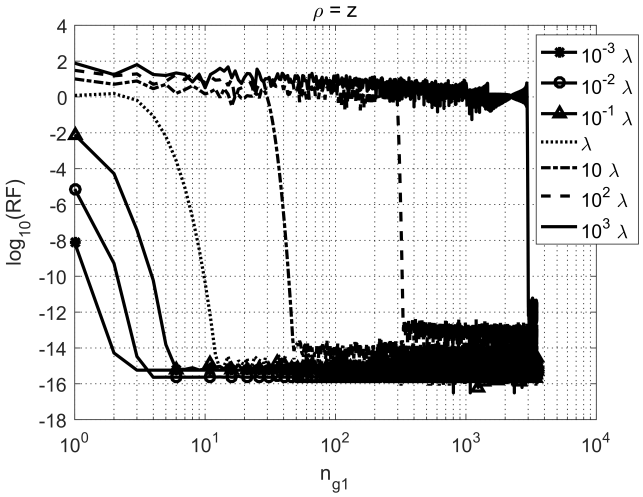

Fig. 3. Relative error of the first subdomain integration vs. number of Gauss-Legendre integration points for different values of ρ (ρ = z).

After a series of simulations and a thorough analysis, we have assembled an empirical expression for estimated number of integration points that is required to reach given accuracy in the first subdomain

$$\hat{n}_{g1} \approx 6 + R_e + \frac{\chi_{\text{desired}}}{3} R_e^{0.3}, \qquad (12)$$

where $R_e = \sqrt{(2.4\rho/\lambda)^2 + (1.8z/\lambda)^2 + 0.4\rho z/\lambda^2}$ and χ_{desired} is the desired number of significant digits.

B. Second subdomain integral

The second subdomain is defined by $k_\rho \in [k, b]$. When the proposed change of variables is applied, we obtain real integrand and real argument. Unlike in the case of the first subdomain, the integrand in the second subdomain changes moderately with respect to k_ρ, but also to s. Parameter ρ dictates the position of breakpoint b, which can impact the size of the subdomain, yet the number of oscillations within is limited, thanks to the floating definition of the breakpoint. On the other hand, parameter z dictates only the damping of the integrand function. For the second subdomain we perform the same error analysis as in previous subsection. We consider the observable $A(n_{g2}) = \tilde{I}_1 + \hat{I}_2(n_{g2}) + \tilde{T}$, and the reference is again $A_{\text{ref}} = g(r)$. Magnitude $\hat{I}_2$ is the evaluated integral over the second subdomain and n_{g2} is the corresponding number of integration points. Integrals $\tilde{I}_1$ and $\tilde{T}$ are computed with the maximum possible accuracy using enough GL integration points and tail half-periods. The plot of the relative error for the second subdomain is given in Fig. 4 for $\rho = z$. We notice that the error characteristic is rather canonical and confined, which implies moderate dependence on distance coordinates within the given set. The error curves can be approximated by a family of slopes which are limited by two extreme cases, roughly determined by $\rho > z$ and $\rho < z$, where the latter case corresponds to the slower convergence.

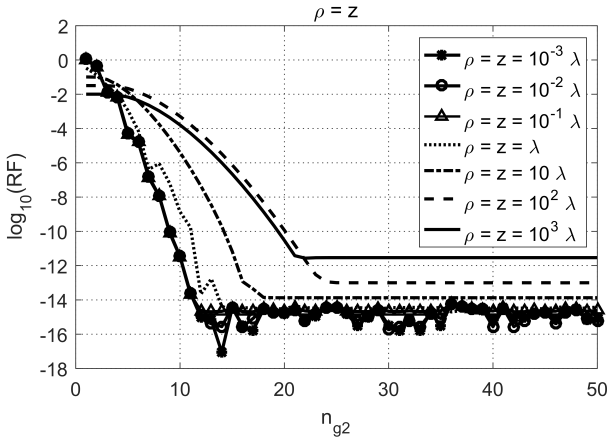

Fig. 4. Relative error of the second subdomain integration vs. number of Gauss-Legendre integration points for different values of ρ (ρ = z).

The numerical nature of the integrand discussed above and performed simulations over D allow us to form an approximate expression for prediction of number of integration points, required for achieving given accuracy in the second subdomain

$$\hat{n}_{g2} \approx \begin{cases} N_1, & \log_{10}\left(\frac{z}{\rho}\right) < B \\ N_1 + (N_2 - N_1)\left(\log_{10}\left(\frac{z}{\rho}\right) - B\right), & \text{elsewhere} \\ N_2, & \log_{10}\left(\frac{z}{\rho}\right) > C \end{cases} \quad (13)$$

where $N_1 = \chi_{\text{desired}} + 3$, $N_2 = N_1 + 10$, $B = -1.2$, and $C = -0.2$. Note in (13) that the two levels, N_1 and N_2, correspond to the slowest and fastest slopes in Fig. 3.

C. Tail subdomain integral

In the tail subdomain, the integrand and, more importantly, the exponent in (1) are real (Fig. 1), making a non-monotonous decreasing function whose damping is dictated by both ρ and z, whereas its oscillation depends exclusively on ρ. For computation of the tail, we do not use any change of variables, but rely on its convergence properties. The tail evaluation is based on partial integrals over half-period segments, yet the shape of the integrand within them is not qualitatively affected by the distance coordinates ρ and z, thus a very weak dependence on the coordinates is expected. However, it should be noted that there is a strong relation to ρ and z in the summation phase of the tail computation, due to their direct impact on the convergence of sequence in (4). Therefore, we propose an expression for approximate number of integration points per half-period that is needed for given accuracy in terms of number of significant digits, χ_{desired}, as

$$\hat{n}_{g,hp} \approx \frac{\chi_{\text{desired}}}{2} + 2. \quad (14)$$

IV. Efficiency of Complete-Domain Integration

In this section we assemble together all three parts of the integral defined in (2) and then look into their total impact on the error level. Based on the analysis in section III, we can fairly predict the required number of integration points for each part, where the number of half-period segments for the tail is automatically determined, for any given error level, RF_{desired}. We will show how well the proposed prediction matches the computation.

In order to verify the algorithm as a whole, we compute the total relative error for given accuracy, RF_{desired}, based on the predicted number of integration points as

$$RF_{\text{tot}}(\rho, z) = \frac{\hat{I}_1(\hat{n}_{g1}) + \hat{I}_2(\hat{n}_{g2}) + \hat{T}(\hat{n}_{g,hp}) - g(r)}{g(r)}. \quad (15)$$

where $\hat{I}_1$, $\hat{I}_2$ and $\hat{T}$ are the respective integral parts obtained by numerical integration, $\hat{n}_{g1}$, $\hat{n}_{g2}$ and $\hat{n}_{g,hp}$ are calculated with empirical equations (12), (13), and (14), respectively. In Fig. 5, the obtained total relative error is shown in the entire set D for $RF_{\text{desired}} = 10^{-10}$. We can see that the error is slightly bellow the desired limit. In Fig. 6 the total estimated number of integration points, $\hat{n}_{g,tot} = \hat{n}_{g1} + \hat{n}_{g2} + N\,\hat{n}_{g,hp}$, is presented with respect to distances, where N is the reached number of tail half-periods. In addition, Fig. 7 shows percentage of the relative difference between the estimated and the exact minimal required number of integration points for the given accuracy,

$$\delta(n_{g,tot})[\%] = 100 \cdot \frac{\hat{n}_{g,tot} - n_{g,tot}}{n_{g,tot}}. \quad (16)$$

It is evident that the estimated number of integration points is only about 10 % higher than the exact number of required points in almost entire space D. The largest error of the estimation occurs in a narrow region where ρ and z are small and of similar values. However, this is not critical, since the required number of integration points in that region is rather low.

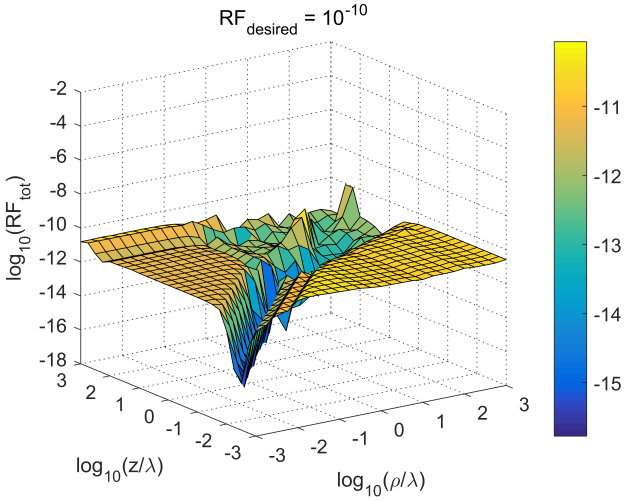

Fig. 5. Total relative error for $RF_{\text{desired}} = 10^{-10}$ vs. normalized ρ and z.

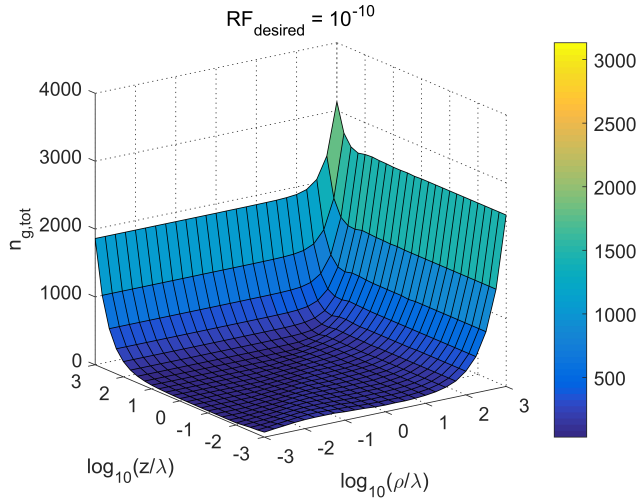

Fig. 6. Total estimated number of integration points for $RF_{\text{desired}} = 10^{-10}$ vs. normalized ρ and z.

We can conclude that for the given change of variables, the proposed equations yield a robust and efficient prediction of

the required number of integration points for free-space SIs.

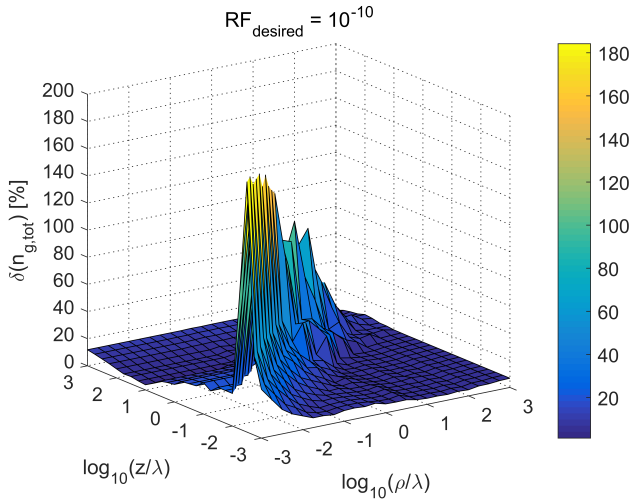

Fig. 7. Relative difference of the estimated and exact required number of integration points vs. normalized ρ and z.

V. Conclusion

A method for computation of pole-free Sommerfeld integrals for a wide range of source-observer distances is presented using the example of free-space Green's function in lossless media. The integral is divided in a standard manner by the branch-point singularity and the lower end point of the tail.

The branch-point singularity is cancelled using a novel variable transform, thus minimizing the number of Gauss-Legendre integration points required for desired accuracy.

The tail beginning is defined as the first extremum after the second zero exceeding the branch point singularity. In this way the tail integral is unaffected by the singularity and the complexity of the second-subdomain integral is kept low. The tail computation relies on the established weighted-averages algorithm that is proven to be very efficient within the given framework. The elements of the number series, to which the weighted-averages method is applied, are partial integrals calculated over intervals defined by the successive extrema, which are simply determined using the sinusoidal large-argument approximation of the Bessel function of the first kind. The definition of thresholds for the weights of the weighted-averages algorithm and for the truncation of the integral provides additional robustness, accuracy and savings of integration points.

Overall, an efficient evaluation of the integral is achieved for a wide range of source-observer distances, up to 1000 free-space wavelengths. Since the Sommerfeld integrals that belong to the same representation have similar numerical properties, the techniques proposed for the free-space case can be transferred to other scenarios, e.g. the half-space problems.

The Influence of Corona on the Lightning Surge Propagation Along Transmission Lines

Milan Ignjatović, Jovan Cvetić and Dragan Pavlović

***Abstract*— Corona is the partial discharge that occurs around the wires and edges in inhomogeneous electric field. Minimum intensity of the electric field for the impact ionization of the gas is around 2.6 MV/m in dry air. In power systems, the corona is the unwanted effect caused by overvoltages. In this study the propagation of the overvoltage wave due to negative lightning along the transmission line is numerically simulated. The effect of the corona is modeled by the drift-diffusion-reaction equations for the electrons, the positive and the negative ions.**

***Index Terms*— Corona, lightning overvoltage, transmission lines, QV curve, streamers**

I. Introduction

THE lightning strike is one of the most common causes of power interruption on transmission lines and substations. Since it is a natural phenomenon, lightning occurrence can not be foreseen, but its performance on power systems can be estimated. The insulation strength is selected to minimize the risk of the failure, taking into account the statistical data of the lightning occurrence in the wider area and the cost of the insulation construction [1]. There are methods to estimate the magnitude and steepness of the average incoming surge that arrives at substations [2].

When the lightning strikes the transmission lines, two initiating events can happen - the shielding failure and the backflash. The shielding failure occurs when the lightning hits the phase conductor directly avoiding the shield wire. If the lightning hits the shield wire, the injected overvoltage can be greater than the critical flashover voltage of the insulation and the backflash occurs.

For the direct lightning strikes the main effect that influence the shape of the overvoltage waveform is the corona. It is a partial discharge that occurs around the conducting wire when the voltage is above the corona inception threshold described by the Peek's formula [3]. The corona effects the delay of the part of the impulse that is above the corona threshold and the attenuation of the overvoltage amplitude due to losses in the ionized gas in the area around the wire.

The main goal of the paper is to numerically simulate the propagation of the overvoltage wave along the transmission line including the corona. The effect of corona is taken into consideration by the drift-diffusion-reaction model which represents the set of the continuity equations for each type of particles (electrons, positive and negative ions, neutrals, etc.) that participate in the discharge. The model enables the inclusion and the analysis of detailed physical and chemical reactions that are taking place in the area around the wire of the transmission line.

Jovan Cvetić is with the School of Electrical Engineering, University of Belgrade, 73 Bulevar kralja Aleksandra, 11020 Belgrade, Serbia (e-mail: cvetic_j@etf.rs).

Dragan Pavlović is with the School of Electrical Engineering, University of Belgrade, 73 Bulevar kralja Aleksandra, 11020 Belgrade, Serbia (e-mail: dragan.lab3@etf.rs).

II. Theory

The equations describing voltage and current along the overhead wire taking into account the effect of corona [4] are

$$\frac{\partial V(t,x)}{\partial x} + L\frac{\partial I(t,x)}{\partial t} = 0, \qquad (1)$$

$$\frac{\partial I(t,x)}{\partial x} + \frac{\partial Q(t,x)}{\partial t} = 0, \qquad (2)$$

These equations represent telegrapher's equations for lossless transmission line where $Q(t,x)$ is the total line charge density. In vacuum, the charge-voltage dependence is linear $Q(t,x) = CV(t,x)$. The inductance and the capacitance per line length, L and C respectively, can be calculated by formula

$$L = \frac{\mu_0}{2\pi}\operatorname{acosh}\left(\frac{h}{a}\right),\ C = 2\pi\varepsilon_0 \Big/ \operatorname{acosh}\left(\frac{h}{a}\right), \qquad (3)$$

where a is the wire radius and h is the height of the wire above the ground.

When the voltage intensity is greater than the critical value for the corona inception, the charge voltage dependence becomes nonlinear with the hysteresis. This function is represented by charge-voltage (QV) curve. In order to study the pulse propagation, it is necessary to know the accumulated charge on the transmission line for the given voltage when corona is formed and to determine the QV curve for every position along the transmission line. For the given time evolution of voltage at some position along the line $V(t,x)$, one can obtain the total line charge density Q by solving the continuity equations for charged species in air in cylindrical geometry [5]

$$\frac{\partial n_e}{\partial t}+\frac{1}{r}\frac{\partial\left(r\Gamma_e\right)}{\partial r}=S_{ph}+n_e(\alpha-\eta_2-\eta_3)\left|W_e\right|-n_e n_p\beta+k_{\text{det}}n_{O_2^-} \quad (4)$$

$$\frac{\partial n_p}{\partial t}+\frac{1}{r}\frac{\partial\left(r\Gamma_p\right)}{\partial r}=S_{ph}+n_e\alpha\left|W_e\right|-(n_e+n_{O^-}+n_{O_2^-})n_p\beta\,, \quad (5)$$

$$\frac{\partial n_{O^-}}{\partial t}+\frac{1}{r}\frac{\partial\left(r\Gamma_{O^-}\right)}{\partial r}=n_e\eta_2\left|W_e\right|-n_{O^-}n_p\beta\,, \quad (6)$$

$$\frac{\partial n_{O_2^-}}{\partial t}+\frac{1}{r}\frac{\partial\left(r\Gamma_{O_2^-}\right)}{\partial r}=n_e\eta_3\left|W_e\right|-n_{O_2^-}n_p\beta-k_{\text{det}}n_{O_2^-} \quad (7)$$

In this study, we take into consideration the concentration of electrons n_e, positive ions n_p, negative O^- and O_2^- ions, n_{O^-} and $n_{O_2^-}$, respectively. On the right hand side of the equations (4)-(7) the terms representing the gain and the loss of the particles due to electron impact ionization, two-body attachment, three-body attachment, recombination and detachment described by the coefficients α, η_2, η_3, β and k_{det} respectively are given. The term S_{ph} denotes the generation of electrons and positive ions through photoionization. Further, W_e, W_p and W_n are the velocities of electrons, positive and negative ion drifts, respectively. The fluxes of charged particles are given by

$$\Gamma_e=W_e n_e-D\frac{\partial n_e}{\partial r},\ \Gamma_p=W_p n_p,\ \Gamma_{O^-}=W_n n_{O^-},\ \Gamma_{O_2^-}=W_n n_{O_2^-}, \quad (8)$$

where Γ_e is the flux of electrons, Γ_p is a flux of positive ions, Γ_{O^-} and $\Gamma_{O_2^-}$ are the fluxes of O^- and O_2^- ions, respectively, D is the diffusion coefficient for electrons. We neglected the diffusion of heavy ions, so the ionic current contains only a drift component. The values of the transport and the reaction coefficients depend on the ratio of the value of the electric field intensity and the concentration of air molecules [6], so the continuity equations (4)-(7) are coupled with the Poisson equation using the potential Φ

$$\nabla^2\Phi=\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial\Phi}{\partial r}\right)=-\frac{e\left(n_p-n_e-n_{O^-}-n_{O_2^-}\right)}{\varepsilon_0}\,. \quad (9)$$

Electric field is calculated assuming the electrostatic approximation

$$E=-grad\ \Phi=-\frac{\partial\Phi}{\partial r}\,. \quad (10)$$

When the concentrations of the charge particles and the electric field intensity are calculated, the total line charge density is

$$Q(t)=\int_0^t I_p(t')dt', \quad (11)$$

where I_p is the current per cylinder length, obtained from Sato-Morrow [7] formula for cylindrical geometry

$$I_p=\frac{2\pi e}{\log\frac{R_2}{R_1}}\int_{R_1}^{R_2}\Gamma dr+\frac{2\pi\varepsilon_0}{\log\frac{R_2}{R_1}}\frac{\partial V}{\partial t}. \quad (12)$$

Final goal is to investigate whether the drift-diffusion model in the cylindrical geometry can be used for the simulation of QV curves for the overvoltage calculations in different geometry for transmission lines. Noda [8] measured the QV curves for the overhead wire 1.83 m above the ground. In order to try to estimate the QV curve measured by Noda in wire to plane geometry we ran the simulation in our wire to cylinder program. The radius of the wire is same as in the experiment, $R_1=5$ mm, and the radius of the outer cylinder is adopted to be the height of the wire above the ground, which is $R_2=1.83$ m. Calculated values for the total line charge density were higher than the measured values, which is expected since the capacitance of the cylindrical capacitor is greater than the capacitance of the wire above the perfectly conducting plane. Therefore, the result for the line charge density should be multiplied by the coefficient k, which is the ratio of the capacitance of the wire above the plane C_p and the capacitance of the cylindrical capacitor C_0

$$C_p=\frac{2\pi\varepsilon_0}{\cosh^{-1}\left(R_2/R_1\right)},\ k=\frac{C_p}{C_0}. \quad (13)$$

In this way, we obtained a very good agreement with the experimental results. The QV curve obtained by the correction of the calculated results and the data measured by Noda for 570 kV impulse are depicted in Fig. 1.

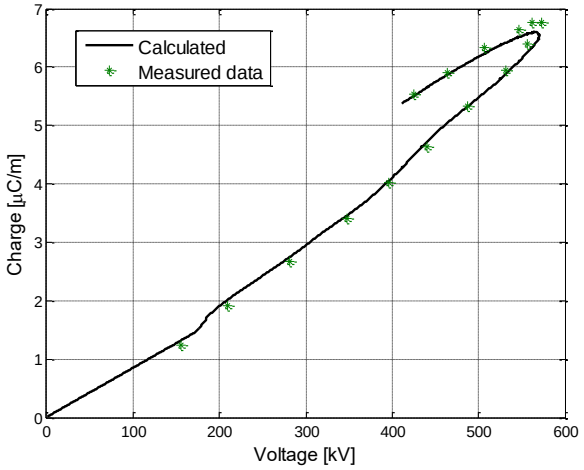

Fig. 1. Calculated QV curve and the measured data by Noda [8]

The final result of the simulation shows excellent agreement with the experimental measurement of the QV curve. It represents affirmation that the drift diffusion model can be used for the calculation of QV curves, which are necessary to complete the equations (1) and (2) in order to study the pulse propagation along the transmission line.

In order to solve the equations (4)-(7) and (9) numerically, great number of time steps is necessary. For the simulation of the 5 μs corona discharge, a million time steps is needed.

Therefore, it would be very time consuming to simulate the corona at every position along the transmission line. So, the corona discharge is simulated only on some nodes along the line and the values between those nodes are obtained by linear interpolation.

III. Results and Discussion

The calculations have been performed for the single overhead wire of the radius $a = 21\,\text{mm}$ placed at the height $h = 15\,\text{m}$ above the ground. The goal is to try to obtain the same results as in the experiments preformed by Wagner et al [9]. The surge generator was located at the one end of the line and the voltage pulse is injected which defines the boundary condition $V(x=0,t)$. Since the pulse can not propagate with the speed greater then the speed of light, two more boundary conditions can be defined $I(x > ct) = 0,\ V(x > ct) = 0$.

The surge generator voltage impulse and the shape of the voltage impulse after the wave travelled the distance of 622 m are given in the Fig. 2. Unfortunately, first result of the simulation did not give the solution that has satisfactory agreement with the measured impulse. On a positive note, simulation confirmed all effects of the corona- the retardation and the attenuation of the impulse and correct value of the corona threshold.

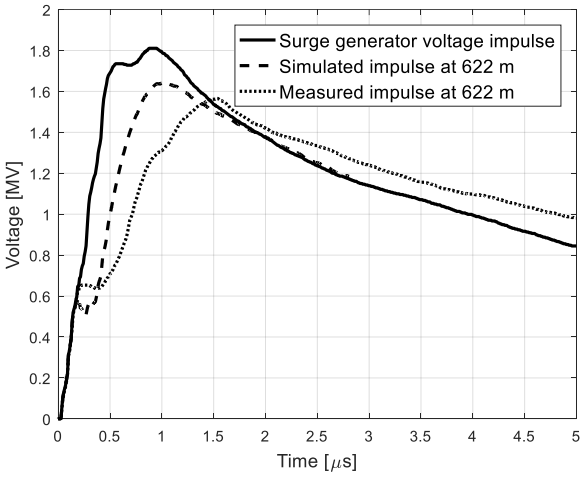

Fig. 2. Simulation of the propagation of the surge pulse at 622 m

In order to obtain better results, we conducted the investigation why results are different. By comparing results of the QV curves with the engineering models it was concluded that drift-diffusion model gives lower values of the charge for wires with the radius greater than 10 mm. For thinner wires drift-diffusion model gives satisfactory solution, as shown in Fig. 1. Therefore, in our example the generated charge is less than it should be and corona effect is not strong enough to obtain agreement with the measured values.

This difference in the results for the thin and wide wires can be explained by the effect of streamer. The structure of the space charge around the wire is not the radially symmetrical fluid, as it is assumed by drift-diffusion model. In reality, the space charge is composed of thin filaments of the discharge – the streamers. These filaments have the head where photoionization occurs and they propagate through space leaving behind the weakly ionized tail [10]. Their significant characteristic is that they can propagate even when the electric field intensity is smaller than the critical electric field for the impact ionization (around 2.6 MV/m for dry air). The minimal value of the electric field for the propagation of the positive streamers is 0.5 MV/m, and for the negative streamers it is around 1 MV/m.

Due to streamers additional charge is generated in the area farther form the wire where the electric field has lower intensity values, which can not be taken into account with the original drift-diffusion model. In order to include this effect, we modified the values of the Townsend coefficient α which represents the number of positive ion-electron pairs generated per unit length. For the atmospheric pressure, the Townsend coefficient depends only on the electric field intensity. The modification is done so that the Townsend coefficient has values high enough for the ionization when the electric field intensity is lowered to 1 MV/m. This procedure gave the result that is in a good overall agreement with the experimental results, as can be seen in Fig. 3.

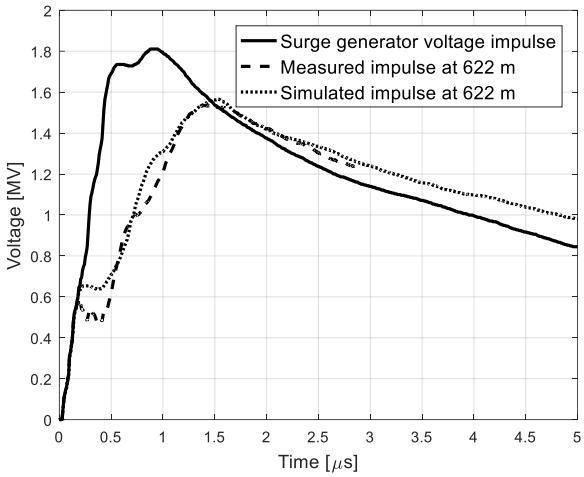

Fig. 3. Simulation of the propagation of the surge pulse at 622 m with the modified Townsend coefficient value

IV. Conclusion

The drift-diffusion model has been used to simulate corona discharge due to lightning surge on transmission lines. In order to obtain a good agreement with the experimental results, reaction coefficient for the impact ionization needs to be modified. It is necessary to include the effect of the streamers, the thin filaments of the discharge that can propagate in the area of lower electric field intensity. The streamers increase the generated charge around the wire and enhance the effects of the corona.

UWB Printed Monopole Antenna With and Without the Reflector

Dragan Nikolić and Miodrag Tasić, *Member IEEE*

***Abstract* - Measured reflection coefficient of a typical UWB monopole antenna is heavily dependent on the measurement setup. The antenna is connected to the network analyzer (NA) using coaxial cables. During the measurement, currents along the inner and the outer conductor of the coaxial cables are unbalanced, causing parasitic radiation. The NA chassis also radiates, so the entire measurement setup behaves like a single antenna under test. As a consequence, a simulated results can be very different from the measured ones, and the single antenna can behave very differently when mounted in different environments. Also, minor errors in the antenna fabrication can cause significant differences in the measured reflection coefficients of similar prototypes.**

In this paper we examine if a reflector connected to the ground of the UWB monopole antenna can provide stabilization in the antenna characteristics, simulated and measured, and the satisfactory matching between reflection coefficients of different prototypes.

***Index term* - UWB antenna; antenna measurements; reflection coefficient; electromagnetic modeling.**

I. INTRODUCTION

The rapid development of UWB (Ultra-Wideband) technology [1] begins as the appropriate standards were adopted in the United States [2] and Europe [3]. UWB devices work in the frequency range from 3.1 to 10.6 GHz (FCC band).

A printed monopole antenna with a circular radiating element [4] can achieve a reflection coefficient less than -10dB, across the entire UWB band. With smaller changes in the shape of the radiating element and the ground plane, it is possible to improve the characteristics of the antenna, but the basic structure of the antenna remains unchanged: one side of the antenna is radiating element with approximately circular shape and a feeder, the other is a substrate with a small ground plane. Minor errors in the antenna fabrication can lead to significant differences between reflection coefficients (return loss) of different prototypes (for the same antenna model). Size and construction of such antenna are the main reason for the difference in results.

Dragan Nikolić – School of Electrical Engineering, University of Belgrade, Kralja Aleksandra Blvd. 73, 11120 Belgrade, Serbia (e-mail: nikolicdragansiki@gmail.com).

Miodrag Tasić – School of Electrical Engineering, University of Belgrade, Kralja Aleksandra Blvd. 73, 11120 Belgrade, Serbia (e-mail: tasic@ etf.bg.ac.rs).

Diameter of the radiating element is about 22 mm, which is about 4 times less than the wavelength at the highest frequency in UWB band. Small ground of antenna causes the current to flow back from the radiator to the outer surface of the coaxial cable. This results in secondary radiation which can influence measurement accuracy [5].

In this paper we examine if a reflector connected to the ground plane of the UWB printed monopole antenna can increase stability of the simulated and measured results, and also lead to the satisfactory matching between different prototypes of the same antenna model. We start with the UWB printed monopole antenna without the reflector. The antenna was modeled using software for polygonal modeling AW Modeler [6], whereas the electromagnetic analysis of the model was performed in the software package for electromagnetic modeling and analysis WIPL-D Pro [7]. The radiating element was modeled using NURBS curves, as explained in [8]. Two prototypes were fabricated and measured, showing considerable differences in the reflection coefficients. Then, we added reflectors to both antennas, and the matching between measured reflection coefficients was excellent.

Different simulation models and measured results of these antennas are shown in the following section.

II. UWB ANTENNA DESIGN

Initial UWB printed monopole antenna (without a reflector) was modeled in [8]. The antenna was made using the substrate with relative permittivity 3,5 and thickness 0,762 mm. The radiating element was modeled using NURBS curve, with three different parameters for the shape control. The antenna is fed trough a microstrip line attached to a SMA connector Optimal design is chosen in a way to minimize reflection coefficient in the frequency range of interest (from 3.1 to 10.6 GHz). The layout for the optimal design is shown in Fig. 1.

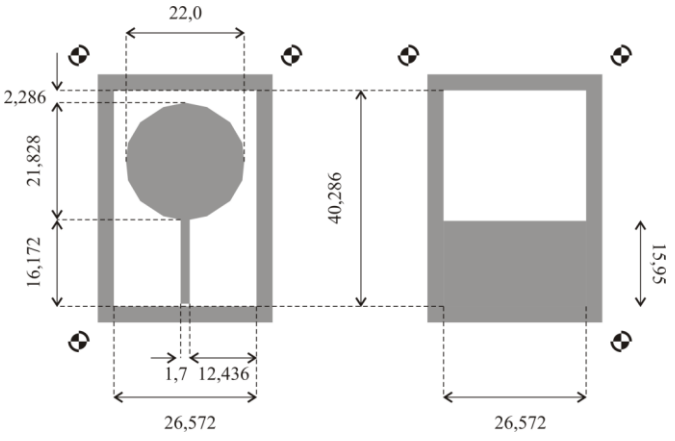

Fig. 1. Layout of UWB printed monopole antenna (top and bottom view)

The model of the antenna, with precise modeling of a SMA connector, is shown in Fig. 2.

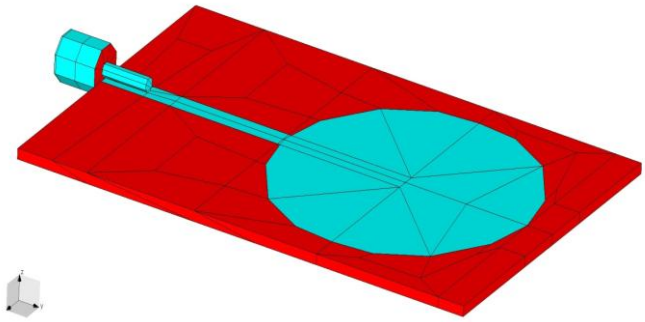

Fig. 2. Model of UWB printed monopole antenna without reflector

The simulated return loss of the UWB printed monopole antenna without reflector is shown in Figure 3. Return loss of the modeled antenna is practically less than -10dB across the entire UWB band.

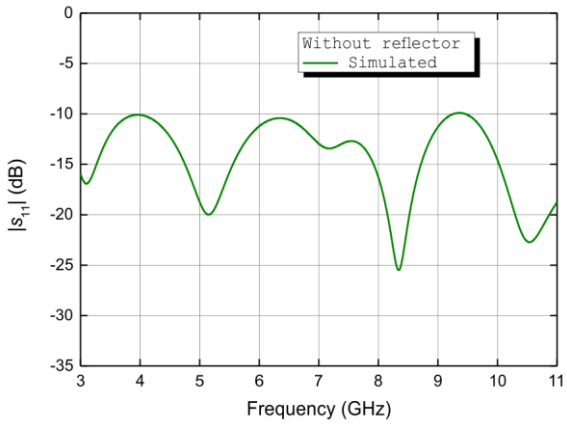

Fig. 3. Simulated return loss of UWB printed monopole antenna without the reflector

Two prototypes were fabricated, and the photo of the antennas, from both sides, with SMA connectors attached, is shown in Fig. 4.

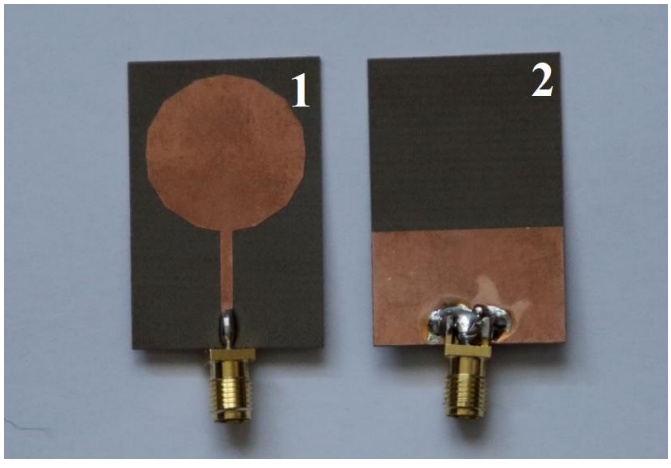

Fig. 4. Photograph of prototypes without the reflector (top view of the first prototype and bottom view of the second prototype)

The measured return loss of the prototypes are shown in Fig. 5. The measured return losses are significantly different between 4 GHz and 8 GHz. Also, both measured results are significantly different from the simulated one.

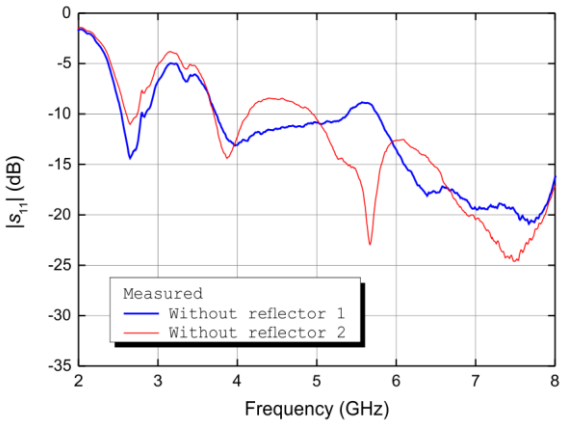

Fig. 5. Measured return loss of two prototypes of UWB printed monopole antenna without reflector

The model of the same UWB printed monopole antenna, but with a reflector, is shown in Fig. 6. The reflector is made from the dielectric substrate with relative permittivity 4,4 and thickness 1,75 mm. The metallization exists on both sides of the substrate, and the metallic vias are made around the connector, electrically connecting the both sides of the substrate. Our analysis show that such reflector is electrically equivalent to the pure metallic reflector, but it is better for mechanical processing and soldering. The dimensions of the reflector are optimized to achieve minimal reflection coefficient.

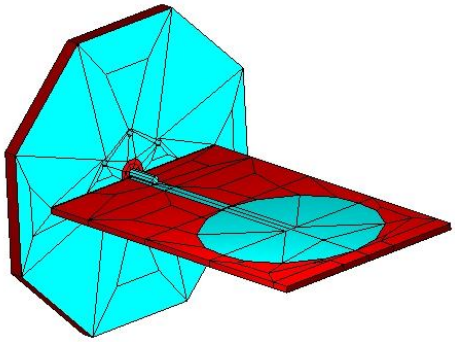

Fig. 6. Model of the UWB printed monopole antenna with the reflector

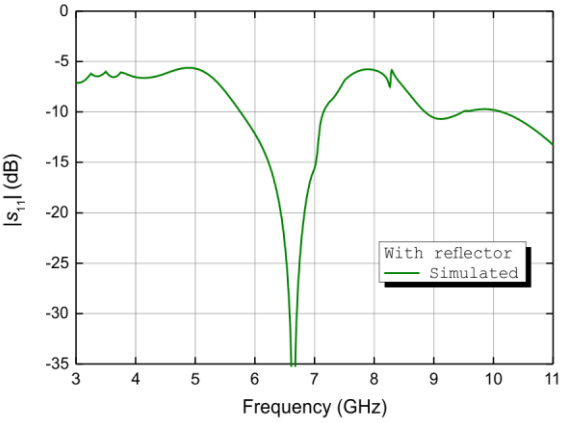

Fig. 7. Simulated return loss of monopole UWB antenna with reflector

The simulated return loss of the UWB printed monopole antenna with the reflector is shown in Fig. 7. There is some degradation in the simulated return loss characteristics compared to the antenna without the reflector.

Two prototypes of the UWB printed monopole antenna with the reflector are fabricated, ant the photos of the antennas are shown in Fig. 8 (top side), and Fig. 9 (bottom side).

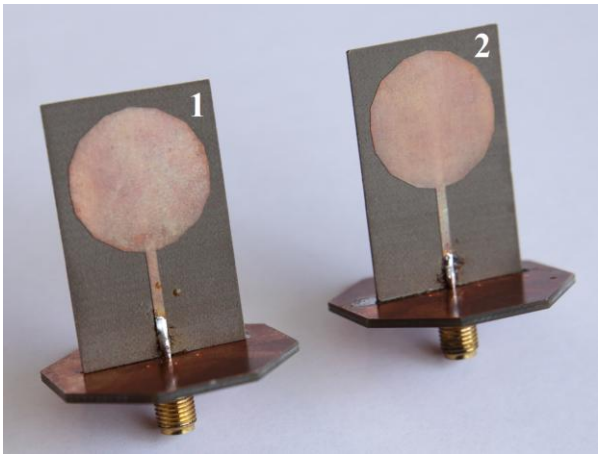

Fig. 8. Photograph of UWB printed monopole antennas with the reflector (top view)

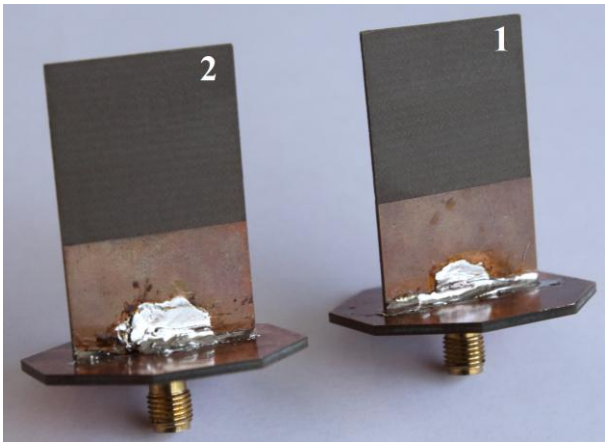

Fig. 9. Photograph of UWB printed monopole antennas with the reflector (bottom view)

Return losses of prototypes with the reflector are shown in Fig. 10. We see that matching between two antennas is almost perfect across the entire UWB band, unlike the prototypes without the reflector.

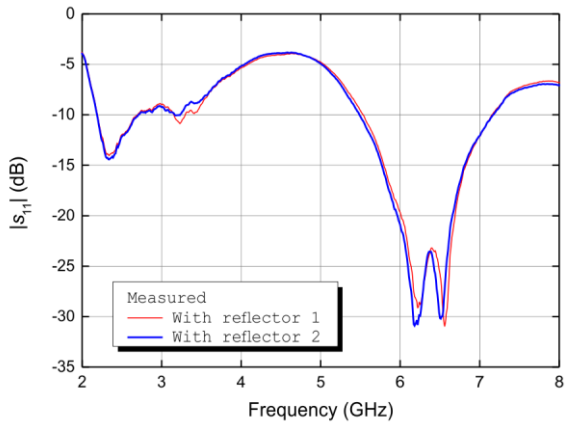

Fig. 10. Measured return loss of prototypes with the reflector

In order to investigate more closely such difference in behavior between the models with and without the reflector, we created the measurement models of the antennas. These models include coaxial cable and a network analyzer (NA). The measurement model for the antenna with the reflector is shown in Fig. 11. The reflection coefficient of the antenna only (without the coaxial cable and NA) is obtained by de-embedding of the parameters, as described in [7]. The de-embedding plane is shown in Fig. 12. The similar model is created for the antenna without the reflector. Finally, the NA boxes are removed from both models, so we can isolate the influence of the NA on the measured results.

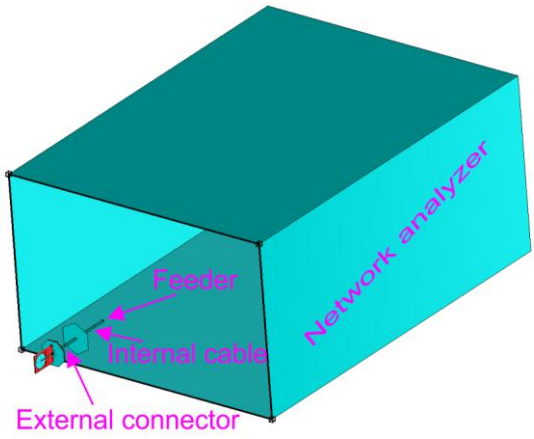

Fig. 11. Measurement model of the antenna with the reflector

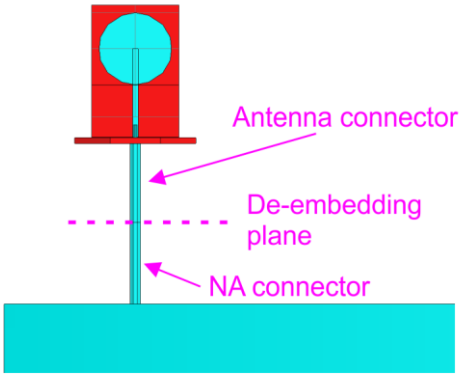

Fig. 12. De-embedding plane in the measurement model

The simulated reflection coefficients for the measurement models of the antenna without the reflector are shown in Fig. 13, whereas corresponding results for the antenna with the reflector are shown in Fig. 14.

We can see that simulated results for the antenna with the reflector are very stable: by removing the NA, only slight change in reflection coefficient is observed. The result with the NA has clear resemblance of the measured results: all resonances are replicated, albeit with somewhat different levels.

On the contrary, the results for the antenna without the reflector are not stable at all, and since measured results for two prototypes are very different, it is hard to establish clear reference for "exact" result.

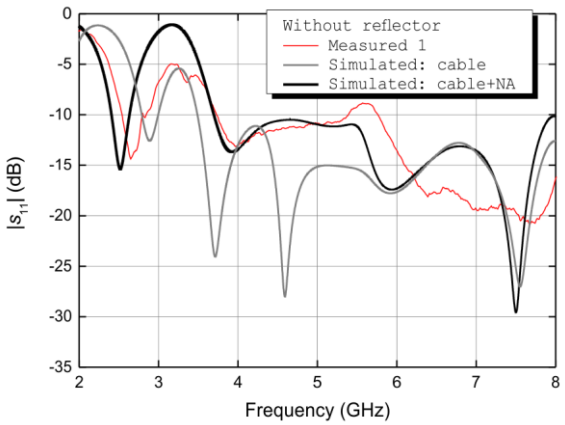

Fig. 13. Simulated reflection coefficients for the measurement model of the antenna without the reflector

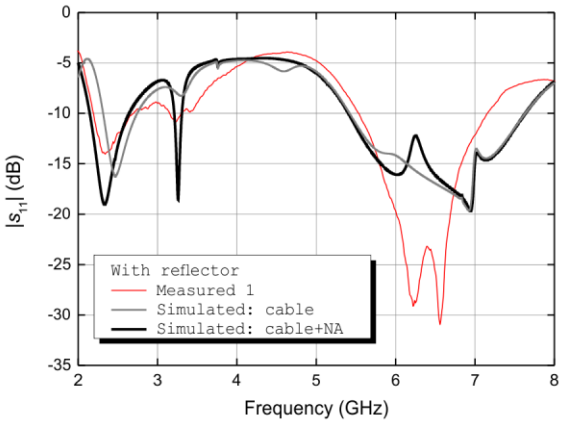

Fig. 14. Simulated reflection coefficients for the measurement model of the antenna with the reflector

III. CONCLUSIONS

Additional reflector changes return loss of the UWB printed monopole antenna, but the stability of the simulated and measured results for the antenna with the reflector is much better. So, it can be attached to various devices without significant changes in the characteristics. The question remains if such antenna with the reflector can be design to fulfill -10dB reflection coefficient in the whole UWB frequency range.

Аналитичко решење Волтерине интегралне једначине прве врсте за генералисани модел повратног удара са путујућим струјним извором

Драган Павловић, Јован Цветић, Градимир Миловановић и Милан Игњатовић

***Апстракт*—Разматрали смо аналитичку методу за решавање специјалне Волтерине интегралне једначине конволуционог типа која се примењује у прорачуну функције пражњења канала код генералисаног модела повратног удара са путујућим струјним извором (GTCS модел). У оквиру аналитичког метода, примењена је Лапласова трансформација уз употребу Meijer-G функције. Разматрани су и методи за инверзну нумеричку Лапласову трансформацију.**

***Кључне речи*—повратни удар, GTCS модел, Волтерина интегрална једначина, Лапласова трансформација.**

I. Увод

Проучавање динамике пражњења канала муње је од великог значаја за физику плазме, као и за електроинжењерску праксу. После детаљног прегледа свих метода који се користе у литератури, одлучено је да се за проучавање динамике канала користи инжењерски GTCS модел [1]. Како би започели овај процес, неопходно је прво израчунати функцију пражњења канала из Волтерине интегралне једначине [2].

Решавање ове једначине представља студију о нелинеарној, нехомогеној Волтериној интегралној једначини прве врсте са импулсним функцијама. Волтерине интегралне једначине прве врсте су саме по себи слабо условљени проблеми.

Математички термин добро условљен проблем, произилази из дефиниције коју је дао француски математичар Жак Адамар [2]. Према Адамару, проблем је добро условљен ако: проблем има решење (егзистенција), ово решење је јединствено одређено (јединственост) и решење непрекидно зависи од улазних података, тј. мале промене улазних података не доводе до велике промене решења (стабилност). Ако један од ових услова није испуњен, проблем је слабо условљен.

Ова слаба условљеност чини нумеричко решење веома тешким, а то значи да мала грешка у улазним подацима може да доведе до дивергентног решења. Упркос извесним ограничењима, једначина је нумерички решена методом модификоване композитне трапезне формуле [3]. Метод је формиран тако да обезбеди висок степен тачности, уз минималне апроксимације и малу сложеност алгоритма, што је и постигнуто. Међутим, оно што је проблематично је пролазак нумеричког решења кроз нулу пре краја интервала, као и извесни пикови на самом почетку интервала, што не проистиче из физике електричних пражњења.

Због поменутих проблема, неопходно је решити Волтерину једначину у аналитичком облику и одредити природу решења.

II. Поставка проблема

Циљ рада је израчунавање функције пражњења канала $f(t-z/v^*)$. Полазимо од Волтерине интегралне једначине прве врсте [4]:

$$i_0(t)=\int_0^{v^*t} q_0'(z)\cdot\frac{\partial}{\partial t}f(t-z/v^*)dz. \qquad (1)$$

по непознатој функцији $f(t-z/v^*)$, где су познате функције: функција струје у тачки удара $i_0(t)$, $q_0'(z)$ укупно подужно наелектрисање у корони пре повратног удара, t је апсолутно време и представља почетак повратног удара, z је висина канала, v је брзина повратног удара, а v^* је редукована брзина повратног удара. Функција $f(t-z/v^*)$ се може записати као $f(u)$. Аргумент функције $f(u)$ је генералисано време и оно се

Јован Цветић – Електротехнички факултет, Универзитет у Београду, Булевар краља Александра 73, 11020 Београд, Србија (електронска пошта: cvetic_j@etf.rs).

Градимир Миловановић – Математички институт САНУ, Кнез Михаилова 36, 11020 Београд, Србија (електронска пошта: gvm@mi.sanu.ac.rs).

Милан Игњатовић – Електротехнички факултет, Универзитет у Београду, Булевар краља Александра 73, 11020 Београд, Србија (електронска пошта: ignjatovic@etf.rs).

може изразити као $u = t - z / v^*$.

За моделовање струје у тачки удара користили смо Хајдлерову функцију (једначина (3) из рада [3]), а за моделовање функције подужног наелектрисања смо користили функцију (5) из рада [3]).

Аналитичко решење мора да задовољи следећа четири услова која следе из саме поставке модела [4]:

$$f(0) = 0 \tag{2}$$

$$f(u) \geq 0 : u \geq 0 \tag{3}$$

$$\lim_{u\to\infty} f(u) = 0 \tag{4}$$

$$\frac{df(u)}{du} \leq 0 : u \geq 0. \tag{5}$$

Полазимо од једначине (1) и уводимо следећу смену $f_1(t - z / v^*) = \partial / \partial t \; f(t - z / v^*)$. После примењене смене, једначина (1) постаје линеарна, нехомогена Волтерина интегрална једначина прве врсте:

$$i_0(t) = \int_0^{v^* t} q_0'(z) \cdot f_1(t - z / v^*) dz. \tag{6}$$

Примењујући математичке трансформације, долазимо до интегралне једначине конволуционог типа коју ћемо решавати методом Лапласове трансформације:

$$i(t) = \int_0^t q(t) f_1(t-\tau) \cdot d\tau = \int_0^t q(t-\tau) f_1(t) \cdot d\tau. \tag{7}$$

где су $i(t) = i_0(t) / v^*$ и $q(\tau) = q_0'(v^* \cdot \tau)$.

III. Метод Лапласове трансформације

Теоријски приступ у решавању Волтерине интегралне једначине подразумева примену Лапласове трансформације. Ово је стандардни метод за проналажење решења Волтерине интегралне једначине конволуционог типа. Лапласова трансформација функције $f_1(t)$ је функција $F_1(\mathrm{s})$:

$$F_1(\mathrm{s}) = L\left[f_1(t) \right](s) = \int_0^\infty e^{-st} f_1(t) dt. \tag{8}$$

Применом Лапласове трансформације на конволуциону једначину добијамо:

$$I(s) = Q(s) \cdot F_1(s), \tag{9}$$

где су $I(s)$ и $\mathrm{Q}(s)$ Лапласове трансформације функција $i(t)$ и $q(t)$, респективно.

За дате функције, директна Лапласова трансформација није могућа. Из овог разлога за трансформације користимо Meijer-G функцију [5], [6]. Да би одредили трансформацију, потребно је знати следећи интеграл:

$$G_k(\alpha) = \int_0^\infty e^{-\alpha x} \frac{x^k}{1+x^k} dx \quad \left(\mathrm{Re}\,\alpha > 0,\, k \in \mathbb{N}\right). \tag{10}$$

Ако изразимо интеграл (10) преко Meijer-G функције, добијамо:

$$G_k(\alpha) = \int_0^\infty e^{-\alpha x} \frac{x^k}{1+x^k} dx = \\ = \frac{1}{\sqrt{\kappa (2\pi)^{\kappa-1}}} G_{1,k+1}^{k+1,1}\left(\frac{\alpha^k}{x^k} \middle| \begin{matrix} -\frac{1}{k} \\ -\frac{1}{k}, 0, \frac{1}{k}, \frac{2}{k}, \ldots, \frac{k-1}{k} \end{matrix} \right). \tag{11}$$

У суштини, овај резултат представља Лапласову трансформацију функције $L\left[\psi_k(t)\right](s) = G_k(s)$. Према особинама Лапласове трансформације можемо писати:

$$L\left[\psi_k(t) \cdot e^{-\gamma t} \right](s) = G_k(s + \gamma). \tag{12}$$

Сада смо у могућности да пронађемо Лапласове трансформације $I(s) = L\left[i(t)\right](s)$ и $Q(s) = L\left[q(t)\right](s)$, за функције $i(t)$ и $q(t)$, респективно:

$$I(s) = A\tau_1 G_n\left(\tau_1\left(s + \tau_2^{-1}\right)\right), \tag{13}$$

$$Q(s) = Q_0' \left\{ \left(1 + \frac{\lambda_{d1}}{v^*} s + \frac{\lambda_{d2}}{v^{*2}} s^2\right) \hat{\tau}_1 G_m\left(\hat{\tau}_1\left(s + \hat{\tau}_2^{-1}\right)\right) - \frac{\lambda_{d2}}{v^{*2}} \delta_{m,1} \right\}, \tag{14}$$

где су параметри I_0, v^*, η, τ_1, τ_2, λ_1, λ_2, λ_{d1} и λ_{d2} дефинисани у раду [3], док је параметар $A = I_0 / (\eta \cdot v^*)$, а $\delta_{m,1}$ је Кронекеров делта симбол.

На основу једначине (9), као и израза за Лапласове трансформације (13) и (14) добијамо:

$$F_1(s) = \frac{K G_n(\tau_1(s + \tau_2^{-1}))}{(1 + \tau_{d1} s + \tau_{d2}^2 s^2) G_m(\hat{\tau}_1(s + \hat{\tau}_2^{-1})) - \left(\frac{\tau_{d2}}{\hat{\tau}_1}\right)^2 \delta_{m,1}}, \tag{15}$$

где је $K = A(\tau_1 / \hat{\tau}_1) / Q = I_0(\tau_1 / \hat{\tau}_1) / (\eta \cdot v^* \mathrm{Q}_0')$.

Коначно решење можемо добити као инверзну Лапласову трансформацију од израза (15):

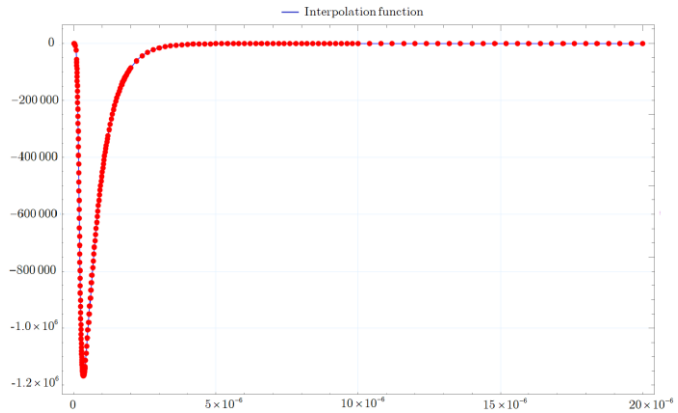
$$f_1(t) = L^{-1}\left[F_1(s)\right](t) = \frac{1}{2\pi i}\int_{\Gamma} e^{st}F_1(s)ds. \qquad (16)$$

У општем случају, овај комплексни интеграл се не може израчунати у аналитичком облику. У таквим случајевима морамо користити неке од метода [7] за приближно израчунавање интеграла (16). Ми смо се у овом раду одлучили да користимо методу Гавера [8] за израчунавање нумеричке инверзне Лапласове трансформације.

IV. Примери

Волтерина интегрална једначина је аналитички решена за велики број примера. Посебно су спроведени прорачуни за функције пражњења језгра, а посебно короне атмосферског пражњења. Ми ћемо у овом раду навести два примера која су урађена.

У примеру 1 смо користили следеће улазне параметре за функцију струје: $I_0 = 13000\,\mathrm{A}$, $\eta = 0{,}87$, $n = 5$, $\tau_1 = 0{,}24\cdot 10^{-6}\,\mathrm{s}$ и $\tau_2 = 3{,}4\cdot 10^{-6}\,\mathrm{s}$. За функцију подужног наелектрисања смо користили параметре: $Q_0' = -1.922\cdot 10^{-4}\,\mathrm{C/m}$, $\lambda_1 = 9\,\mathrm{m}$, $\lambda_2 = 255\,\mathrm{m}$, $\lambda_{d1} = 45\,\mathrm{m}$, $\lambda_{d2} = 0\,\mathrm{m}$ и $m = 4$. Резултат прорачуна за овај пример је приказан на слици 1.



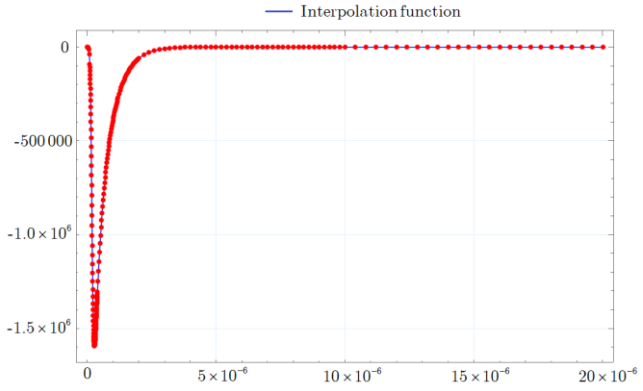
Сл. 1. Први извод функције пражњења добијен Гаверовим методом за пример 1.

Примењујући Гаверов метод добили смо нумеричке вредности решења на целом интервалу. При израчунавању поделили смо цео интервал на следећих шест подинтервала:

$$[0,\ t_6] = [0,\ t_1] \cup [t_1,\ t_2] \cup [t_2,\ t_3] \cup [t_3,\ t_4] \cup [t_4,\ t_5] \cup [t_5,\ t_6], \qquad (17)$$

где вредности $t_1, t_2, t_3, t_4, t_5, t_6$ представљају границе подинтервала. Прорачун је изведен на интервалу $[0,\ t_5] = [0,\ T_{\max}] = \left[0,\ 20\cdot 10^{-6}\right]$. Први подинтервал има границе $[0,\ t_1] = [0,\ T_{\max}/200]$, а корак на овом интервалу је $h_1 = T_{\max}/1000$. Други подинтервал има границе $[t_1,\ t_2] = [26T_{\max}/5000,\ T_{\max}/50]$, а корак на овом интервалу је $h_2 = T_{\max}/5000$. Трећи подинтервал има границе $[t_2,\ t_3] = [21T_{\max}/1000,\ 6T_{\max}/100]$, а корак на овом интервалу је $h_3 = T_{\max}/1000$. Четврти подинтервал има границе $[t_3,\ t_4] = [31T_{\max}/1000,\ T_{\max}/10]$, а корак на овом интервалу је $h_4 = T_{\max}/500$. Пети подинтервал има границе $[t_4,\ t_5] = [11T_{\max}/1000,\ T_{\max}/2]$, а корак на овом интервалу је $h_5 = T_{\max}/100$, док последњи, шести, подинтервал има границе $[t_5,\ t_6] = [26T_{\max}/50,\ T_{\max}]$, а корак на овом интервалу је $h_6 = T_{\max}/50$. Израчунавања су вршена у аритметици двоструке прецизности. Поступак за нумеричку инверзију траје 31 минут. Израчунавање инверзне Лапласове трансформације за овај пример је извршено у програму Mathematica, Ver. 11.3, на рачунару који има следећу конфигурацију: Intel Core i3-3220 CPU, 12GB RAM, 500 GB Sdd, Windows 10 Pro.

Приказаћемо још један пример. За примеру 1 смо користили следеће улазне параметре за функцију струје: $I_0 = 13000\,\mathrm{A}$, $\eta = 0{,}87$, $n = 5$, $\tau_1 = 0{,}24\cdot 10^{-6}\,\mathrm{s}$ и $\tau_2 = 3{,}4\cdot 10^{-6}\,\mathrm{s}$. За функцију подужног наелектрисања смо користили параметре: $Q_0' = -1.979\cdot 10^{-4}\,\mathrm{C/m}$, $\lambda_1 = 4.5\,\mathrm{m}$, $\lambda_2 = 255\,\mathrm{m}$, $\lambda_{d1} = 45\,\mathrm{m}$, $\lambda_{d2} = 0\,\mathrm{m}$ и $m = 1$. Резултат прорачуна за овај пример је приказан на слици 2.



Сл. 2. Први извод функције пражњења добијен Гаверовим методом за пример 2.

С обзиром да је облик улазних функција сличан као у претходном примеру, користили смо исту расподелу тачака да би дошли до крајњег решења. Резултат је добијен у аритметици двоструке прецизности, а поступак за нумеричку инверзију траје 35 минута. Израчунавање инверзне Лапласове трансформације за овај пример је извршено у програму Mathematica, Ver. 11.3, на рачунару који има следећу конфигурацију: Intel Core i3-3220 CPU,

12GB RAM, 500 GB Sdd, Windows 10 Pro.

V. Закључак

Прикладнији приступ за решавање интегралних једначина је примена релевантних нумеричких метода, међутим због слабе условљености датог проблема, једначина се мора решити аналитички. Аналитичко решење за функцију пражњења канала захтева употребу Meijer-G функције, због немогућности директног преласка у Лапласов домен, а затим и коришћење Гаверовог метода за инверзну Лапласову трансформацију. Добијена решења сматрамо егзактним и користићемо их као потврду да ли је одређени нумерички поступак довољно прецизан.

Захвалница

Abstract

We analyzed the analytical method for solving the special kind of Volterra integral equation of the convolution type, which is applied in the calculation of the channel discharge function in the generalized traveling current source return stroke model (GTCS model). Within the analytical method, Laplace transformation was applied using the Meijer-G function. The methods for the inverse numerical Laplace transform were also considered.

Numerical Solution of Volterra Integral Equation of First Kind for GTCS Return Stroke Model

Lokalizacija tačkastih izvora elektromagnetskog zračenja tehnikom retkih signala

Marija Stevanović, *Member, IEEE*, Jelena Dinkić i Antonije Đorđević

***Apstrakt*—Tehnika retkih signala primenjena je za lokalizaciju tačkastih izvora elektromagnetskog polja. Iako posmatrani problem lokalizacije spada u klasu "loše-definisanih" problema, korišćenjem l_1 regularizacije, tj. predznanja da je broj izvora mali, moguće je odrediti nepoznate lokacije i momente električnih i magnetskih dipola. Predloženi algoritam za lokalizaciju testiran je na podacima dobijenim numeričkim simulacijama bez šuma, kao i sa dodatim šumom.**

***Ključne reči*—Električni dipol, lokalizacija, magnetski dipol, tehnika retkih signala.**

I. Uvod

Električki mali izvor elektromagnetskog polja može se u opštem slučaju modelovati pomoću tri ortogonalna električna i tri ortogonalna magnetska dipola čiji se centri nalaze u istoj tački [1]. Ovakav model se može primeniti za lociranje aktivnih logičkih kola u FPGA (engl. *Field-Programmable Gate Array*) integrisanim sistemima kao u [2], [3], gde je razmatrana lokalizacija magnetskih dipola u kvazistacionarnom magnetskom polju korišćenjem standardnih metoda optimizacije.

U cilju pripreme metode za obradu rezultata eksperimenata, u ovom radu primenjujemo obradu retkih signala za lokalizaciju električki malih izvora brzopromenljivog prostoperiodičnog elektromagnetskog polja na osnovu poznavanja polja u malom broju tačaka. Ekvivalentne dipole tražimo na diskretnim pozicijama, u okviru uniformne pravougaone mreže pretraživanja. Smatrajući da se u svakom čvoru mreže nalaze tri električna i tri magnetska dipola, razvijen je linearan elektromagnetski model koji povezuje momente dipola na mreži i elektromagnetsko polje u posmatranim tačkama. Model koristi analitičke izraze za zračenje dipola u prisustvu savršeno provodne ravni. S obzirom na to da je broj nepoznatih momenata mnogo veći od broja merenja, problem spada u klasu "loše-definisanih" problema (engl. *ill-posed problems*). Međutim, ukoliko iskoristimo predznanje da je broj dipola sa značajnim momentima mali, odnosno, mnogo manji od dimenzija mreže za pretraživanje, problem se može rešiti primenom l_1 regularizacije [4]. Predloženi algoritam je dodatno poboljšan uvođenjem normalizacije kojom se ujednačavaju slabljenja prenosa između različitih dipola u mreži i tačaka u kojima se posmatra polje.

Marija Stevanović, Jelena Dinkić i Antonije Đorđević – Univerzitet u Beogradu – Elektrotehnički fakultet, Bulevar Kralja Aleksandra 73, 11120 Beograd, Srbija (e-mail: mnikolic@etf.bg.ac.rs, jdinkic@etf.bg.ac.rs i edjordja@etf.bg.ac.rs).

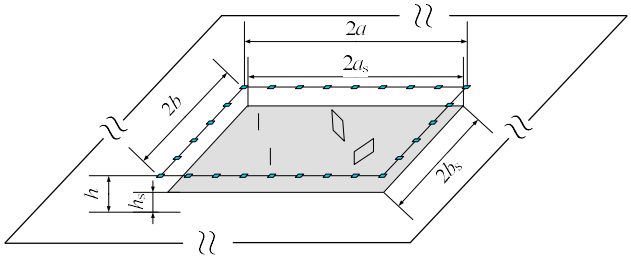
II. Model sistema

U cilju rešavanja inverznog elektromagnetskog problema lokalizacije izvora brzopromenljivog prostoperiodičnog elektromagnetskog polja u vakuumu, posmatra se sistem prikazan na sl. 1. Izvori elektromagnetskog polja smešteni su iznad beskonačne, savršeno provodne ravni, na visini $h_\mathrm{s} = 5\,\mathrm{mm}$ u odnosu na provodnu ravan, u pravougaoniku dimenzija $2a_\mathrm{s} \times 2b_\mathrm{s} = 97{,}5\,\mathrm{mm} \times 78\,\mathrm{mm}$. Izvori elektromagnetskog polja su električni i magnetski dipoli postavljeni na proizvoljnim lokacijama i proizvoljno orijentisani. Radna učestanost je $f = 1\,\mathrm{GHz}$.

Cilj lokalizacije je određivanje pozicije izvora, kao i električnih momenata električnih dipola i magnetskih momenata magnetskih dipola.

Elektromagnetsko polje određuje se u tačkama oko prostora u kome se nalaze izvori. Smatramo da se u svakoj tački nalazi virtuelni senzor za određivanje elektromagnetskog polja (označen kvadratićem na sl. 1). Senzori su postavljeni duž stranica pravougaonika dimenzija $2a \times 2b = 100\,\mathrm{mm} \times 80\,\mathrm{mm}$, na visini $h = 30\,\mathrm{mm}$ iznad provodne ravni. Duž svake duže stranice pravougaonika ekvidistantno je raspoređeno po 10 senzora, a duž svake kraće stranice po 8 senzora, što ukupno čini $N_\mathrm{s} = 36$ senzora.

Svaki senzor meri po tri kompleksne Dekartove komponente električnog i magnetskog polja. Dakle, na mestu svakog senzora poznato je 6 kompleksnih skalarnih veličina.



Sl. 1. Skica sistema.

III. Analitički model

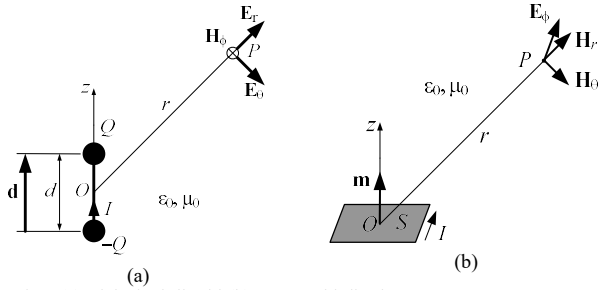
Izrazi za brzopromenljivo električno i magnetsko polje električnog i magnetskog dipola izvode se polazeći od zakasnelih potencijala [1].

Na sl. 2a prikazan je električni dipol (Hercov dipol). Pretpostavljamo da je kompleksna struja $\underline{I}$ uniformna duž ose dipola. Električno i magnetsko polje u tački P posmatranog dipola dati su izrazima:

$$\underline{\mathbf{E}} = \underline{E}_r \mathbf{u}_r + \underline{E}_\theta \mathbf{u}_\theta$$
$$= \frac{(\mathrm{j}\beta)^2}{4\pi\varepsilon_0 r}\left(\left(1+\frac{3}{\mathrm{j}\beta r}+\frac{3}{(\mathrm{j}\beta r)^2}\right)\left(\underline{\mathbf{p}}\cdot\mathbf{u}_r\right)\mathbf{u}_r\right)\mathrm{e}^{-\mathrm{j}\beta r}$$
$$-\frac{(\mathrm{j}\beta)^2}{4\pi\varepsilon_0 r}\left(1+\frac{1}{\mathrm{j}\beta r}+\frac{1}{(\mathrm{j}\beta r)^2}\right)\underline{\mathbf{p}}\,\mathrm{e}^{-\mathrm{j}\beta r}, \quad (1)$$

$$\underline{\mathbf{H}} = \underline{H}_\phi \mathbf{u}_\phi = \frac{(\mathrm{j}\beta)^2 \underline{\mathbf{p}}\times\mathbf{u}_r}{4\pi\varepsilon_0 r}\sqrt{\frac{\varepsilon_0}{\mu_0}}\left(1+\frac{1}{\mathrm{j}\beta r}\right)\mathrm{e}^{-\mathrm{j}\beta r}, \quad (2)$$

gde je $\beta = 2\pi f / c_0$, r rastojanje između dipola i tačke u kojoj se računa polje, $\underline{\mathbf{p}} = \dfrac{\underline{I}\mathbf{d}}{\mathrm{j}\omega}$ kompleksni električni moment dipola, $\omega = 2\pi f$ kružna učestanost, ε_0 i μ_0 permitivnost i permeabilnost vakuuma, respektivno, a $\mathbf{u}_r$, $\mathbf{u}_\theta$ i $\mathbf{u}_\phi$ ortovi sfernog koordinatnog sistema.



Sl. 2. (a) Električni dipol i (b) magnetski dipol.

Na sl. 2b prikazan je magnetski dipol (strujna petlja). Uvedena je slična pretpostavka kao u slučaju električnog dipola: kompleksna struja $\underline{I}$ je uniformna duž petlje. Električno i magnetsko polje strujne petlje u tački P dati su izrazima:

$$\underline{\mathbf{E}} = -\frac{(\mathrm{j}\beta)^2 \underline{\mathbf{m}}\times\mathbf{u}_r}{4\pi r}\sqrt{\frac{\mu_0}{\varepsilon_0}}\left(1+\frac{1}{\mathrm{j}\beta r}\right)\mathrm{e}^{-\mathrm{j}\beta r}, \quad (3)$$

$$\underline{\mathbf{H}} = \underline{H}_r \mathbf{u}_r + \underline{H}_\theta \mathbf{u}_\theta$$
$$= \frac{(\mathrm{j}\beta)^2}{4\pi r}\left(\left(1+\frac{3}{\mathrm{j}\beta r}+\frac{3}{(\mathrm{j}\beta r)^2}\right)\left(\underline{\mathbf{m}}\cdot\mathbf{u}_r\right)\mathbf{u}_r\right)\mathrm{e}^{-\mathrm{j}\beta r}$$
$$-\frac{(\mathrm{j}\beta)^2}{4\pi r}\left(1+\frac{1}{\mathrm{j}\beta r}+\frac{1}{(\mathrm{j}\beta r)^2}\right)\underline{\mathbf{m}}\,\mathrm{e}^{-\mathrm{j}\beta r}, \quad (4)$$

gde je $\underline{\mathbf{m}} = \underline{I}\,\mathbf{S}$ kompleksni magnetski moment magnetskog dipola, a $\mathbf{S}$ površina površi ograničene petljom, čija je orijentacija pravilom desne zavojnice vezana za referentni smer struje.

U sistemu opisanom u prethodnom odeljku, uticaj beskonačne, savršeno provodne ravni, na osnovu teoreme likova, može se modelovati likom odgovarajućeg izvora.

IV. Merni model

Za potrebe formiranja mernog modela, neophodno je definisati mrežu tačaka u kojima će se vršiti pretraživanje. Mreža se prostire po površi pravougaonika $(2a_\mathrm{s} \times 2b_\mathrm{s})$, tj. u oblasti u kojoj se nalaze izvori. Mreža tačaka za pretraživanje, korišćena u ovom mernom modelu, sastoji se od 980 tačaka (35×28 tačaka).

Tokom pretraživanja se pretpostavlja da se u svakom čvoru mreže za pretraživanje nalaze ortogonalni električni i magnetski dipoli. Bez umanjenja opštosti, pretpostavićemo da se provodna ravan nalazi u xOy ravni Dekartovog koordinatnog sistema. U tom slučaju, možemo smatrati da dominantan doprinos elektromagnetskom polju stvaraju samo električni dipoli postavljeni duž z ose Dekartovog koordinatnog sistema, kao i magnetski dipoli čiji su momenti paralelni x i y osi Dekartovog koordinatnog sistema. Polja originala i lika električnih dipola postavljenih duž x i y ose, kao i magnetskog dipola čiji je magnetski moment postavljen duž z ose, praktično se poništavaju. Stoga definišemo da se u svakom čvoru mreže za pretraživanje nalazi samo po jedan električni dipol postavljen duž z ose i samo po dva magnetska dipola čiji su magnetski momenti postavljeni duž x i y.

U tehnici obrade retkih signala [4], [5] pretpostavlja se da su svi dipoli pobuđeni. Međutim, značajne električne, odnosno magnetske momente ima samo mali broj dipola.

Merni model je definisan jednačinom:

$$[\mathbf{b}] = [\mathbf{A}][\mathbf{d}], \quad (5)$$

gde je $[\mathbf{b}]$ vektor merenih podataka, $[\mathbf{A}]$ matrica sistema, a $[\mathbf{d}]$ nepoznati vektor.

Na mestu svakog senzora određuju se tri komponente magnetskog i tri komponente električnog polja:

$$[\mathbf{b}] = \begin{bmatrix} \mathbf{h}_x \\ \mathbf{h}_y \\ \mathbf{h}_z \\ \mathbf{e}_x \\ \mathbf{e}_y \\ \mathbf{e}_z \end{bmatrix}, \quad (6)$$

$$\mathbf{h}_\mathrm{p} = \left[H_\mathrm{p}(\mathbf{r}_1) \quad \cdots \quad H_\mathrm{p}(\mathbf{r}_{36})\right]^\mathrm{T}, \quad (7)$$

$$\mathbf{e}_\mathrm{p} = \left[E_\mathrm{p}(\mathbf{r}_1) \quad \cdots \quad E_\mathrm{p}(\mathbf{r}_{36})\right]^\mathrm{T}, \quad (8)$$

gde p označava x, y ili z komponentu, a $\mathbf{r}_n$ poziciju n-tog senzora $(n = 1,2,3,\ldots,36)$.

Nepoznati vektor $[\mathbf{d}]$ sadrži magnetske i električne momente dipola koji se nalaze u čvorovima mreže po kojoj se vrši pretraživanje:

$$[\mathbf{d}] = \begin{bmatrix} \mathbf{m}_x \\ \mathbf{m}_y \\ \mathbf{p}_z \end{bmatrix}, \ \mathbf{m}_\mathrm{p} = \left[m_{\mathrm{p},1} \quad \cdots \quad m_{\mathrm{p},980}\right]^\mathrm{T}, \quad (9)$$

$$\mathbf{p}_z = \left[p_{z,1} \quad \cdots \quad p_{z,980}\right]^\mathrm{T}, \quad (10)$$

gde p označava x ili y komponentu magnetskog momenta.

Matrica sistema $[\mathbf{A}]$ je definisana na sledeći način:

$$[\mathbf{A}] = \left[\mathbf{A}_{m_x} \quad \mathbf{A}_{m_y} \quad \mathbf{A}_{p_z}\right], \quad (11)$$

$$\mathbf{A}_{m_x}=\begin{bmatrix}\mathbf{H}_{x,m_x}\\ \mathbf{H}_{y,m_x}\\ \mathbf{H}_{z,m_x}\\ \mathbf{E}_{x,m_x}\\ \mathbf{E}_{y,m_x}\\ \mathbf{E}_{z,m_x}\end{bmatrix},\ \mathbf{A}_{m_y}=\begin{bmatrix}\mathbf{H}_{x,m_y}\\ \mathbf{H}_{y,m_y}\\ \mathbf{H}_{z,m_y}\\ \mathbf{E}_{x,m_y}\\ \mathbf{E}_{y,m_y}\\ \mathbf{E}_{z,m_y}\end{bmatrix},\ \mathbf{A}_{p_z}=\begin{bmatrix}\mathbf{H}_{x,p_z}\\ \mathbf{H}_{y,p_z}\\ \mathbf{H}_{z,p_z}\\ \mathbf{E}_{x,p_z}\\ \mathbf{E}_{y,p_z}\\ \mathbf{E}_{z,p_z}\end{bmatrix},\quad (12)$$

gde svaka submatrica (12) predstavlja doprinos odgovarajućeg magnetskog, odnosno električnog momenta.

Submatrice (12) se mogu detaljnije predstaviti u obliku:

$$\mathbf{H}_{\mathrm{p,s}}=\begin{bmatrix}H_{\mathrm{p}}(\mathbf{r}_1,\mathbf{t}_1,\mathrm{s}) & \dots & H_{\mathrm{p}}(\mathbf{r}_1,\mathbf{t}_{980},\mathrm{s})\\ \vdots & \ddots & \vdots\\ H_{\mathrm{p}}(\mathbf{r}_{36},\mathbf{t}_1,\mathrm{s}) & \dots & H_{\mathrm{p}}(\mathbf{r}_1,\mathbf{t}_{980},\mathrm{s})\end{bmatrix},\quad (13)$$

$$\mathbf{E}_{\mathrm{p,s}}=\begin{bmatrix}E_{\mathrm{p}}(\mathbf{r}_1,\mathbf{t}_1,\mathrm{s}) & \dots & E_{\mathrm{p}}(\mathbf{r}_1,\mathbf{t}_{980},\mathrm{s})\\ \vdots & \ddots & \vdots\\ E_{\mathrm{p}}(\mathbf{r}_{36},\mathbf{t}_1,\mathrm{s}) & \dots & E_{\mathrm{p}}(\mathbf{r}_1,\mathbf{t}_{980},\mathrm{s})\end{bmatrix},\quad (14)$$

gde se p, $\mathrm{p}\in\{x,y,z\}$, odnosi na komponente magnetskog i električnog polja, dok s, $\mathrm{s}\in\{m_x,m_y,p_z\}$, označava odgovarajući moment magnetskog, odnosno električnog dipola. Dalje, $\mathbf{t}_l$ predstavlja poziciju l-te tačke u mreži, $l=1,2,3,\dots,980$. Odatle su dimenzije submatrica $\mathbf{H}_{\mathrm{p,s}}$ i $\mathbf{E}_{\mathrm{p,s}}$ jednake 36×980. Izrazi za električno i magnetsko polje dobijaju se iz (1)–(4) kada se uvrsti $r=\|\mathbf{t}_l-\mathbf{r}_n\|$, $\mathbf{u}_r=\dfrac{\mathbf{t}_l-\mathbf{r}_n}{r}$ i primeni teorema likova kako bi se u obzir uzeo i uticaj provodne ravni.

Kako je broj čvorova u mreži za lokalizaciju mnogo veći od broja senzora, lokalizacija električnih i magnetskih izvora, kao i procena njihovih intenziteta, primer je "loše-definisanog" problema. Za rešavanje ovog problema može se iskoristiti l_1 regularizacija [4], [5]. Funkcija koja se minimizira je:

$$\left[\hat{\mathbf{d}}\right]=\min_{\mathbf{d}}\left\{\|[\mathbf{b}]-[\mathbf{A}][\mathbf{d}]\|_2^2+\gamma\|\mathbf{d}_{\mathrm{s}}\|_1\right\},\quad (15)$$

$$\mathbf{d}_{\mathrm{s}}=\begin{bmatrix}\sqrt{m_{x,1}^2+m_{y,1}^2+m_{z,1}^2}\\ \vdots\\ \sqrt{m_{x,980}^2+m_{y,980}^2+m_{z,980}^2}\end{bmatrix},\quad (16)$$

gde $\hat{\mathbf{d}}$ označava estimaciju nepoznatog vektora. Prvi član u (15) predstavlja kvadratnu grešku između merenih rezultata i modela, drugi član favorizuje rešenje koje je retko, a regularizacioni parametar γ balansira između ovih zahteva.

U cilju sprečavanja isticanja čvorova mreže za pretraživanje koji se nalaze bliže nizu senzora u odnosu na čvorove koji su dalje, uvedena je normalizacija. Submatrice (11) pišemo u sledećem obliku:

$$\mathbf{A}_{\mathrm{s}}=\begin{bmatrix}\mathbf{a}_{\mathrm{s},1} & \dots & \mathbf{a}_{\mathrm{s},980}\end{bmatrix},\quad (17)$$

gde se svaka kolona odnosi na jednu tačku mreže. Kao i malopre, $\mathrm{s}\in\{m_x,m_y,p_z\}$. Definišemo vektore čiji su elementi kvadratne norme svake od kolona (17):

$$\mathbf{w}_{m_x}=\begin{bmatrix}w_{m_x,1} & \dots & w_{m_x,980}\end{bmatrix}^{\mathrm{T}},\ w_{m_x,l}=\|\mathbf{a}_{m_x,l}\|_2,\quad (18)$$

$$\mathbf{w}_{m_y}=\begin{bmatrix}w_{m_y,1} & \dots & w_{m_y,980}\end{bmatrix}^{\mathrm{T}},\ w_{m_y,l}=\|\mathbf{a}_{m_y,l}\|_2,\quad (19)$$

$$\mathbf{w}_{p_z}=\begin{bmatrix}w_{p_z,1} & \dots & w_{p_z,980}\end{bmatrix}^{\mathrm{T}},\ w_{p_z,l}=\|\mathbf{a}_{p_z,l}\|_2.\quad (20)$$

S obzirom na to da u svakoj tački mreže imamo dva magnetska dipola, uvodimo vektor:

$$\mathbf{w}_m=\begin{bmatrix}w_{m,1} & \dots & w_{m,980}\end{bmatrix}^{\mathrm{T}},\ w_{m,l}=\sqrt{{w_{m_x,l}}^2+{w_{m_y,l}}^2}.\quad (21)$$

Normalizovana matrica sistema glasi:

$$[\mathbf{A}_{\mathrm{n}}]=\begin{bmatrix}\mathbf{A}_{m_x,\mathrm{n}} & \mathbf{A}_{m_y,\mathrm{n}} & \mathbf{A}_{p_z,\mathrm{n}}\end{bmatrix},\quad (22)$$

$$\mathbf{A}_{m_x,\mathrm{n}}=\begin{bmatrix}\dfrac{\mathbf{a}_{m_x,1}}{w_{m,1}} & \dots & \dfrac{\mathbf{a}_{m_x,980}}{w_{m,980}}\end{bmatrix},\quad (23)$$

$$\mathbf{A}_{m_y,\mathrm{n}}=\begin{bmatrix}\dfrac{\mathbf{a}_{m_y,1}}{w_{m,1}} & \dots & \dfrac{\mathbf{a}_{m_y,980}}{w_{m,980}}\end{bmatrix},\quad (24)$$

$$\mathbf{A}_{p_z,\mathrm{n}}=\begin{bmatrix}\dfrac{\mathbf{a}_{p_z,1}}{w_{p_z,1}} & \dots & \dfrac{\mathbf{a}_{p_z,980}}{w_{p_z,980}}\end{bmatrix}.\quad (25)$$

Na ovaj način ujednačava se slabljenje prenosa između senzora i različitih tačaka mreže. Finalna optimizaciona funkcija je:

$$\left[\hat{\mathbf{d}}\right]=\min_{\mathbf{d}}\left\{\|[\mathbf{b}]-[\mathbf{A}_{\mathrm{n}}][\mathbf{d}]\|_2^2+\gamma\|\mathbf{d}_{\mathrm{s}}\|_1\right\}.\quad (26)$$

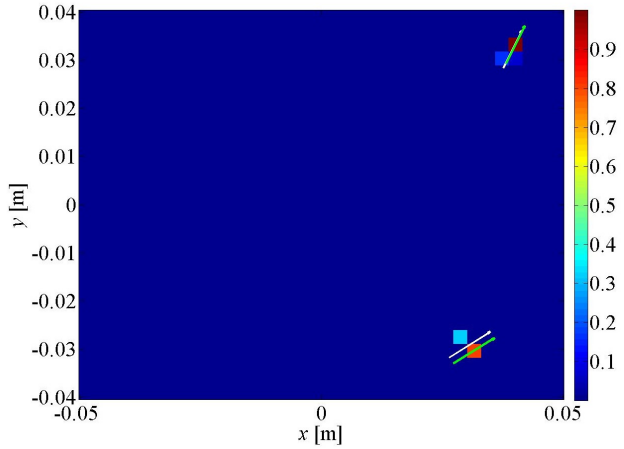
Za rešavanje (26) korišćen je CVX, softverski paket za konveksno programiranje [6], [7].

V. Rezultati lokalizacije

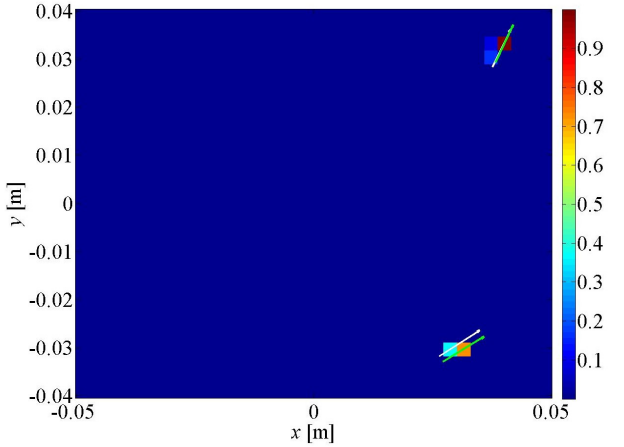
Opisani algoritam za lokalizaciju električnih i magnetskih izvora testiran je na primerima u kojima su bila prisutna dva i tri izvora. Lokacije izvora, kao i magnetski i električni momenti izvora, birani su proizvoljno. Električno i magnetsko polje izvora, na pozicijama senzora, računato je korišćenjem (1)–(4) pre primene algoritma za lokalizaciju. Pritom, pozicije izvora se ne poklapaju sa pozicijama tačaka za pretraživanje. Ovi podaci su tokom lokalizacije tretirani kao rezultati merenja. Algoritam za lokalizaciju je testiran i u slučaju kada je računatim podacima dodat Gausov šum, što je ekvivalentno dodavanju šuma na izlazu senzora.

Na sl. 3 i 6 prikazani su rezultati lokalizacije dva i tri izvora bez dodatog šuma, na sl. 4 i 7 su rezultati lokalizacije uz dodat šum, pri čemu je odnos signal-šum *SNR* = 20 dB, dok su na sl. 5 i 8 predstavljeni rezultati lokalizacije pri odnosu signal-šum *SNR* = 10 dB. Bele strelice na sl. 3–8 označavaju vektore magnetskih momenata stvarnih izvora, dok zelene strelice označavaju magnetske momente lokalizovanih izvora. Lokacije strelica odgovaraju lokacijama izvora. U tabeli I dati su odnosi z komponenti električnih momenata lokalizovaih i stvarnih izvora.

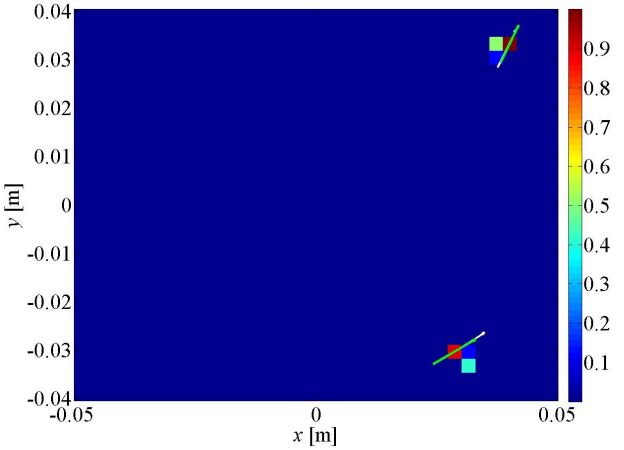
Predstavljeni rezultati potvrđuju da je opisanim algoritmom moguće izvršiti lokalizaciju, kao i procenu jačine elektromagnetskih izvora.



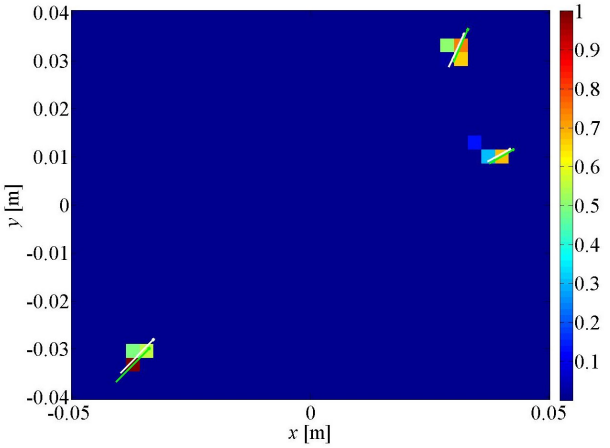
Sl. 3. Rezultati lokalizacije dva izvora bez dodatog šuma.



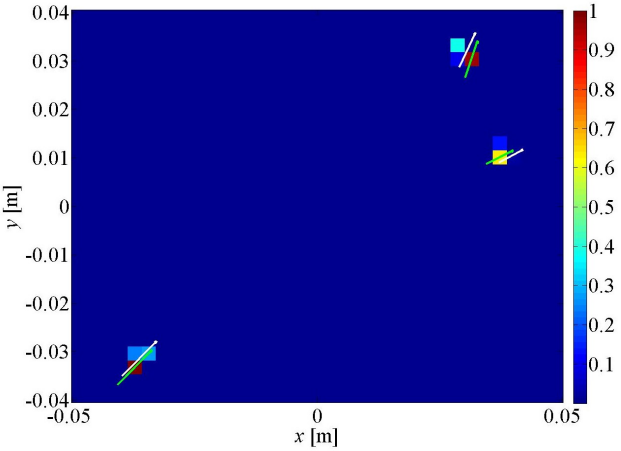
Sl. 4. Rezultati lokalizacije dva izvora sa dodatim šumom, za odnos signal-šum *SNR*=20 dB.



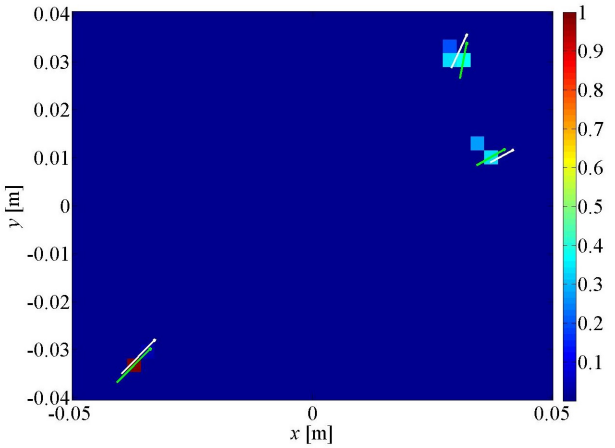
Sl. 5. Rezultati lokalizacije dva izvora sa dodatim šumom, za odnos signal-šum *SNR*=10 dB.



Sl. 6. Rezultati lokalizacije tri izvora bez dodatog šuma.



Sl. 7. Rezultati lokalizacije tri izvora sa dodatim šumom, za odnos signal-šum *SNR*=20 dB.



Sl. 8. Rezultati lokalizacije tri izvora sa dodatim šumom, za odnos signal-šum *SNR*=10 dB.

TABELA I
ODNOS *Z* KOMPONENTI STVARNIH I LOKALIZOVANIH ELEKTRIČNIH MOMENATA

$\frac{p_{z,s}}{p_{z,l}}$	bez šuma	*SNR*=20 dB	*SNR*=10 dB
2 izvora	1,02	1,02	1,00
	0,97	0,97	0,98
3 izvora	0,99	0,92	0,95
	1,03	0,93	0,87
	1,00	0,96	0,92

VI. ZAKLJUČAK

U radu je prikazan algoritam za lokalizaciju električki malih izvora elektromagnetskog polja primenom analitičkih izraza za zračenje električnih i magnetskih dipola. Primenjena je l_1 regularizacija, koja je posebno pogodna kada je broj izvora mali. Numeričke simulacije su pokazale sposobnost algoritma da odredi pozicije izvora, kao i odgovarajuće momente u slučaju dva i tri izvora. Rezultati izloženi u radu predstavljaju pripremu za budući eksperiment u kome će umesto rezultata numeričkih simulacija biti korišćeni rezultati merenja. Kao senzori za merenje polja biće korišćeni električni dipoli i magnetske petlje. Senzori mogu biti postavljeni na fiksnim lokacijama ili mogu biti fiksirani za pokretnu robotsku ruku koja ih pozicionira na željenu lokaciju. Signal sa senzora biće meren mernim prijemnikom, pri čemu je očekivani nivo signala reda veličine $-100\,\mathrm{dBm}$.

ZAHVALNICA

Ovaj rad je delimično finansiran iz projekta TR32005 Ministarstva prosvete, nauke i tehnološkog razvoja Republike Srbije i iz projekta F133 Srpske akademije nauka i umetnosti.

ABSTRACT

Sparse processing is used for the localization of electromagnetic point sources. Although this localization belongs to the class of ill-posed problems, by utilizing the l_1 regularization, i.e., a priori knowledge that the number of sources is small, it is possible to predict the locations and moments of the electric and magnetic dipoles. The proposed algorithm was tested on noiseless and noisy numerically simulated data.

Recent Results on Modeling and Control Methods Applying the "Fractional" Approach

Guido Maione, *Senior Member, IEEE*

***Abstract*—This paper illustrates some recent results the author obtained in fractional modeling and control of complex engineering systems. Obviously the description is not exhaustive and does not consider many other appreciable results given by the literature. However, by the considered applications, the author aims at proving how the paradigm of fractional-order modeling and control as opposed to the usual integer-order modeling and control can offer benefits that are sometimes unpredicted or underestimated by researchers and practitioners.**

***Index Terms*—Fractional-order models, fractional-order controllers, injection system, common rail, compressed natural gas, electro-injector.**

I. Introduction

NOWADAYS the scientific field of control systems engineering has received interesting applications in many engineering problems. Consequently, it is strategically important to know both classic tools, like PID control, and innovative methods for automatic control. It is not only a matter of industrial automation for products manufacturing or regulation and control of well-known processes involving physical variables (temperature, flow, pressure). Namely, there are many contexts (robotics, mechatronics, cyber-physical systems, networked systems, autonomous vehicles, smart cities, smart grids, energy efficiency in industry, applications with IoT and big data, healthcare systems, home and building automation, intelligent transport systems, etc.) that require effective and innovative control approaches.

This paper examines some applications in the field of automotive systems. Automotive industry is the scene of a continuous improvement of technologies that are developed and finalized to limit fuel consumption and operating costs, reduce harmful emissions (CO_2, CO, NO_x, HC, particulate matter, noise, etc.) and adhere to increasingly strict regulations. It is known that a goal in EU for 2030 is reducing greenhouse gases (GHGs) emission by at least 40% below 1990 levels, thanks to the increase of share of renewable energy, and improving energy efficiency by 27%. Moreover, the goal for 2050 is reducing GHGs emission by 80%-90% and, in particular, GHGs emission from transport by 60%.

To achieve the mentioned goals, several innovative technologies have been introduced. For example, in powertrain control, fuel injection systems, combustion systems, exhaust after-treatment devices. Alternative fuels, electrified vehicles, hybrid powertrains combining an internal combustion engine and an electric traction motor were also made available. An important contribution has also been given by intelligent transport systems, e.g. in optimization of vehicle configuration and transport tasks to improve energy efficiency, hence to reduce emissions.

To reduce fuel consumption and emissions, the automotive engines considered here are based on two peculiar approaches that employ the Common Rail Injection System technology. The first uses the conventional Diesel fuel. The second is based on compressed natural gas (CNG).

In the first case, all the components of the Common Rail Diesel Injection System (CRDIS) have received increased attention, especially in designing advanced electronic control units and electro-injectors. Moreover, efforts were spent to improve combustion strategies and to realize sensors and production process technologies for obtaining low polluting Diesel engines. The performance of CRDIS can be analyzed in terms of the available power, fuel consumption, noise reduction, pollutant emission reduction, etc. In more details, note that, to achieve an efficient combustion, the electronic control unit (ECU) of a CRDIS must accurately meter the amount of fuel and the air-fuel mixture that is injected into the cylinders. In addition, an injection rate shaping (IRS) strategy is frequently employed: the distance between main injections is very short to practically obtain an equivalent single injection according to a desired profile of the flow rate, which gives a more accurate fuel metering and a considerable emissions reduction. As for the electro-injectors, an accurate model is beneficial for optimizing their layout, parameters, and operation and for controlling IRS.

In the second case, CNG is considered because of low cost, availability in many countries, and the obvious capability to reduce pollution from harmful gaseous emissions and fuel consumption. However, for efficient combustion, accurate metering of the air-gas mixture is required by controlling both injection timing and injection pressure at specified levels. In the first case, precise adjustment is possible by the electro-injectors. In the second case, obtaining the desired levels is a challenge and defining the most adequate control technique is an open problem. Namely, the gas compressibility makes the working point of the CNG injection system change a lot, on dependence of the speed and power requested by the driver, so that complex phenomena affect the performance.

II. Why Fractional-Order Models and Controls?

As mentioned in the introduction, modeling, identification,

Guido Maione is with the Department of Electrical and Information Engineering, Polytechnic University of Bari, Via E. Orabona, 4, 70125 Bari, Italy (e-mail: guido.maione@poliba.it).

optimization and control can effectively help to solve the engineering problems of reduction of emissions and fuel consumption in automotive engines.

In particular, fractional-order models and controllers can be used. They derive from fractional calculus [32, 35], which is an ever-growing field that started from a visionary idea of Leibniz generalizing derivatives with integer order to derivatives with non-integer orders and sharing this possibility in a famous exchange of letters with L'Hôpital [39]. Later on, many scientists contributed to the field, both from the theory and from the applications point of view, in particular in automatic control. The reader is referred to [33, 36, 19, 29, 30, 3, 4, 5, 6, 10, 21], to cite just a few contributions.

But why fractional-order modeling and control should be used? In short words, these models and controllers obtain benefits with respect to integer-order ones. Namely, fractional-order differential equations (for linear or nonlinear systems) or fractional-order transfer functions (for linear time-invariant systems) are advantageous because of two main reasons:

- By using fractional calculus, fractional-order models may better describe certain real dynamical processes as heat flow, viscoelastic materials, the electro-magnetic waves propagation in biological tissues, anomalous diffusion, long-term memory effects, etc., that are efficiently represented by non-integer order models.
- The tentative to fit all the processes and systems to integer-order models can be unsuccessful or require too much effort. On the contrary, fractional calculus gives an opportunity for new ideas and better results. As Heaviside said, *"There is a universe of mathematics lying in between the complete differentiations and integrations"* [13].

As an example, in this paper, a fractional-order model of the high-pressure Diesel flow in an electro-injector of a CRDIS will be described.

On the other hand, fractional-order controllers (FOC) are exploited because they offer several advantages. Namely:

- According to Bode, a non-integer order integrator is the ideal open-loop transfer function for ensuring robustness to gain variations in the design of feedback amplifiers [2]. This ideal function was mostly equivalent to $G(s) = A_0/[1+(s/\omega_0)^{\alpha}]$, where Bode chose $\alpha = 5/3$ and achieved a phase margin of 30° for large variations of A_0. The same robustness feature can be obtained to other parametric variations as well. Also Tustin realized this benefit in motion control of massive objects subject to saturation due to power limitation [43]. Namely, Tustin suggested $G(s) = (\omega_{gc}/s)^{\alpha}$, where ω_{gc} is the gain crossover frequency and $\alpha = 1/5$. Then the slope of the asymptotic magnitude diagram was –30 dB/decade and a nearly constant phase margin of 45° was obtained over a wide range around ω_{gc}, i.e. for $0.2\ \omega_{gc} < \omega < 1.4\ \omega_{gc}$.
- Control loops compensated by FOC usually guarantee the ISO-damping feature, i.e. the closed-loop step response maintains the same maximum overshoot with gain variations. This key feature is strictly connected to the flatness of the Bode phase diagram around the gain crossover frequency, i.e. to a typical nearly constant phase margin in a sufficiently wide range around such frequency.
- Adequate realization of FOC is important. Bode designed controllers by a suitable integer number of stages to properly approximate the ideal open-loop gain in a specified frequency range. In the same way, the FOC irrational transfer function must be realized by means of a rational transfer function approximating the FOC [23, 24, 26, 27, 28, 34, 37]. The rational analog realizations must be stable, minimum-phase functions which usually show interlaced zeros and poles along the negative real half-axis in the *s*-domain [25].
- FOC improve the tradeoff between stability robustness and dynamic performance in control loops. Namely, specifications are more easily satisfied by the further design degrees of freedom provided by the non-integer orders of integration and differentiation.
- FOC can be very useful to cope with model uncertainty, disturbances, etc., and provide more flexibility in controller design by the non-integer orders of differentiation and integration.

Many successful applications of fractional-order modeling and control exists. Here, it is shown how to represent the fuel flow in an electro-injector, which is part of a common rail Diesel injection system. More in details, the obtained fractional-order system has a better ability to describe and predict a kind of wave propagation inside the injector, and hence the consequent flow rate injected into the cylinder.

Moreover, the fractional-order PI (FOPI) control of the common rail pressure in the injection system of a CNG engine will be designed and realized. The proposed control approach shows improvements with respect to the usually employed approach, which is based on gain scheduled PI controllers.

III. Fractional-Order Modeling Fuel Flow in an Electro-Injector of a CR Diesel Injection System

This section provides a fractional-order model for the fuel flow in an electro-injector of a common rail Diesel injection system. First of all, the injection system and the fuel dynamics in the electro-injector are described. Then, an integer-order model of the wave pressure propagation in the injector is introduced and a fractional-order model of the same wave pressure propagation is presented. Finally, after some information on the numerical method used to approximate time-fractional partial differential equations, simulation results compare the integer- and fractional-order models.

A. The Injection System and Electro-injector

The CRDIS is very often employed in automotive engines, especially in the light- or heavy-duty Diesel engines. To optimize combustion inside the engine cylinders, the injection system is designed to accurately meter both the fuel amount and air/fuel ratio.

The fuel flows inside the system at different pressures. In a low-pressure circuit, fuel is delivered from a tank to a first low-pressure pump providing fuel to a second high-pressure pump, which is necessary to increase pressure. In a high-pressure circuit, fuel flows from the high-pressure pump to the common rail volume, through a specific valve, and then to the electro-injectors. In a backflow circuit, fuel from the high-pressure pump, the common rail volume and the injectors is sent back to the tank. An Electronic Control Unit (ECU) controls the process in all operating conditions to regulate the pressure in the common rail to constant, high reference values. If a higher vehicle speed and an engine torque are required, the ECU determines the amount of fuel that must be injected and the necessary reference value of the common rail pressure. Moreover, the ECU commands the solenoid valve of the electro-injectors: this valve is responsible to let the fuel enter the injectors, hence to increase or decrease the pressure forces in mechanical elements of the injectors; the vertical displacement of these elements determines the opening or closing of the injectors then fuel injection into the cylinders. Basically, the ECU utilizes a PID control to achieve regulation of common rail pressure with an acceptable transient response (fast transient with limited overshoot and undershoot).

An efficient combustion into the cylinders depends on the air-fuel mixture. The ECU meters the air-fuel ratio and shapes the injected flow rate in two ways: *a*) by adjusting the opening (closing) time intervals of injectors; *b*) by regulating the fuel pressure in the common rail at the specified reference levels. Moreover, note that particular injection rate shaping strategies are commonly used. Namely, the distance between consecutive injections is established so that a single injection is obtained according to a desired *profile* of the flow rate, which gives a more accurate fuel metering and a considerable reduction of emissions. Obviously, a special attention must be paid to the electro-injectors operation and an accurate model is beneficial for both design and optimization of injectors (i.e. their layout, parameters, and operation) and for controlling the injection by shaping the fuel flow rate.

To properly describe the fuel flow in the electro-injector, both an accurate representation of nonlinear fuel dynamics and of the mechanical deformation of relevant parts are necessary. The fuel dynamics can be described by a standard integer-order model or by an innovative fractional-order model, which is based on fractional-order partial differential equations that describe the wave pressure propagation inside a specific part of the injector, as shown below. The model can be further refined by optimizing the injector layout and its mechanical parameters. Namely, internal parts of the injector are subject to pressure forces, and hence to mechanical deformations affecting the fuel flow. These parts constitute the so-called plunger-needle mechanical coupling. In details, several cylindrical parts, with different length and sections and different mechanical parameters (stiffness and mass), are linked in a top-down fashion to form the plunger and the needle. The needle element is responsible to open or close the injector nozzles, then to inject or not the fuel.

Now let us see in which way the fuel flows inside the electro-injector. Basically, two circuits can be distinguished: a *control circuit* and a *feeding circuit*. In the control circuit, fuel arriving from the common rail passes through orifices and enters into a "control chamber", in which the fuel pressure determines if the plunger-needle element is pushed down or up. In the feeding circuit, fuel arriving from the common rail flows through a high-pressure pipe, enters an accumulation volume and then a terminal "SAC" (from French *cul-de-sac*) volume, from which it is injected into the cylinders if the nozzles are open (Fig. 1).

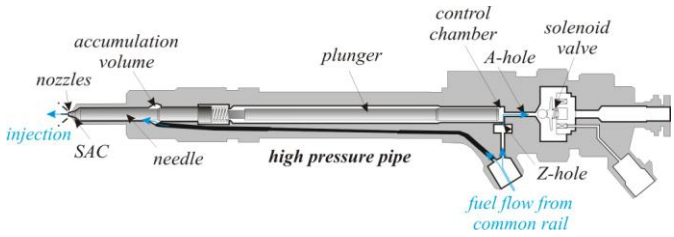

Fig. 1. Electro-injector in a common rail Diesel injection system, with its characteristic pipe to deliver fuel from the common rail volume.

More in details, fuel flow is regulated by a solenoid valve, which is employed to change the pressure acting on the plunger in the control chamber. If the valve is open, the fuel flows from the control chamber to a low-pressure zone. Then pressure on the plunger decreases and the mechanical element, namely the needle part, is pushed up by the pressure in the accumulation volume. In this case, the injector is opened because the accumulation volume is connected to the SAC volume and fuel is injected. On the contrary, if the valve is closed, the high pressure fuel from the common rail increases the pressure in the control chamber that pushes down the plunger (and the needle). In this case, injection is stopped because the needle part closes the nozzles at the end of the SAC volume.

Note that the fuel is compressible, that the feeding pipe is subject to elastic deformation, and that distributed friction losses occur. Moreover, since the needle in the injector is opened and closed very quickly, a kind of water hammer effect generates in the injector pipe. Also cavitation through the holes is considered. Finally note that a pressure wave is generated and damped because of viscous effects. As shown below, this wave propagation is better described by the proposed fractional-order model.

B. Integer-order Model

The complete model is obtained by partitioning the injector in connected volumes in which fuel is accumulated. For some of these volumes, a lumped parameters representation is suitable because the pressure is uniform and time-varying and there is no wave propagation. Then ordinary differential equations are sufficient. For other volumes, namely the elements of the injector pipe, a distributed parameters model is necessary because pressure is nonuniform and time-varying and a wave propagation is experimentally observed. For these

volumes, partial differential equations are used.

Other important assumptions are that the moving elements, i.e. the components of the plunger-needle mechanical coupling, are subject to elastic deformation. Moreover, fuel parameters depend on pressure but not on temperature.

To summarize, the mathematical model is obtained by applying the continuity equation, the momentum equation, the Newton's second law of motion, and the Faraday's law.

The lumped parameters representation is used to represent how pressure p changes with volume v due to the motion of mechanical elements and with intake and outtake flow rates q_i. In general, it can be written:

$$\frac{dp}{dt} = -\frac{K_f}{v}\left(\frac{dv}{dt} - q_l + \sum\nolimits_i q_i\right), \tag{1}$$

where K_f is the Bulk modulus for compressible fuel, q_l is the leakage flow rate, $q_i = \mathrm{sgn}(\Delta p_i)\, c_d\, A_0 \sqrt{2\,\rho_i^{-1}\,|\Delta p_i|}$, in which Δp_i is the pressure gradient across the flow section A_0, c_d is the discharge coefficient, and, finally, ρ_i is the fuel density.

As regards the motion of mechanical elements in the injector, the instantaneous flow sections and volumes depend on the axial displacement of the moving elements. In particular, the displacement of the valve shutter changes the section between the control chamber and the low-pressure zone in which the valve is located. Moreover, the displacement of the plunger-needle coupling changes the section between the accumulation volume and the SAC volume. Moreover, the Newton's second law of motion can be applied to the valve anchor-shutter coupling and to the plunger-needle coupling. Note that, to represent elastic deformation and contact forces, the plunger-needle is modeled as a series of mass-spring-damper systems.

If the high-pressure pipe between the common rail and the accumulation volume is considered, a distributed parameters representation is necessary to describe the wave pressure propagation. Then the classical Navier-Stokes partial differential equations can be used to model fuel dynamics. They originate the standard continuity and momentum equations that are respectively specified as follows:

$$\frac{\partial p}{\partial t} + c_0^2\,\rho_0^2\,\frac{\partial u}{\partial x} = 0\,, \tag{2}$$

$$\frac{\partial u}{\partial t} + \frac{1}{\rho_0}\frac{\partial p}{\partial x} - (\lambda + 2\mu)\frac{\partial^2 u}{\partial x^2} = 0\,, \tag{3}$$

where $p = p(t,x)$ is the fuel pressure depending on time t and on the location x on the (unique) direction of propagation along the pipe, $u = u(t,x)$ is the fuel wave velocity, $c_0 = c_0(p)$ is the speed of sound, $\rho_0 = \rho_0(p)$ is the density, $\lambda = \lambda(p)$ is the dilatation viscosity, $\mu = \mu(p)$ is the dynamic viscosity. If the Stokes' assumption holds, then $\lambda = -2\mu/3$ and the extended wave equation is obtained:

$$\frac{\partial^2 p}{\partial t^2} = c_0^2\,\frac{\partial^2 p}{\partial x^2} + \frac{4\mu}{3\rho_0}\,\frac{\partial}{\partial t}\left(\frac{\partial^2 p}{\partial x^2}\right), \tag{4}$$

which provides a classical integer-order model of wave pressure propagation in the considered pipe.

C. Fractional-order Model

Although there is not a clear evidence of fractional fluid dynamics, the model can be changed to a non-integer order one. Namely, in this way, a better fitting to experimental data will be obtained, as shown below. Moreover, it was shown that since several fluids are characterized by hereditary dependencies of power type [44], then fractional calculus tools based on non-integer-order time derivatives become essential.

The first idea is to extend equations (2) and (3):

$$\frac{\partial^\alpha p}{\partial t^\alpha} + c_0^2\,\rho_0^2\,\frac{\partial u}{\partial x} = 0\,, \tag{5}$$

$$\frac{\partial^\beta u}{\partial t^\beta} + \frac{1}{\rho_0}\frac{\partial p}{\partial x} - \frac{4\mu}{3}\frac{\partial^2 u}{\partial x^2} = 0\,, \tag{6}$$

in which the non-integer orders are $0 < \alpha \le 1$ and $0 < \beta \le 1$. The limit unitary value allows to perform comparisons with the integer-order model.

Remark. One could question about the physical meaning of equations (5)-(6). A physical explanation of (5) and (6), showing how conservation laws are preserved, can be obtained by starting from the Navier-Stokes equations and using fractional viscosity, but it is not the scope of this paper. However, as shown below, this model provides a better fitting to experimental data than a classical integer-order model.

To the best of the author's knowledge, equations (5)-(6) can not be analytically solved. Then an approximating numerical method is employed by using boundary conditions, i.e. the instantaneous pressures and flows at the pipe inlet and outlet sections. In particular, the input pressure is available from measurements of the common rail pressure, while the output pressure in the accumulation volume can be obtained by integration of (1). The method is based on finite differences [12, 11]. Discretization of time-fractional derivatives uses the Grünwald-Letnikov scheme for its excellent stability properties. The approximations are inserted in the momentum and continuity equations in a mixed implicit/explicit way.

Discretization of space derivatives is based on partitioning the pipe in several distinct volume cells. A staggered grid is obtained. Pressure is computed at the center of each cell, and speed is computed on every face between two adjacent cells. For details about the fully discretized fractional-order partial differential equations and their solution, see [12, 11].

D. Comparison by Simulation of Non-Optimized Integer-Order and Fractional-Order Model

Simulation was performed in the MATLAB/Simulink environment. Experimental data for the injected flow rate are available in the following conditions: the exciting time interval of injectors is 700 μs, the common rail reference pressure is 800, 1200, and 1600 bar. Then simulation will compare results with these data. Moreover, the real common rail pressure is used as input to the pipe. A constant uniform pipe section is assumed, the time discretization points are $3000 \leq N \leq 10000$, the space discretization points are $20 \leq M \leq 100$. The non-integer orders α and β are varied to evaluate the effect on model prediction capability.

A first test with $\alpha = \beta$ was made in the most common condition (1600 bar). See Fig. 3 in [12]. The best fitting to experimental data was obtained with $\alpha = \beta = 0.8$. Lower values provide an output in an injection interval that is too small, which is not acceptable for the consumption and emissions. The case $\alpha = \beta = 1$ gives the integer-order model.

A second test with $\alpha \neq \beta$ was made, by setting one order to 1 and letting the other vary as non-integer number. Also in this case, data from the 1600 bar condition were used. See Fig. 4 in [12]. The best results were obtained with $\alpha = 1$, $\beta = 0.95$ or $\alpha = 0.85$, $\beta = 1$. The results somewhat improve the fitting with respect to the case $\alpha = \beta$.

A third test with $\alpha \neq \beta$ was made, in this case allowing any non-unitary, non-integer values for the two orders. All the three cases of experimental data were considered for comparison (1600, 1200 and 800 bar). See Fig. 6 in [12]. The best results were provided by $\alpha = 0.85$, $\beta = 0.98$. The matching to experimental data from a real electro-injector is acceptable if one considers the simplifying assumptions (uniform pipe section, non-optimized values of mechanical parameters of plunger and needle) and the approximation by the numerical method to solve the fractional partial differential equations. Moreover, the model allows prediction of the injected flow rate in several working conditions.

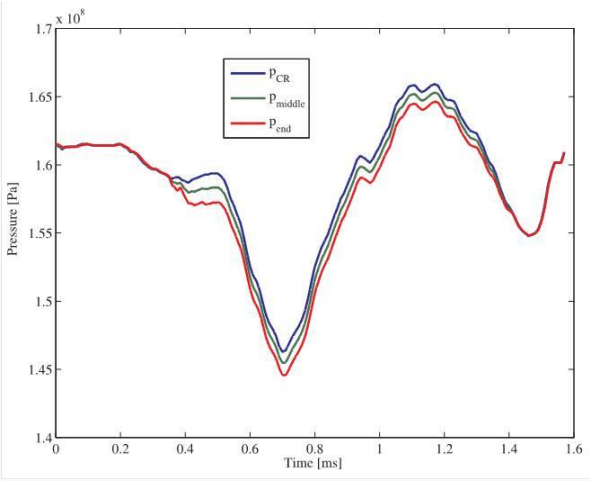

Fig. 2. Pressure trend in three different pipe sections.

To further confirm that results from the fractional-order model are correct, the pressure trend in three different pipe sections is shown in Fig. 2. The sections are at the input, middle and output of the pipe (the input pressure is the common rail pressure). It is clear that a wave propagation is obtained in all sections.

E. Optimization of Fractional-order Model

A further improvement is obtained by optimizing the non-integer orders α and β and the values of mechanical parameters in the representation of the plunger and needle as a series of ideal spring-mass-damper systems. This optimization is important because the deformation of the plunger-needle coupling, which is due to pressure forces, changes the cross-section of flow through the nozzles, namely the cross-section below the needle tip.

In particular, the coupling is divided in seven cylinder elements, each being characterized by a different section and mass m_i ($i = 1, \ldots, 7$). The plunger is formed by five cylinders, the needle by two cylinders. As a consequence, the first and last mass elements in the series model are characterized by one-half of the mass of the first and last cylinders, respectively, whereas every other mass element in the model has half of the masses of two adjacent cylinders (see Table I). Moreover, springs (with elastic constants) and dampers (with viscous damping coefficients) connect the masses as specified in Table I and only one spring links the plunger and needle. The issue is finding the optimal parameters that improve model prediction and correspondence to real measurements of the injected flow rate.

TABLE I
MECHANICAL MODEL PARAMETERS

Mass	Value
M_1	$m_1/2$
M_2	$(m_1+m_2)/2$
M_3	$(m_2+m_3)/2$
M_4	$(m_3+m_4)/2$
M_5	$(m_4+m_5)/2$
M_6	$m_5/2$
M_7	$m_6/2$
M_8	$(m_6+m_7)/2$
M_9	$m_7/2$
Spring, damper coefficients	Element location
k_1, c_1	Between M_1 and M_2
k_2, c_2	Between M_2 and M_3
k_3, c_3	Between M_3 and M_4
k_4, c_4	Between M_4 and M_5
k_5, c_5	Between M_5 and M_6
k	Between M_6 and M_7
k_6, c_6	Between M_7 and M_8
k_7, c_7	Between M_8 and M_9

For each mass M_i in the model, the following general equation is derived from the Newton's second law:

$$M_i\,\ddot{z}_i + c_{i-1}(\dot{z}_i - \dot{z}_{i-1}) + c_i(\dot{z}_i - \dot{z}_{i+1}) + \\ + k_{i-1}(z_i - z_{i-1}) + k_i(z_i - z_{i+1}) = \sum_i F_i\,, \tag{7}$$

where z_i is the deformation of M_i, $k_i = E\,A_i / l_{0i}$, with E being the Young's modulus, A_i the cross-section area of the considered cylinder, l_{0i} the initial length of the cylinder, $c_i = 0.01\sqrt{k_i\,M_i}$ [9] and the right side of (7) specifies pressure forces. Solving the system of equations resulting from (7), provides the displacement z_9, which determines the position of the needle tip, i.e. the outflow section from the SAC volume to the nozzles, then the injector closing/opening, and depends on all the pressures and the valve command.

Given the relation between c_i and k_i, the parameters under optimization are k_i, for i = 1, …, 7. In particular, an evolutionary technique named Differential Evolution is employed to overcome the nonlinearity and complexity of the problem. If $\mathbf{x} = [k_1\ k_2\ k_3\ k_4\ k_5\ k_6\ k_7\ \alpha\ \beta]$, the cost function is

$$J(\mathbf{x}) = \sum_{t_j} \left| y_{\mathrm{mod}}(t_j, x) - y_{\mathrm{exp}}(t_j) \right|, \tag{8}$$

where $y_{\mathrm{mod}}(t_j, \mathbf{x})$ is the output (injected flow rate) predicted by the simulation model at the sampling time instant t_j and depending on the current parameter values in $\mathbf{x}$, while $y_{\mathrm{exp}}(t_j)$ is the experimental output value at t_j. The initial parameter values are given by the theoretical values specified by geometrical dimensions. Minimization of $J(\mathbf{x})$ is subject to the following constraints:

$$\begin{aligned} & k_7 < k_2 < k_3 < k_5 < k_4 < k_1 < k_6\,, \\ & 0 < \alpha < 1, \\ & 0 < \beta < 1, \\ & \left(1 - \frac{pv_1}{100}\right)\mathbf{x}_{\mathrm{nom}} < \mathbf{x} < \left(1 + \frac{pv_2}{100}\right)\mathbf{x}_{\mathrm{nom}}\,, \end{aligned} \tag{9}$$

where the first inequalities express the geometrical differences among the cylinders that compose the plunger and needle hence the different stiffness. The last inequalities define the search space for each component of $\mathbf{x}$, by expressing the maximum allowed variation as a function of the nominal parameter values in $\mathbf{x}_{\mathrm{nom}}$ given by the previously specified theoretical values. The percentage variations $0 < pv_1 < 100$ and $0 < pv_2 < 100$ are set at the beginning of the optimization.

Differential Evolution (DE) [42, 45, 38, 8, 7] efficiency allows to save time and to perform optimization with time and computational constraints, moreover DE has superior performance and robustness with respect to other evolutionary techniques [45]. DE works as follows. It improves a population of N_{pop} possible solutions $\{\mathbf{x}_{ig},\ i = 1, \ldots, N_{\mathrm{pop}}\}$ through evolution of successive generations (g = 0, 1,…, $G_{\max}$) aiming at a solution as close as possible to the optimum [38]. The search space is defined by $\mathbf{x}_{\min} \le \mathbf{x}_{ig} \le \mathbf{x}_{\max}$, where the minimum and maximum are specified by (9).

The initial population (g = 0) is randomly taken from a uniform distribution

$$\mathbf{x}_{i0}(j) = \mathbf{x}_{\min}(j) + r\,[\mathbf{x}_{\max}(j) - \mathbf{x}_{\min}(j)]\,, \tag{10}$$

for j = 1, …, 9, i.e. for each component of $\mathbf{x}$, where r is a random number between 0 and 1. Then it is evaluated as every generation, by using $J(\mathbf{x}_{i0})$ for all i. Evolution goes until the optimum or the final maximum generation is reached. N_{pop} and $G_{\max}$ are usually determined by trial and error.

In each generation, DE performs mutation, crossover and selection. Mutation is to better explore the search space. For each candidate $\mathbf{x}_{ig}$, it creates a mutant $\mathbf{v}_{ig}$ by using other three candidate solutions:

$$\mathbf{v}_{ig} = \mathbf{x}_{i1g} + F\,[\mathbf{x}_{i2g} - \mathbf{x}_{i3g}]\,, \tag{11}$$

where $0 < F < 2$ is a scaling factor, and $i1$, $i2$, and $i3$ are mutually exclusive integer numbers, distinct from the integer number i, and each between 1 and N_{pop}.

Crossover increases diversity and includes best solutions from the previous generation. It creates a new solution $\mathbf{u}_{ig}$ that inherits at least one component from $\mathbf{v}_{ig}$:

$$\mathbf{u}_{ig}(j) = \begin{cases} \mathbf{v}_{ig}(j) & \text{if } r \le CR \text{ or } \quad j = j_r \\ \mathbf{x}_{ig}(j) & \text{if } r > CR \text{ and } \quad j \ne j_r \end{cases} \tag{12}$$

where $0 < CR < 1$ is a crossover ratio, r is a random number from the uniform distribution between 0 and 1, and $j_r \in \{1,\ldots,9\}$ is taken from the uniform distribution.

Selection determines the best solutions that must be considered in the new generation $h = g+1$:

$$\mathbf{x}_{ih}(j) = \begin{cases} \mathbf{x}_{ig} & \text{if } J(\mathbf{x}_{ig}) < J(\mathbf{u}_{ig}) \\ \mathbf{u}_{ig} & \text{if } J(\mathbf{u}_{ig}) \le J(\mathbf{x}_{ig}) \end{cases} \tag{13}$$

The optimized values of parameters are shown in Table II.

TABLE II
OPTIMIZED PARAMETERS

Parameter	Optimized Value
α	0.975
β	0.900
k_1	1.44×10^8
k_2	6.21×10^7
k_3	8.62×10^7
k_4	1.23×10^8
k_5	1.01×10^8
k_6	3.50×10^8
k_7	7.68×10^7

F. Comparison by Simulation of Optimized Integer-Order and Fractional-Order Model

Two phases are distinguished. A first phase in which the model is tested in the condition of 1600 bar. A second "validation" phase in which the model is tested in the other conditions of 1200 and 800 bar. In all cases, the excitation time interval of injectors is kept the same (700 μs). The injected flow rate is measured for about 1.2 ms.

The injection flow rate predicted by the model is compared with the available experimental flow rate in the mentioned conditions. Moreover, comparison is made with prediction by the nominal model related to non-optimized parameter values for coeffiecients k_i and c_i.

Finally, as term of comparison, the flow rate given by a simplified model, in which the plunger-needle coupling is considered as a unique rigid body that is not subject to deformation by pressure forces.

In all cases, results confirm that the optimized model gives the best fitting. See Table III that provides the values of the optimization index in all considered cases. As it is shown, the rigid body model gives much higher values because the model prediction is not effective. The nominal model improves the prediction, but not as much as the optimized one that gives a significant optimization function reduction.

TABLE III
OPTIMIZATION INDEX BY VARIOUS MODELS

Model	Optimization Index J
Rigid-body 1600 bar	1486
Nominal 1600 bar	681
Optimized 1600 bar	164
Rigid-body 1200 bar	1529
Nominal 1200 bar	794
Optimized 1200 bar	171
Rigid-body 800 bar	1706
Nominal 800 bar	738
Optimized 800 bar	145

IV. FRACTIONAL-ORDER CONTROL OF COMMON RAIL PRESSURE IN CNG ENGINES

Compressed natural gas (CNG) prototype engines were proposed to reduce costs and consumption, to take advantage of gas reservoirs and wide-spread gas distribution, and to drastically reduce polluting emissions [16].

To achieve combustion efficiency, an accurate metering of the air-fuel mixture is required. To this aim, the metering system is based on the common rail technology and electro-injectors (usually four in number). Two modalities are contemporaneously used.

The first involves the control of injection timing and guarantees a precise adjustment by commanding the opening and closing of electro-injectors. The second controls injection pressure in the common rail volume at required reference levels. This last control problem is a challenge. Namely, difficulty arises mainly from gas compressibility and the working points of the injection system, depending on power and speed requirements, vary a lot. Therefore complex phenomena and disturbances occur.

In the CNG engine injection system (Fig. 3), gas is delivered from a high-pressure tank (40-200 bar) to a common rail volume (4-20 bar). Since the pressure in the tank slowly varies, it can be assumed constant in a large time interval.

Gas flows through different pipes and passes through a mechanical pressure reducer, in which a piston separates a control chamber from a main chamber, in its turn linked to the common rail volume.

A solenoid valve regulates the flow into the control chamber. It may let more gas enter the control chamber, then push the piston down, open an inflow section from the tank to the main chamber, hence to let more gas arrive to the common rail. Otherwise, if the valve closes, less gas in the control chamber is obtained, the gas in the main chamber pushes the piston up and the outflow section to the main chamber is closed under the action of a spring: in this case, less gas arrives to the common rail. The valve and all the process is under control of an electronic control unit (ECU).

The flow injected into the cylinders depends on the common rail pressure and the opening time intervals of injectors, both controlled by the ECU. Namely, the ECU determines the common rail pressure and controls gas flow by setting the injection timing (which depends on the required speed and applied load) and the current driving the valve.

To derive an analytical model, the system is divided in connected control volumes in which the fuel flows and the pressure is uniform. The pipes are uncompressible and not directly represented to describe pressure propagation. Also the transient intervals in which injectors open or close are neglected with respect to the main gas dynamics, as well as the dynamics of mechanical parts of the valve (i.e. the anchor and shutter) because inertia is small and the valve vertical displacement is limited. Finally, the inertia of the piston and the shutter closing the main chamber are neglected.

By applying physical laws (continuity law, conservation of momentum, Newton's second law), a nonlinear mathematical model is obtained in the state-space form [16]. The chosen state variables are the pressures in the control chamber (x_1) and in the common rail (x_2). The main chamber is not considered because its pressure is almost equal to the rail pressure. The available inputs are the command to the valve (u_1) and to the injectors (u_2), the last being considered as a disturbance. The obvious output is the rail pressure: $y = x_2$.

The injection system works in several conditions that depend on the driver power request, the engine speed, and the applied load. On their basis, the output must properly reach a reference level.

In practice, the ECU sets the proper value of the command to injectors and the reference for the output, and controls the process by the valve regulation until the actual output reached the reference one.

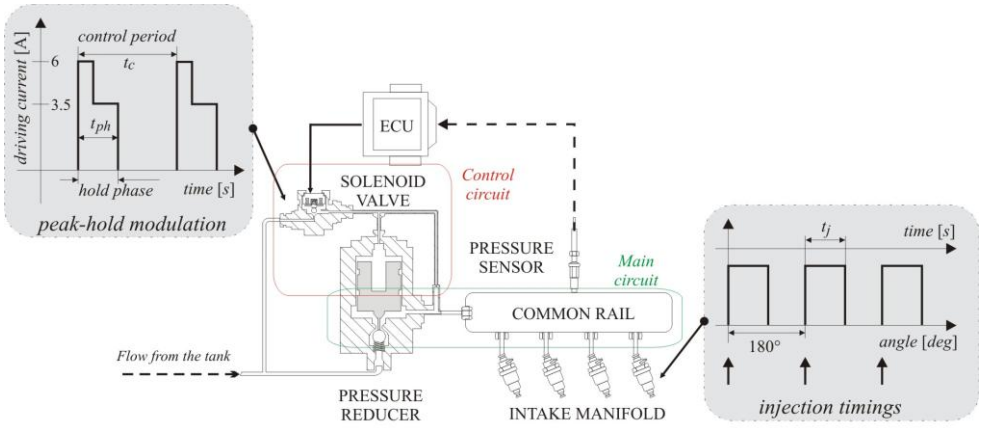

Fig. 3. Operation of the CNG injection system.

Since the system dynamics is through transition among several working points, the equilibrium points of the mathematical model are considered. Then, the variations with respect to the equilibrium values of u_1 and y are considered as input and output. It follows that linearization around working points and Laplace transform of the linearized system provide a transfer function, which can be expressed as a first-order system by considering the dominant pole only:

$$G_p(s) = \frac{K_e}{1+T_e} e^{-L_e s}, \tag{14}$$

where K_e is the equivalent static gain, T_e is the equivalent time constant, L_e is the equivalent dead-time. The triple (K_e, T_e, L_e) depends on the working point, in particular on the pressure in the tank. Hence a family of models is obtained. However L_e can be assumed constant to represent the pressure propagation delay from the main chamber to the common rail.

A. Design of the Fractional-Order Controller

The control methodology employs fractional-order controllers and gain scheduling. Fractional-order PI (FOPI) controllers improve robustness with respect to integer-order PI controllers, for each considered working point. Gain scheduling is used to switch between FOPI controllers that are designed for different working points: namely, the gain scheduling approach is very common in industry and allows switching from one controller to another in order to adapt to various working points.

In more details, the FOPI controllers are designed for specific reference working points by a loop-shaping technique [17], which is reinforced by the *D*-decomposition methodology [18]. The loop-shaping technique allows to achieve a good tradeoff between frequency-domain performance specifications for an optimal feedback system and robustness specifications for a nearly constant phase margin in a sufficiently wide frequency range. The *D*-decomposition approach enhances the robust stability of the closed-loop system.

Remark. In the problem of pressure control of injection systems, PI controllers are mostly applied, as well as in more than 90% of the industrial control loops [1]. This fact shows one more time, namely for automotive industry and for an important purpose, that FOC (in this case FOPI controllers) can give benefits with respect to integer-order controllers. Moreover, the tuning of FOPI controllers [17] takes inspiration and properly modifies popular rules used for PI controllers, namely the symmetrical optimum method [15].

The controller design takes advantage of the Bode's idea on the optimal open-loop frequency response [2]: it consists in shaping the asymptotic gain diagram, mainly in choosing the slope of the segment crossing the frequency axis, and maintaining this slope in a wide frequency interval around the crossover frequency. Hence the phase will have a nearly flat trend and the phase margin will be constant in the same interval. This characteristic is a clear indication of stability robustness even for high gain variations.

Moreover, to obtain an optimal feedback system in the Kalman's sense [14], in a unitary feedback loop with the closed-loop transfer function $F(s) = 1/[1 + G^{-1}(s)]$, a high open-loop gain $|G(j\omega)|$ would be required for each ω, such that $|1 + G^{-1}(j\omega)| \approx 1$ and $|F(j\omega)| \approx 1$. Namely, this condition would imply an almost perfect input-output tracking. To avoid stability problems, $|G(j\omega)|$ is shaped to get high gains at low frequencies and a roll off at high frequencies [40].

Then the practical procedure is in two steps: *a*) to choose the bandwidth in which optimality is desired and determine the crossover frequency where to guarantee a specified phase margin; *b*) to determine the fractional integrator so that the phase plot of the open-loop gain is nearly flat (constant phase margin) in a sufficiently large range around the crossover frequency.

Consider the controller

$$G_C(s) = K_P + \frac{K_I}{s^\nu} = \frac{K_I\,(1+T_I\,s^\nu)}{s^\nu}, \tag{15}$$

where K_P and K_I are the proportional and integral gains, $T_I = K_P/K_I$ and $1 < \nu < 2$, which adds an integer-order integrator (not in the plant) to obtain zero steady-state error to reference step input and to reject disturbance. Then the open-loop frequency response $G(j\omega) = G_c(j\omega)\, G_p(j\omega)$ is given by:

$$G(j\omega) = \frac{K_I K_e [1 + T_I\, \omega^{\nu}\, (C + jS)]\, e^{-j\omega L_e}}{\omega^{\nu}\, (C + jS)\, (1 + j\omega T_e)}, \qquad (16)$$

where $C = \cos(\nu\pi/2)$ and $S = \sin(\nu\pi/2)$. Then the magnitude and the phase are:

$$|G(j\omega)| = \frac{K_I K_e}{\omega^{\nu}} \sqrt{\frac{1 + 2T_I \omega^{\nu} C + T_I^2 \omega^{2\nu}}{1 + \omega^{\nu} T_e^2}}, \qquad (17)$$

$$\langle G(j\omega) = \operatorname{atan}\left(\frac{T_I \omega^{\nu} S}{1 + T_I \omega^{\nu} C}\right) - \operatorname{atan}(\omega T_e) - \omega L_e - \frac{\nu\pi}{2}. \qquad (18)$$

Now the first specification is enforced on the bandwidth ω_B in which to ensure input-output tracking. The gain crossover frequency is estimated by $\omega_C \in [\omega_B/1.7,\ \omega_B/1.3]$, for example $\omega_C = \omega_B/1.5$, according to a rule of thumb [20, 22]. The phase is set to be constant around ω_C. Then the phase margin computed at ω_C, i.e. $PM = \langle G(j\omega_C) + \pi$, should be in its turn constant in a range around ω_C. This requirement implies that

$$PM = \operatorname{atan}\left(\frac{T_I \omega_C{}^{\nu} S}{1 + T_I \omega_C{}^{\nu} C}\right) - \operatorname{atan}(\omega_C T_e) - \omega_C L_e - \frac{\nu\pi}{2} + \pi \qquad (19)$$

is set equal to $PM = \pi - \pi\nu/2 = (2-\nu)\,\pi/2$. As it can be verified after applying simple algebra, the only way to get this result is to choose:

$$T_I = \frac{\omega_C T_e + \tan(\omega_C L_e)}{\omega_C{}^{\nu}[(S - \omega_C T_e C) - (C + \omega_C T_e S)\tan(\omega_C L_e)]}. \qquad (20)$$

Given the phase margin specification PM_S, it holds:

$$PM_S = (2-\nu)\frac{\pi}{2} \Leftrightarrow \nu = 2 - \frac{PM_S}{\pi/2}. \qquad (21)$$

The last two relations show the strict link that is obtained between the fractional order and the phase margin. A specification on the phase margin imposes the value of ν. Moreover, the left side of (20) shows that a selected value of determines the phase margin that can be obtained.

By putting $|G(j\omega_C)|=1$, the integral gain is obtained:

$$K_I = \frac{\omega_C^{\nu}}{K_e} \sqrt{\frac{1 + \omega_C^{\nu} T_e^2}{1 + 2T_I \omega_C^{\nu} C + T_I^2 \omega_C^{2\nu}}}. \qquad (22)$$

B. Realization of the Fractional-Order Controller

Since the fractional integral operator and the associated FOPI controller are infinite-dimensional and irrational, the controller can be realized only by an approximation specified by a rational transfer function. To this aim, many different approximating methods exist, among which the most popular is the Oustaloup's recursive approximation [34].

For a control purpose, it is important that the rational transfer function is characterized by stable poles and minimum-phase zeros. Moreover, zeros and poles are usually chosen alternating on the negative real half-axis: this property is referred to as interlacing between zeros and poles [25]. Also, the number n of zero-pole pairs should be limited to simplify the realization.

An efficient method to obtain stable poles interlaced with non-minimum phase zeros is based on a continued fraction expansion (CFE) [24]. By this method, the truncated CFE that specifies the so-called *convergent* can be converted to a rational transfer function of order n by simple formulas. It holds, for $0 < \nu < 1$:

$$s^{\nu} \approx \frac{p_{n,0}\, s^n + p_{n,1}\, s^{n-1} + \ldots + p_{n,n-1}\, s + p_{n,n}}{q_{n,0}\, s^n + q_{n,1}\, s^{n-1} + \ldots + q_{n,n-1}\, s + q_{n,n}}, \qquad (23)$$

where the numerator and denominator coefficients are provided by the following closed-form expressions [24]

$$p_{n,j} = q_{n,n-j} = (-1)^j \binom{n}{j} (\nu + j + 1)_{(n-j)}\, (\nu - n)_{(j)}, \qquad (24)$$

for $j = 0, \ldots, n$. In such expression, $\binom{n}{j}$ is the binomial coefficient and the other two factors are Pochhammer functions:

$$\begin{cases} (\nu + j + 1)_{(n-j)} = (\nu + j + 1)\,(\nu + j + 2)\cdots(\nu + n), \\ (\nu - n)_{(j)} = (\nu - n)\,(\nu - n + 1)\cdots(\nu - n + j - 1), \end{cases} \qquad (25)$$

in which the first function includes n–j factors and the second function includes j factors. Note that it is set $(\nu+n+1)_{(0)} = 1$, if $j = n$ in the first function, and $(\nu-n)_{(0)} = 1$, if $j = 0$ in the second function. Obviously, if the fractional integral operator $1/s^{\nu}$ must be approximated, the reciprocal of (23) is considered. Usually an order $n = 5$ or 6 is sufficient to obtain a good approximation. If an approximation for $1 < \nu < 2$ is required, then the operator is split as $s^{\nu} = s\, s^{\nu-1}$, such that the factor $s^{\nu-1}$ is approximated according to (23).

Interlacing between simple, real negative poles and zeros is often achieved in an empirical way. Instead, it was proven that the described CFE-based method guarantees interlacing in a systematic way by closed-form formulas [25]. This result was achieved thanks to the special structure of the employed CFE and to the Stieltjes' form of continued fraction [41].

C. Robust Stability Analysis by D-decomposition

The employed loop-shaping technique to design the FOPI controllers guarantees a robust control system. This can be verified by the *D*-decomposition methodology, which is a classical approach for robust stability analysis [31].

Namely, this approach allows to determine the entire domain/set *D* of controller gains leading to a stable closed-loop system. If PI/PID controllers are used, this set is defined in a two- or three-dimensional space and, once the controller gains are fixed, a point in the set is determined. The approach is beneficial for two main reasons:

- It avoids time-consuming stability checks of new controller settings required for new working conditions. Checking should be frequent due to the fact that the reference rail pressure changes, as previously explained.
- If the point associated to the designed controller gains is far from the set boundary, then stability is still ensured for bounded variations that can be graphically observed.

The approach is based on the analysis of the roots of the fractional-order characteristic pseudo-polynomial equation, which can be derived by $F(s) = 1+G(s) = 0$ where $G(s)$ is specified in (16), in the frequency domain:

$$E(s) = (1+T_e\, s)\, s^{\nu} + K_e\, K_I\, (1+T_I\, s^{\nu})\, e^{-L_e s} = 0\,. \quad (26)$$

If all roots of (24) lie in the open left-half of the *s*-plane (LHP roots), then the closed-loop system is BIBO stable.

The set *D* of stabilizing controllers can be defined as follows: if $(K_P, K_I, \nu) \in D$ then all roots lie in the LHP.

D is usually defined by determining its boundaries: the real root boundary (RRB), the infinite root boundary (IRB), and the complex root boundary (CRB). RRB comes from the solutions of $E(s = 0) = 0$: in the present case of a FOPI controller, $K_I = 0$. IRB is defined for $s \to \infty$ and does not exist. CRB comes from the solutions of $E(s = j\omega) = 0$:

$$\begin{cases} K_P(\omega) = \dfrac{(\omega T_e S - C)\sin(\omega L_e) - (S + \omega T_e C)\cos(\omega L_e)}{K_e S}, \\ K_I(\omega) = \dfrac{\omega^{\nu}[\sin(\omega L_e) + \omega T_e \cos(\omega L_e)]}{K_e S}, \end{cases} \quad (27)$$

where $C = \cos(\nu\pi/2)$, $S = \sin(\nu\pi/2)$, and $\omega \in (0,\infty)$. If the fractional order ν is varying, the complete three-dimensional stability domain is obtained. Otherwise, by fixing ν and letting ω to change, a closed curve defines the stability region in the two-dimensional space of coordinates K_P and K_I.

Now assume to consider a specific working condition, which is typically specified by the desired common rail pressure, the injection time interval, and the engine speed. This condition determines the plant parameters (K_e, T_e, L_e), then assume to design a FOPI controller with reference to the condition and the associated reference value of the common rail pressure. FOPI parameters are represented by a point in the stability region (see Fig. 4). This point corresponds to the specified crossover frequency ω_C (then to the bandwidth ω_B) and phase margin PM_S. More in details, it belongs to a relative stability line that can be determined by using the specified phase margin.

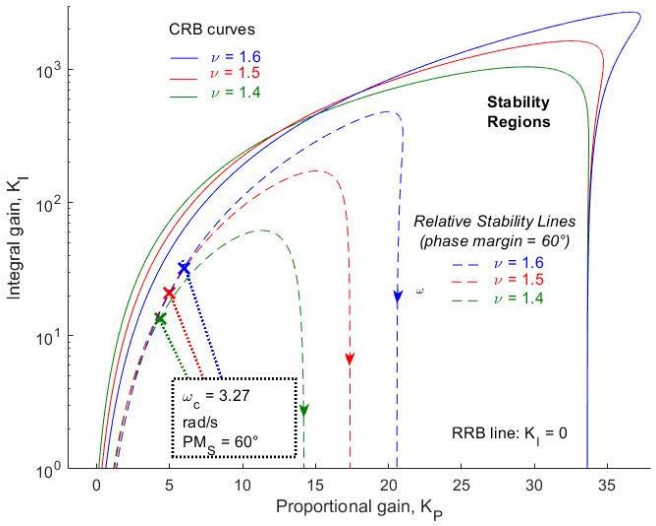

Fig. 4. Stability regions (with CRB curves and IRB line) and relative stability lines for different fractional orders (1.4, 1.5, 1.6) to obtain performance specifications (crossover frequency and phase margin) for a representative working point.

If ν changes, the specified and obtained phase margin changes by (21), then both the relative stability line and the CRB curve of the stability region change (see Fig. 4). However, for each value of ν, the point lies in the stability region and the system is robustly stable. The distance between the CRB curve and the point (its relative stability line) gives a measure of robustness.

Moreover, if the bandwidth specification is modified while the desired phase margin is not, then the point moves along the relative stability line and stays inside the stability region.

One could also consider the relative stability line (not shown in Fig. 4) associated to a gain margin specification GM_S: the point would correspond to the phase crossover frequency.

D. Controllers Gain Scheduling

In industry, to adapt to different working conditions in which the common rail pressure varies to a large extent, it is common to use gain scheduling. Integer-order PI controllers are tuned by heuristic rules and their parameters are adapted by simple gain scheduling. Then, if the injection system operation must change from one condition to another, there is a switching from one PI controller to another, the last being determined by the condition to reach. It is easy to understand that each condition (set of plant parameters) requires a different controller to keep the rail pressure close to the reference value for that condition.

Here the new strategy is to use a FOPI controller for each condition and a new gain scheduling technique. Firstly, a FOPI increases the robustness-performance balance for each

condition. Secondly, the gain scheduling to switch between FOPI controllers is based on a sensitivity analysis of model coefficients.

In details, for each tank pressure of the CNG injection system, the working condition is determined by the reference value of the common rail pressure (p_{CR}) and the average duration of injection (t_{inj}). Assume step variations (worst case) of such variables from an initial to a final working condition. The gain scheduling technique distinguishes two cases:

- *I) Small variations*, in which p_{CR} is bounded by 2 bar and t_{inj} by 6 ms: in this case only one controller is designed with reference to the parameters (K_e, T_e, L_e) of the final working point to reach.
- *II) Large variations*, in which intermediate reference values are considered for p_{CR} and t_{inj}, then intermediate values of (K_e, T_e, L_e) and associated intermediate controllers.

By this technique, a smooth transition between sufficiently close working points is achieved so that each controller guarantees stability in the neighbors of its associated working point and problems are prevented.

E. Comparison by Simulation of Gain Scheduled PI and FOPI Controllers

Simulation tests were performed by using a nonlinear accurate model of the CNG injection system, which was implemented by the AMESim virtual prototyping tool. This tool properly describes complex fluid dynamic phenomena of injection at different working points, and to obtain a simulated system very close to the real one. Moreover, typical value for the reference pressure p_{CR} and injection timing t_{inj} were considered, each yielding a different triple (K_e, T_e, L_e), then a different controller. The aim was to compare PI and FOPI controllers, both gain scheduled in the same way. The most important result should be limiting the overshoot in the actual common rail pressure, i.e. the output of (14). Namely, overshoot would imply too much injected fuel, which alters the air-fuel ratio and increases consumption and emissions.

A first test considered a small step variation in the reference rail pressure (case I above) from 4 to 5 bar, with t_{inj} = 5 ms. Fig. 5 shows the actual rail pressure when controlled by a PI controller or FOPI controllers with different fractional orders of integration. Overshoot increases with the fractional order but it is much less than with PI, which then provides an inaccurate metering of the injected fuel. Moreover, the response by the PI controller shows large, high-frequency oscillations that are determined by large variations or saturation of the control signal (valve command). These results can be explained by the lower sensitivity of FOPI controllers to nonlinearities in the injection process.

A second test applied a large variation in reference pressure from 4 to 10 bar (case II above). Then intermediate reference pressures were considered and the gain scheduling determined the switch between three FOPI or PI controllers. Again, it can be verified that FOPI yielded better and smoother responses with reduced overshoots, and that nonlinearities considerably affect performance of PI controllers (see Fig. 6).

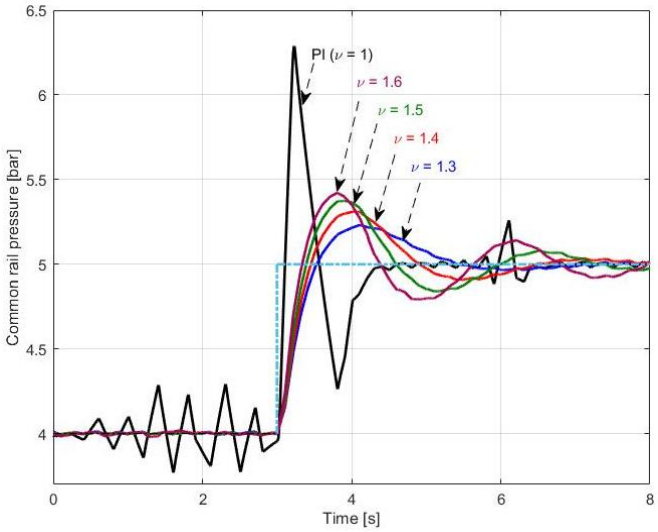

Fig. 5. Rail pressure in CNG injection system in response to a small step.

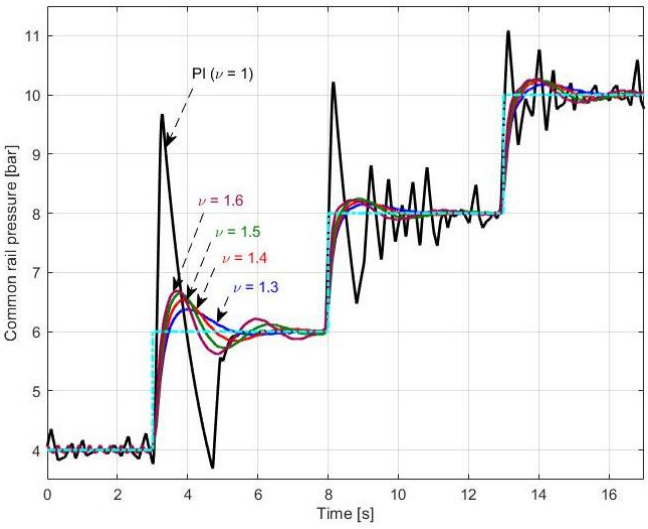

Fig. 6. Rail pressure in CNG injection system in response to a large step.

V. Conclusion

In some engineering applications, like those shown in this paper, the fractional-order models can be more effective than integer-order models in behavior prediction and data fitting.

As for an electro-injector in a CR Diesel injection system, the proposed model is able to match experimental data from a real electro-injector, to predict injected flow rate in several working conditions, and to optimize the parameters for a model-based control of fuel injection. Research is ongoing to improve the model accuracy, to improve the numerical methods that solve fractional partial differential equations, to design model-based control strategies for fuel injection.

Moreover, fractional-order PI controllers can replace PI controllers at a reduced realization cost to improve robustness, performance, sensitivity to nonlinearities, etc. The FOPI controllers can be designed by a loop-shaping method that guarantees robustness (flat Bode phase plot in a sufficient

range around the crossover frequency) to gain changes and performance (bandwidth to pursue an optimal feedback system). Design and realization formulas are given by closed-form expressions that enforce stability, minimum-phase and interlacing properties of the controller. Robust stability of the control system is shown by *D*-decomposition. Finally, gain scheduling is used to cope with various working points of the system and to switch between FOPI controllers.

Distributed Consensus-Based Multi-Target Tracking without Measurement Assignment

Srdjan S. Stanković, Nemanja Ilić and Miloš S. Stanković

***Abstract*—In this paper the problem of distributed multi-target tracking in sensor networks is discussed. A new algorithm, based on a combination of probabilistic data association methodology requiring no explicit measurement assignment and consensus communication scheme, is proposed. Unlike standard joint data association methodologies, which enumerate all possible measurement-to-track assignments resulting in a numerical complexity that is combinatorial in the number of measurements and tracks, we propose an approach which is linear in this respect. This is accomplished by constructing a data association scheme which appropriately modifies the clutter spatial density at the location of the measurements and subsequently uses single target tracking filters. The proposed data association algorithm is combined with a multi-step consensus scheme, which provides an adaptive distributed tracking solution when sensors have limited sensing and communication ranges. Numerical experiments illustrate the underlying principles and performance of the proposed algorithm.**

***Index Terms*—Distributed multi-target tracking, Sensor networks, Data Association, Consensus.**

I. Introduction

In recent years sensor networks have attracted significant attention in the research community. One of the main applications has been target tracking, where sensors such as radars, sonars or cameras have been spatially dispersed in order to contribute to the task of wide area surveillance, environment monitoring, disaster response, etc [1]. This task can be solved using a centralized approach, where necessary information for global target state estimation is collected at specific points in the network, called fusion centers. The centralized solution fails in situations when fusion centers become inoperable or when communications with them cease. On the other side, distributed algorithms, where all nodes in the network can be used as global target state estimators, and where global decision is obtained only through local communications between nodes, offer more robust, fault tolerant and scalable solutions.

Consensus scheme has been widely used as one of the most popular algorithms in the domain of distributed state estimation [2], [3], [4], and, more specifically, in the domain of target tracking [5]. One of the main challenges for the successful consensus-based distributed target tracking has been addressing the problem of limited sensing range sensors [6], [7], [8], where at each time instant there can be a vast majority of sensors not observing the target. In addition, there can be sensor measurements coming from some random sources other than target, usually termed clutter; this issue is commonly solved by combining Probabilistic Data Association (PDA) methodologies [9] with consensus-based estimation. Further, the existence of multiple targets complicates the problem even more, and this situation has been solved using the Joint Probabilistic Data Association (JPDA) methodologies [10], [11], [12], [13]. PDA and JPDA approaches can also be extended, by incorporating the concept of target perceivability and target existence, toward Integrated Probabilistic Data Association (IPDA) solutions [14], [15] for track initiation, confirmation and termination, as well as track maintenance [16].

While tracking multiple targets, it is possible that, for each target track, one applies the PDA methodology by assuming that all measurements not associated with that track are false (*i.e.*, they come from clutter) [12]. In practical applications this often leads to track coalescence in cases of spatially close tracks. The JPDA approach assumes that, for each target, measurements not associated with it may come from both other targets and clutter. It creates a list of all feasible joint measurement-to-track assignments which is used for computing measurement association probabilities. Feasible events do not include situations where a single measurement has been assigned to multiple targets, which turns to be beneficial in view of suppressing track coalescence. However, the process of enlisting all feasible measurement-to-track assignments is combinatorial in the number of measurements and the number of tracks, representing a significant computational burden.

In [17] the computational requirements of JPDA have been bypassed by introducing a novel methodology, called linear multi-target (LM) method. Namely, similarly as the PDA approach, LM assumes that, for each target track, all measurements not associated with it come from clutter. However, unlike the PDA approach, which assumes one global level of clutter spatial density (average number of measurements coming from clutter per unit volume), LM modifies this clutter spatial density for each target track with the measurement intensity of other targets. This effectively reduces the degree of association of a measurement to a target when that measurement is strongly associated with another target. As a result, coupling between individual tracks without explicit measurement-to-track combinatorial enumeration process is achieved, linear in the number of measurements and tracks. LM also belongs to the class of IPDA algorithms, incorporating the concepts of target perceivability and target existence.

Regarding the choice of the data association methodology,

consensus-based distributed multi-target tracking algorithms have followed several directions in the literature so far. In [11] the so-called Kalman Consensus Filter (KCF) has been combined with the JPDA methodology. It assumed a simplified scenario of all sensors observing the whole surveillance region. The Information Consensus Filter (ICF) has been combined with the PDA algorithm in [12]. KCF and ICF rely on the exchange between the nodes of the so-called information vectors and matrices which are subsequently used to calculate the target state estimates. In [13], the Adaptive Consensus Filter (ACF) from [18] has been combined with the JPDA methodology. It assumes the exchange of state estimates between the nodes and adaptively tunes the consensus parameters in order to take into account the adopted multi-target scenario with cluttered measurements and limited sensing range sensors.

The goal of this paper is to propose a novel algorithm which combines the LM approach from [17] with the ACF algorithm from [13], [18], in order to obtain a distributed multi-target tracking solution whose computational requirements are significantly smaller than those of solutions incorporating JPDA. The scheme will also allow for extensions involving track-to-track association, as well as integration of track initiation, confirmation and termination with the track maintenance process. It will be shown that the proposed tracking algorithm provides accurate network-wide estimations of the positions of all targets, and that it exhibits the best overall performance, when compared to its version which uses JPDA, as well as to other state-of-the-art algorithms. Also, the illustration of some properties of the proposed algorithm, aimed at clarification of the main ideas upon which it is built, will be given.

The outline of the paper is as follows. Problem setting and the proposed linear multi-target method are discussed in Section II. The adaptive multi-step consensus scheme is presented in Section III. Section IV gives illustration of some of the features of the proposed algorithm, together with the results of characteristic multi-target tracking simulations.

II. Distributed Consensus-Based Linear Multi-Target Tracking Algorithm

In the first part of this Section, we shall present the main concepts of the adopted multi-target tracking strategy, applied to local estimators taken separately. In the second part, the complete distributed algorithm, including the consensus based scheme applicable at the network level, will be given.

A. Problem Formulation. Basic Concepts

Consider the problem of tracking N_T targets by N intelligent sensors forming a network represented by a directed graph $\mathcal{G} = (\mathcal{N}, \mathcal{E})$, where $\mathcal{N}$ is the set of nodes and $\mathcal{E}$ the set of arcs. Since the scope of this paper is track maintenance only, it is assumed that N_T is known to each node [11], [12], [13]. Each sensor (*e.g.*, radar, sonar, camera) is supposed to have, in general, limited sensing and communication ranges, determining the sets of nodes that can observe the targets (one set for each target) and the set of neighboring nodes exchanging messages. Let $\mathcal{N}_i$ be the in-neighborhood of node i, and $\mathcal{J}_i = \mathcal{N}_i \cup \{i\}$. We shall assume cluttered environment, *i.e.*, a set of measurements is acquired by each sensor without information of their origin: at time t, node i, $i = 1, \ldots, N$, gets m_i measurements, denoted as $z_{i,j}(t)$, $j = 1, \ldots, m_i$. The measurement of a potential target followed by track k, $k = 1, \ldots, N_T$, is present at node i with a probability of detection $P^k_{D,i}$; it is also corrupted by a zero mean white measurement noise, with covariance R_i. Target detection is assumed to be in the selection gate or window with probability $P^k_{W,i}$. Let $z^k_{i,j}(t)$ denote j-th measurement in the selection gate of track k, and let its a priori probability density function (pdf) $p^k_{i,j}(t)$ be Gaussian; let Z^t_i be the set of measurements at node i up to and including the instant t. The clutter spatial density at $z_{i,j}(t)$ is denoted by $\rho_{i,j}(t)$ (see [17] for more details).

A track may follow a target, when it is called true track; otherwise, it is a false track. We introduce the following important random events at time t: $\chi^k_i(t)$ - the event that track k at node i is following a target, *i.e.*, the target k exists; $\chi^k_{i,0}(t)$ - the event that none of the gated measurements are from target k; $\bar{\chi}^k_{i,0}(t)$ - complement of $\chi^k_{i,0}(t)$; $\chi^k_{i,j}(t)$ - the event that measurement $z^k_{i,j}(t)$ is the target detection.

The classical multi-target tracking methodology (*e.g.*, [10]) considers the origin of each acquired measurement. The number of unique joint assignments of all measurements to all tracks is combinatorial in the number of measurements and tracks [17]. The existing approaches to distributed multi-target tracking [11], [13] assume application of the Joint Probabilistic Data Association (JPDA) methodology and suffer from the corresponding computational burden, especially pronounced in networked systems. In order to obtain a more efficient and effective solution, we shall follow in this paper the Linear Multi-target (LM) methodology, proposed in [17]. Essentially, it is based on the single target tracking methodology, allowing for the possibility that a measurement originates either from a target or some other scatterer, which may produce clutter returns or be other targets. In effect, the LM approach is to run a bank of single target tracking filters, achieved though modifying the clutter density for each tracking filter.

Let $P^k_{i,j}(t) = P(\chi^k_{i,j}(t)|Z^{t-1}_i)$ denote a priori probability that measurement j of node i at time t is from target k. According to [17], we shall use the following approximation

$$P^k_{i,j}(t) \approx P^k_{D,i} P^k_{W,i} P(\chi^k_i(t)|Z^{t-1}_i) \frac{p^k_{i,j}(t)}{\rho^k_{i,j}(t)} \Big(\sum_{\mu=1}^{m^k_i(t)} \frac{p^k_{i,\mu}(t)}{\rho^k_{i,\mu}(t)} \Big)^{-1} \tag{1}$$

where

$$\rho^k_{i,j}(t) = \rho_{i,j}(t) + \sum_{\sigma=1, \sigma \neq k}^{N_T} P^k_{D,i} P^k_{W,i} P(\chi^k_i(t)|Z^{t-1}_i) p^\sigma_{i,j}(t);$$

$P(\chi^k_i(t)|Z^{t-1}_i)$ is the a priori probability of target k existence.

We shall assume the Markov chain one model for the propagation of the probability of target existence, see [14], [15] for details. Accordingly, computation of the a posteriori probability of track existence is done by

$$P(\chi^k_i(t)|Z^t_i) = \frac{(1 - \delta^k_i(t)) P(\chi^k_i(t)|Z^{t-1}_i)}{1 - \delta^k_i(t) P(\chi^k_i(t)|Z^{t-1}_i)}, \tag{2}$$

where

$$\delta_i^k(t) = P_{D,i}^k P_{W,i}^k (1 - \sum_{\mu=1}^{m_i^k(t)} \frac{p_{i,\mu}^k(t)}{\tilde{\rho}_{i,\mu}^k(t)}). \quad (3)$$

Following [17], $\tilde{\rho}_{i,j}^k(t)$ is the a priori scatterer measurement density of $z_{i,j}(t)$ given by

$$\tilde{\rho}_{i,j}^k(t) = \rho_{i,j}(t) + \sum_{\sigma=1,\sigma\neq k}^{N_T} p_{i,j}^\sigma(t) \frac{P_{i,j}^\sigma(t)}{1 - P_{i,j}^\sigma(t)}. \quad (4)$$

Introduction of $\tilde{\rho}_{i,j}^k(t)$, instead of $\rho_{i,j}(t)$ utilized in conventional trackers of PDA or IPDA type [9], [10], [14], represents the core of the LM tracking methodology [17]. The aim is to take into account the presence of targets nearby by calculating the probability of target existence using (2). The effect of $\tilde{\rho}_{i,j}^k(t)$ is to decrease the influence of a measurement if it is likely to be the detection of another target, without requiring explicit joint measurement-to-track assignment.

The a posteriori probabilities that the target exists and that measurement $i \geq 0$ is its detection ($i = 0$ denotes the null measurement) are given by

$$P(\chi_i^k(t), \chi_{i,0}^k(t)|Z_i^t) = \frac{1 - P_{D,j}^k P_{W,j}^k}{1 - \delta_i^k(t) P(\chi_i^k(t)|Z_i^{t-1})} P(\chi_i^k(t)|Z_i^{t-1}), \quad (5)$$

$$P(\chi_i^k(t), \chi_{i,j}^k(t)|Z_i^t) = \frac{P_{D,j}^k P_{W,j}^k}{1 - \delta_i^k(t) P(\chi_i^k(t)|Z_i^{t-1})} \frac{p_{i,j}^k(t)}{\tilde{\rho}_{i,j}^k(t)} P(\chi_i^k(t)|Z_i^{t-1}). \quad (6)$$

B. Tracking Algorithm

The proposed tracking algorithm consists of two main parts: a) correction part and b) prediction part.

a) The correction part of the algorithm is defined according to the algorithm from [8], [19], combined with [9], [10], modified using the above exposed LM concept [17]:

$$\xi_i^k(t|t) = \xi_i^k(t|t-1) + L_i^k(t)\tilde{z}_i^k(t), \quad (7)$$

$i = 1, \ldots, N$, where $\xi_i^k(\cdot)$ is an estimate of the true target state $x^k(\cdot)$, generated by *i*-th node

$$\tilde{z}_i^k(t) = \sum_{j=1}^{m_i^k(t)} \beta_{i,j}^k(t)\tilde{z}_{i,j}^k(t), \quad (8)$$

$\tilde{z}_{i,j}^k(t) = z_{i,j}^k(t) - H_i\xi_i^k(t|t-1)$, where matrix H_i is a part of the observation model

$$z_{i,j}^k(t) = H_i x^k(t) + v_i(t), \quad (9)$$

in which $z_{i,j}^k(t)$ is a measurement of node i originated from k-th target and $v_i(t)$ a zero mean white noise term with covariance $R_i > 0$,

$$L_i^k(t) = P_i^k(t|t-1)(H_i^k)^T S_i^k(t)^{-1}, \quad (10)$$

$$P_i^k(t|t) = P_i^k(t|t-1) + [\beta_{i,0}^k(t) - 1]L_i^k(t)S_i^k(t)L_i^k(t)^T + \tilde{P}_i^k(t,t), \quad (11)$$

$$\tilde{P}_i^k(t,t) = L_i^k(t)[\sum_{j=1}^{m_i(t)} \beta_{i,j}^k(t)\tilde{z}_{i,j}^k(t)\tilde{z}_{i,j}^k(t)^T - \tilde{z}_i^k(t)\tilde{z}_i^k(t)^T]L_i^k(t)^T, \quad (12)$$

$$S_i^k(t) = H_i^k P_i^k(t|t-1)(H_i^k)^T + R_i, \quad (13)$$

$$\beta_{i,0}^k(t) = \frac{P(\chi_{i,0}^k(t), \chi_i^k(t)|Z_i^t)}{P(\chi_i^k(t)|Z_i^t)} = \frac{1 - P_{D,i}^k P_{W,i}^k}{1 - \delta_i^k(t)}, \quad (14)$$

$$\beta_{i,j}^k(t) = \frac{P(\chi_{i,j}^k(t), \chi_i^k(t)|Z_i^t)}{P(\chi_i^k(t)|Z_i^t)} = \frac{P_{D,i}^k P_{W,i}^k}{1 - \delta_i^k(t)} \frac{p_{i,j}^k(t)}{\tilde{\rho}_{i,j}^k(t)}. \quad (15)$$

Formally, at the first glance, the correction part of the algorithm is identical to the ACF algorithm proposed and discussed in [16], [13]. The essential difference stems from the new definition of the β-coefficients: in (14) and (15) a new expression for clutter density is introduced, directly taking care of the influence of the existence of other targets (see (4), (3)).

b) The prediction part of the algorithm assumes the standard target model (equal for all targets for the sake of clarity)

$$x^k(t+1) = Fx^k(t) + Ge^k(t), \quad (16)$$

where F and G are constant matrices of appropriate dimensions and $e^k(t)$ Gaussian white noise term, with covariance $Q^k > 0$. The algorithm contains, as its basic part, the following relation for state prediction

$$\xi_i^k(t+1|t) = F\mathcal{C}_{[l]}^k\{\xi_i^k(t|t)\}, \quad (17)$$

where $\mathcal{C}_{[l]}^k\{\cdot\}$ denotes the l-step consensus operator, obtained from the following recursion for an adopted l:

$$\mathcal{C}_{[l]}^k\{\xi_i^k(t|t)\} = \sum_{j\in\mathcal{J}_i} c_{[l],ij}^k(t)\mathcal{C}_{[l-1]}^k\{\xi_j^k(t|t)\}, \quad (18)$$

with $\mathcal{C}_{[0]}^k\{\xi_i^k(t|t)\} = \xi_i^k(t|t)$, $i = 1, \ldots, N$. Coefficients $c_{[l],ij}^k(t)$, $i, j = 1, \ldots, N$, are, in general, dependent on l; they are elements of the $N \times N$ consensus matrix $C_{[l]}^k(t)$, which is row-stochastic and with nonnegative elements, such that $c_{[l],ij}^k(t) = 0$ for $j \notin \mathcal{J}_i$ [2], [4], [20].

Furthermore,

$$P_i^k(t+1|t) = FP_i^k(t|t)F^T + GQ^kG^T. \quad (19)$$

In the case of single node operation (fixed i and $\mathcal{C}_{[l]}^k\{\xi_i^k(t|t)\} = \xi_i^k(t|t)$), the algorithm approximates the posterior state estimate pdf by a single Gaussian pdf

$$p(x_i^k(t)) \sim \mathcal{N}(\xi_i^k(t|t), P_i^k(t|t)), \quad (20)$$

[17]. In general, the presence of the consensus operator (18) implies that (20) does not hold. The overall covariance of the estimates generated by the proposed algorithm is significantly different from the local covariances defined by (11) and (19); it is, in general, a function of all the local estimates and the consensus parameters. It is to be taken into account that, for a large number of consensus steps l, we have $\xi_i^k(t+1|t) \approx \xi_j^k(t+1|t)$,

$i, j = 1, \ldots, N$, and that, consequently, it can be expected that the resulting prediction covariance of the estimates is lower than the majority of the local covariances (provided some general properties hold for the consensus matrices - see the discussion below). This implies that practical implementation of the algorithm is faced with the problem of adequate real-time estimation of the estimation error covariance, having in mind that this covariance is to be incorporated in $p^k_{i,j}(t)$, which plays an essential role in the whole algorithm based on the LM tracking methodology. The problem is that the estimation of this covariance cannot be done in a distributed way - it is feasible only off-line, including all the nodes and their interconnections. However, based on numerous experiments with different target models and diverse problem settings, we have found that $P^k_i(t|t)$ in (20) can be successfully replaced by $\Pi^k_{[l],i}(t|t)$ defined by

$$\Pi^k_{[l],i}(t|t) = [\alpha_k \mathcal{C}^k_{[l]}\{P^k_i(t|t)^{-1}\}]^{-1}, \tag{21}$$

where $\alpha_k \geq 1$. Obviously, we have, for l large enough, $\Pi^k_{[l],i}(t|t) \approx \Pi^k_{[l],j}(t|t)$, $i, j = 1, \ldots, N$, under the same conditions leading to consensus on the estimates themselves.

It is to be noticed that incorporating (21) in the distributed tracking algorithm brings additional communication burden since the estimation error covariances should now also be exchanged between nodes. This requirement is already implicitly present with other consensus-based distributed target tracking algorithms [11], [12]. However, if one wants to lift this burden off toward off-line estimation of error covariances, the facts that different values in (21) are for l large enough very similar, and that (having in mind the nature of the tracking process) they do not vary significantly in time, may be taken into account. Therefore, while computing (4), it is possible to introduce the approximation of (21) by simply using $\Pi^k_{[l],i}(t|t) = \Pi^k_{const}$, where Π^k_{const} is some empirically obtained constant (see Section IV for details).

III. Adaptive Multi-Step Consensus Scheme

One of the essential features of the proposed tracking algorithm is its possibility to adapt behavior to the availability of measurements; this Section deals with the problem of generating consensus matrices $C^k_{[l]}(t) = [c^k_{[l],ij}(t)]$ in (18) that will allow this feature. The underlying idea is directed toward the desirable asymptotic properties of the consensus scheme. It aims to achieve that all nodes have at each time t equal target state estimates, in the form of a weighted average of the target state estimates, in which the weights are designed in such a way as to reflect the current node probability of observing a target. Generalizing analogous considerations from [16], we use $1 - \beta^k_{i,0}(t)$, where $\beta^k_{i,0}(t)$ is given by (14), as an indicator of the i-th node probability of observing the target. Therefore, the formal goal of the multi-step consensus operator in (18) should be to achieve asymptotically (when $l \to \infty$) that

$$\xi^k_i(t+1|t) = \xi^k(t+1|t) = \sum_{i=1}^{N} w^k_i(t)^T F \xi^k_i(t|t), \tag{22}$$

where

$$w^k_i(t) = \frac{1 - \beta^k_{i,0}(t)}{\sum_{j=1}^{N}(1 - \beta^k_{j,0}(t))}. \tag{23}$$

To this end, at each time instant t, we shall apply l consensus steps. In each consensus step, the nodes exchange the scalar variables based on $\gamma^k_i(t) = 1 - \beta^k_{i,0}(t)$, as well as the target state estimates. The variables are used for weighting the communicated estimates. Let $\gamma^k_{[\kappa],i}(t)$ and $\xi^k_{[\kappa],i}(t|t)$, $\kappa = 1, \ldots, l$, be the weight and the estimate of the i-th node connected to the κ-th consensus step, respectively. The algorithm starts from $\gamma^k_{[1],i}(t) = \gamma^k_i(t)$ and $\xi^k_{[1],i}(t|t) = \xi^k_i(t|t)$. The weights $\gamma^k_{[\kappa],i}(t)$ are being exchanged through A_c (satisfying $\lim_{n\to\infty} A^n_c = \mathbf{1}\mathbf{1}^T/N$, where $\mathbf{1}$ is a column vector of ones, see [18], [13] for details), so that the corresponding consensus matrix is given by

$$C^k_{[\kappa]}(t) = \left(A_c \cdot diag\left(\gamma^k_{[\kappa],1}(t), \ldots, \gamma^k_{[\kappa],N}(t)\right)\right)_{rs}, \tag{24}$$

where $(\cdot)_{rs}$ denotes an operator making the resulting matrix row-stochastic. Using the obtained matrix $C^k_{[\kappa]}(t) = [c^k_{[\kappa],ij}(t)]$, $i, j = 1, \ldots, N$, the target state estimates are given by $\xi^k_{[\kappa+1],i}(t|t) = \sum_{j\in\mathcal{J}_i} c^k_{[\kappa],ij}(t)\xi^k_{[\kappa],j}(t|t)$. For the next consensus step, the design requires that the weight of each node corresponds to the sum of the weights it received previously, so that $\gamma^k_{[\kappa+1]}(t) = \begin{bmatrix}\gamma^k_{[\kappa+1],1}(t) & \cdots & \gamma^k_{[\kappa+1],N}(t)\end{bmatrix}^T = A_c \cdot \gamma^k_{[\kappa]}(t)$. At this point one can repeat the described procedure for the total of l consensus steps. It is shown [18] that, for $l \to \infty$, this scheme achieves consensus equivalent to $\lim_{l\to\infty} \xi^k_{[l],i}(t|t) = \sum_{j\in\mathcal{J}_i} c^k_{[\infty],ij}(t)\xi^k_j(t|t)$, where $c^k_{[\infty],ij}(t) = \gamma^k_j(t)/\sum_{j=1}^{N}\gamma^k_j(t)$, which represents the desired result.

To sum it up, the consensus operator $\mathcal{C}^k_{[l]}\{\cdot\}$ in (18) is obtained by applying l consensus steps defined in (24), which is equivalent to the application of a single consensus step whose corresponding consensus matrix $\tilde{C}^k_{[l]}(t)$ is defined by:

$$\tilde{C}^k_{[l]}(t) = C^k_{[l]}(t) \cdot C^k_{[l-1]}(t) \cdot \ldots \cdot C^k_{[1]}(t). \tag{25}$$

The described consensus algorithm can be optimized in the sense of obtaining fast convergence rate, enabling efficient implementation in practice [18]. The procedure aims to minimize the spectral radius of $A_c - \mathbf{1}\mathbf{1}^T/N$ subject to the inherent network constraints (see [18] for details).

IV. Simulations

The problem of distributed tracking of $N_T = 4$ targets via a network of $N = 15$ sensors, each target moving within a 500×500 space, was considered [12], [18], [13]. The sensors were randomly distributed in the space with random orientations resulting in overlapping field-of-views (FOVs), represented by equilateral triangles with the height of 300 units; the communication range was set to 200 units. The initial prior state estimates were randomly selected around initial target states with noise covariance of $P_0 = diag(100, 100, 10, 10)$. The initial error covariance matrices were also set to P_0 for all nodes. The number of consensus steps was set to $K = 10$ and α_k was set to 1. Regarding the parameters included in calculating $\beta^k_{i,j}(t)$ (see [17] for details), false measurements (clutter) were assumed Poisson distributed with the nominal spatial density of $1/32$, gate probability was set to 0.99,

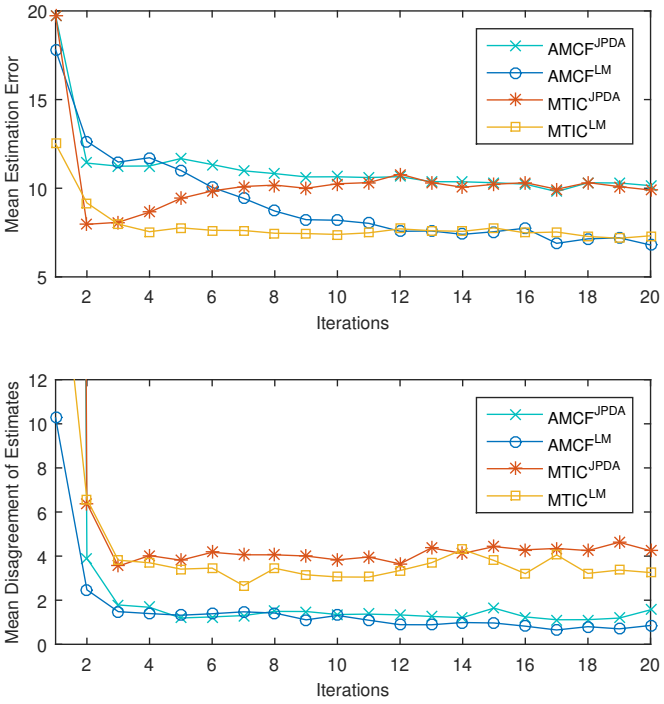

Fig. 1. Average distance per node per target between the true and the estimated positions (top) and average variance of the estimates per target (bottom) versus time.

and probability of detection was calculated by integrating the probability density function of the predicted estimate over the triangular FOV. For other parameters, see, *e.g.*, [12], [18], [13].

An experiment with 100 different randomly selected networks, each with 4 randomly generated tracks, was designed. Estimation error (average distance per node per target between targets positions estimates and the actual positions) and disagreement between the nodes (average variance of the estimates per target) were calculated. The proposed algorithm (named AMCF$^{\text{LM}}$) was also simulated by using JPDA instead of LM (AMCF$^{\text{JPDA}}$). The existing state-of-the-art algorithm from the literature based on the Information Consensus Filter [12] was likewise simulated in two versions (MTIC$^{\text{LM}}$ and MTIC$^{\text{JPDA}}$). It can be seen from Fig. 1 that the proposed algorithm with LM provides the best results both in terms of the average estimation error and the disagreement of estimates. In terms of the estimation error, LM versions of the algorithms provide better results over using JPDA; in terms of the disagreement between estimates, AMCF algorithms exhibit better performance than MTIC algorithms.

In order to illustrate the underlying principles of how LM scheme actually works, an experiment was set with 2 moving targets and with clutter nominal spatial density of $1/4$. The calculated a priori scatterer measurement density $\tilde{\rho}^k_{i,j}(t)$ from (4) is depicted in Fig. 2, for all nodes and all their measurements obtained during the course of the experiment, $i = 1, \ldots, N$, $j = 1, \ldots, m_i$. It can be seen that, for each target, the proposed algorithm indeed amplifies the clutter density of a measurement when that measurement is strongly associated with another target (which subsequently reduces its degree of association to the original target).

As a supplement to the discussion following (21), values of error covariance matrices used in calculating (4) were, for each target, set to two constant values ($\Pi^k_{const} = P_0$ and $\Pi^k_{const} = 10P_0$), in an experiment of tracking 4 moving targets. As can be seen from Fig. 3, this empirical procedure can lead to a successful multi-target tracking scheme, but one should be careful about the quantities chosen, since greater values can lead to track coalescence (right subfigure).

V. Conclusion

In this paper we proposed a novel algorithm for distributed multi-target tracking in sensor networks, based on a combination of: 1) probabilistic data association methodology whose computational requirements are linear in the number of measurements and tracks, and 2) adaptive multi-step consensus scheme, robust in the context of cluttered observations and limited sensing range sensors. The proposed algorithm exhibits better performance than analogous algorithms that use JPDA - this seems to be the consequence of the numerical overflows and underflows inherently present when calculating association probabilities via JPDA [10]. It also exhibits better performance than analogous algorithms from the literature that use Information Consensus Filters (ICF) [12] - this is due to the adopted general consensus strategy that is not restricted to average consensus only.

The future work should address the problem of track-to-track association, which is herein assumed to be perfect (as in [12], [13]). However, this represents a straightforward task, in contrast to the case of using ICF algorithms which do not explicitly exchange state estimates between nodes. Also, the assumed integrated PDA methodology allows for the introduction of track initiation, confirmation and termination phases into the proposed scheme, which would than represent a complete tracking solution.

QQ-plot Based Clustering

Željko Nedeljković, Željko Đurović

***Abstract*— Clustering is widely applied, from everyday life to the most diverse fields of scientific activities. Different techniques of clustering are present, with their advantages and disadvantages. This paper examines the possibility of multidimensional QQ-plot based clustering. First, the multidimensional samples are transformed into a scalar form, using the Fibonacci sequence, after that the QQ-plot is formed for the such shaped samples, and then the piecewise linear approximation is constructed. On the basis of the linear segments of the piecewise linear approximation, clusters are segregated. The proposed procedure can be applied multiple times in order to obtain a better result. The initial tests indicate that the proposed method achieves results comparable with conventional clustering methods.**

***Index Terms*—clustering; QQ-plot; Fibonacci sequence.**

I. Introduction

Clustering implies grouping of items, according to a common characteristic, which allows perceiving and drawing conclusions for the entire group, instead of looking at individual cases separately. Grouping is done in such a way that the similarity of data within a group is large, with simultaneous, small similarity of data from different groups. Clustering has a wide application in a variety of fields, and some of the applications in the area of signal processing are pattern recognition, speech processing, image segmentation. Some of the most commonly used clustering methods are K-means [1], Fuzzy C-means [2], Mountain [3], Subtractive [4].

This paper presents a new approach to clustering using QQ (quantile-quantile) plot [5]. The basic application of QQ-plot is a graphical comparison of the distributions of the given sample sets, whereas in this case, it is used for determining points with similar characteristics. In paper [6], the QQ-plot was applied to the problem of estimating the probability density function (pdf). After the formation of the QQ-plot, a piecewise linear approximation is constructed, where the statistics of each linear segment are used to construct a probability density function. This paper relates to the paper [6] in the sense of idea that the points of one linear segment of QQ-plot approximation have the same characteristics. One problem that needed to be solved was the representation of an arbitrary length vector as a scalar, for what the Fibonacci sequence was used [7]. For the obtained scalar values, a QQ-plot was formed, and subsequently, the piecewise linear approximation as well, on the basis of which it was concluded which points belong to the same cluster. Since, during representation of a multidimensional value by one-dimensional, a part of the information was inevitably lost, the procedure was repeated several times for different variations of the formation of scalar representations, and in the end, the aggregation of thus obtained results was performed.

The next chapter summarizes a brief overview of the QQ-plot. The proposed algorithm is presented in chapter three. Test results and conclusions are provided in chapters four and five.

II. QQ-plot

The QQ-plot was primarily created as a measure of goodness-of-fit. It can be used to determine the degree of probability distributions matching for two given sets of samples, or to determine the matching of the distributions of a given set of samples with a certain theoretical distribution or to compare two theoretical distributions. The QQ-plot is a quantiles graph of one against the other sets of samples. Thereby, the quantile implies a portion of the points (percentage), below the given value. Quantiles of a given set of samples are obtained by sorting, while quantiles of theoretical distribution are obtained using inversion of the cumulative distribution function. For sets of samples that have the same or linearly dependent probability density functions, an approximately linear QQ-plot is obtained. Any deviation from the straight line indicates a mismatch in the distributions of the tested sample sets, and conclusions can be drawn based on the deviation type.

III. Proposed algorithm

The proposed algorithm relies on the idea outlined in the paper [6], where the QQ-plot, formed for a given set of points relative to the theoretical distribution, is interpreted in such a way, that the linear segments of the QQ-plot are observed, and it can be concluded that the points belonging to the same linear segment have the same characteristics, i.e. belong to the same group. In the paper [6], the observed groups are used to determine statistics for the formation of the probability density function, which represents a given set of points. In this paper, the points forming the linear segment are proclaimed representatives of the same cluster.

One limitation of the QQ-plot is that it is applicable to one-dimensional problems only. In practical application, the problems we deal with are usually multidimensional. In compliance with this, this paper has a tendency to cover multidimensional cases. The assumption is that a set of vectors is provided $V_1, V_2, \dots, V_N$, where the dimension of the individual vectors is D. For the purpose of mapping the

vectors of arbitrary length into a scalar value, the Fibonacci sequence was used, similar to the one in the paper [7], $F_n = F_{n-1} + F_{n-2}$, where $F_1 = 5$, $F_2 = 8$ was adopted, thereby forming a Fibonacci numbers' vector of a dimension equal to that of the given vectors $F = [F_1, F_2, \dots, F_D]^T$. A series of indexes is then formed $index = [i_1, i_2, \dots, i_D]$, as one permutation without repetition of integer numbers from 1 to D. The $index$ vector determines the order of multiplication during formation of scalar representation of the input vector $S_n = \hat{V}_n(i_1) \cdot F_1 + \hat{V}_n(i_2) \cdot F_2 + \cdots + \hat{V}_n(i_D) \cdot F_D, \quad n \in [1, N]$, where $\hat{V}_n(i) \in [0,1]$, $i \in [1, D]$ is the normalized value of the i coordinate over all vectors $V_n, n \in [1, N]$. This way, the sequence of the input vectors $V_1, V_2, \dots, V_N$ is represented by the sequence of scalar values $S_1, S_2, \dots, S_N$.

The formation of the QQ-plot begins with the adoption of the theoretical distribution of the samples, and unless there is additional information, it is reasonable to adopt a normal distribution. By forming the inversion of the cumulative distribution function P^{-1}, quantiles of one axis is defined $P^{-1}\left(\frac{n-0.5}{N}\right)$, $n = 1,2, \dots, N$. It is then necessary to sort the scalar representations $S_1, S_2, \dots, S_N$, by which the quantiles of the other axis is determined $y_1, y, \dots, y_N$. By pairing the quantiles, the QQ-plot is determined.

The deviation of the QQ-plot formation from the straight line is expected, but local linear segments that represent groups of points of similar characteristics can be detected. In order to extract linear segments, the piecewise linear approximation of the QQ-plot is constructed. Points belonging to the same linear segment are considered members of the same cluster. In [6], approximation was performed by dividing intervals with the largest error of approximation, which produced a good result in the formation of the probability density function, with the emphasis on the best curve approximation, in order to obtain a better estimation of pdf, and the number of segments was not essentially important. When it comes to the problem that is solving here, the number of segments is important, because it indicates the number of formed groups, so it is necessary to apply a slightly different approach to the formation of linear approximation. In this paper, the set of points is divided into groups of several successive points first, and then, for each group formed in such a way, determination of linear approximation and the error of approximation is performed. Subsequently, iterative conjugation of adjacent linear segments is made, so that the error of approximation remains as small as possible. The stopping criterion is reaching defined number of linear segments. Upon completion of the iterative procedure, it needs to be checked whether there are insufficient points involved in any of the linear segments, in which case, an annexation is applied to one of the adjacent segments. This leads to the final piecewise linear approximation of the QQ-plot.

Based on the formed linear approximation of the QQ-plot, it is possible to draw a conclusion about the belonging of the given samples to clusters. However, if one takes into account that in one of the steps of the algorithm, the vector of arbitrary length has been presented with a scalar, it is clear that a part of the information is lost, with the different components of the training vector being preserved at varying degrees, depending on element of the Fibonacci sequence it is weighted. This leads to the conclusion that, in order to obtain more robust clustering, it makes sense to repeat the previously described steps several times, for the differently formed $index$ vector. In order to form the final result, a square matrix T is formed with dimensionally equal to the number of vectors in the training set N. Each position (n_1, n_2) of the T matrix carries information about the number of occurrences of vectors V_{n_1} and V_{n_2} in the same group (linear segment), for different $index$ vector setups. Maximum value $maxT$, which can appear in the matrix T, is equal to the number of evaluated $index$ vectors. If $T(n_1, n_2) \geq 0.8 \cdot maxT$, it can be concluded that the points V_{n_1} and V_{n_2} are in the same group. Validation is conducted for groups formed in such manner, in terms of the number of contained points. Then, the valid groups are joined to the given number of clusters K, and later, the groups that have not been declared as valid are joined to the valid groups, as well. Conjugation of the groups is performed based on the smallest Euclidean distance of the group centers. This way, the clustering of the given vectors $V_1, V_2, \dots, V_N$ in K clusters was performed.

IV. Results

The proposed algorithm remains an open question when it comes to selecting setups of vector $index$. One possibility is to examine all possible $index$ vector setups, which, for the dimension of the input vectors D, is equal to the number of permutations without repetition for series of integer numbers from 1 to D, which is equal to $D!$. The number of possible setups grows significantly with the increase of D, so it becomes impractical for higher D values. The second option is to randomly select the setups up to the specified number, which meets the requirement of practical applicability. However, the question arises as to whether it is possible to find a measure of goodness of different setups in order to evaluate only those that have the greatest contribution to the final result.

During the following experiments, it will be examined whether it is possible to achieve valid clustering using only one $index$ vector setup. It should also be determined what kind of result is obtained by including all possible $index$ vector setups. Additionally, it makes sense to analyze the change in the quality of the results for a variety of included setups, from one to all.

For simulation purposes, $N = 1000$ three-dimensional samples was generated with three noticeable, balanced groups with normal distributions $G_1 \sim N(\mu_1, \Sigma_1)$, $G_2 \sim N(\mu_2, \Sigma_2)$ and $G_3 \sim N(\mu_3, \Sigma_3)$, where the vectors of mean values are $\mu_1 = [1,1,1]$, $\mu_2 = [6,6,4]$, $\mu_3 = [0,6,6]$ and the diagonal covariance matrices are $\Sigma_1 = diag(2^2, 1, 1)$, $\Sigma_2 = diag(1, 1, 2^2)$, $\Sigma_3 = diag(1, 2^2, 1)$. Fig. 1 illustrates the generated samples, whereby Bhattacharya distances [8] of the

pairs of generated groups of samples are $D_B(G_1, G_2) = 4.83$, $D_B(G_1, G_3) = 4.59$, $D_B(G_2, G_3) = 4.85$.

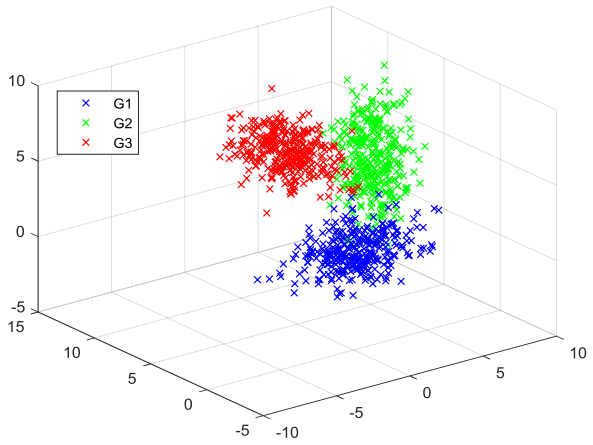

Fig. 1. Generated samples.

Generated vectors of the samples will be transformed into a scalar representation using the Fibonacci sequence using one of the $index$ vector setups: $index_1 = [3, 2, 1]$, $index_2 = [3, 1, 2]$, $index_3 = [2, 3, 1]$, $index_4 = [2, 1, 3]$, $index_5 = [1, 3, 2]$ and $index_6 = [1, 2, 3]$. For the first setup $index_1$, probability density functions of the given groups are presented in Fig. 2. It is clear that the Fibonacci representation has significantly preserved the diversity of the groups, but it is also clear that overlapping of the groups will be reflected on the quality of clustering. Also, by inspecting the Bhattacharya distance of the pairs of the one-dimensional samples obtained this way, it can be observed that the separability is clearly degraded $D_B(G_1, G_2) = 3.41$, $D_B(G_1, G_3) = 0.84$, $D_B(G_2, G_3) = 1.03$. For the formed Fibonacci representation, the QQ-plot has the shape shown in Fig. 3. It is clear that different parts of the curve can be related to the samples that constitute it, but overlapping in certain parts is also evident, which will directly affect the result of the clustering. The result of the clustering based only on first setup is given in Fig. 4, where 16.22% of the samples were clustered differently from their original belonging. Looking at Fig. 4, it is clear that the group 3 was dominantly mixed with groups 1 and 2, which is to be expected on the basis of Figs. 2 and 3, as well as the calculated Bhattacharya distances.

Based on the preceding example, it can be concluded that using only one setup can produce meaningful results. Fig. 5 represents the results for a combination of all possible setups. It is clear that the result is quite good where it comes to just 0.60% of samples in clusters different from the given groups. If the same set of samples is clustered using K-means clustering, 0.70% of wrong clustering is obtained, indicating that the proposed method achieves results in range of the verified methods.

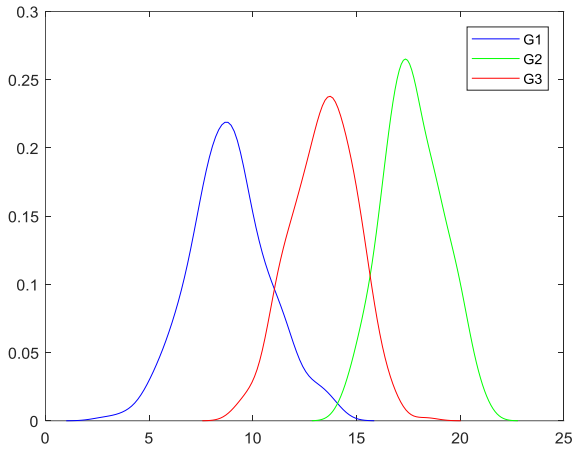

Fig. 2. Pdf of Fibonacci representation for setup 1.

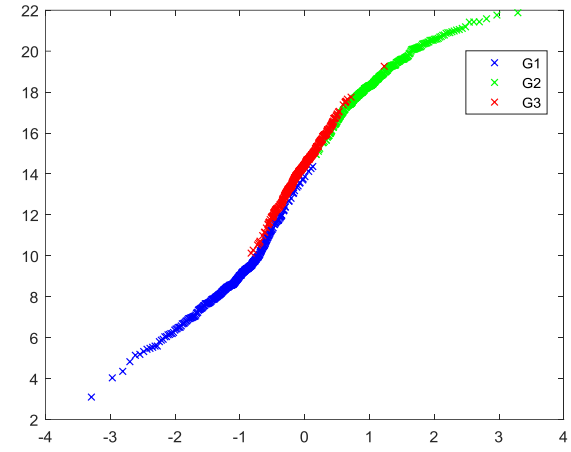

Fig. 3. QQ-plot for setup 1.

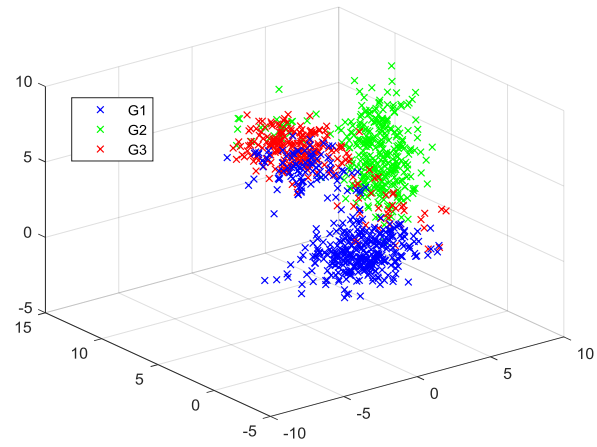

Fig. 4. Clusters based on setup 1 only.

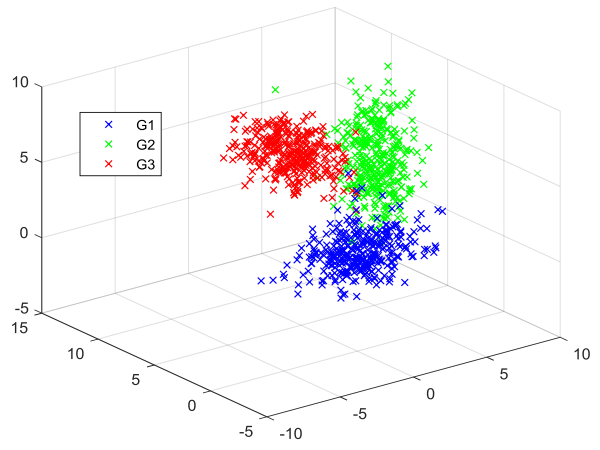

Fig. 5. Clusters based on all setups.

TABLE I
ITERATIVE EXTENSION OF NUMBER OF SETUPS

Number of setups	Included setups	Clustering error
1	3	15.12%
2	3, 4	2.50%
3	3, 4, 1	17.02%
4	3, 4, 1, 6	1.20%
5	3, 4, 1, 6, 2	0.40%
6	3, 4, 1, 6, 2, 5	0.60%

The question as to whether it is necessary to examine all the setups in order to obtain good results arises, also when it comes to vectors of larger dimensions, the examination of all possibilities becomes impractical. Next experiment aimed analyzing the effect of the number of setups on the clustering result, as well as the importance of different setups. The experiment was organized in a way that the number of included setups was iteratively expanded from one to all, adding new setups that maximize the result. The results of the experiment are given in Table 1. Two phenomena are noticed, one is that it is possible to get a result comparable with the result that includes all the setups by using less setups. It can also be noticed that the inclusion of certain setups results in degradation of the end result. It is worth paying attention to researching the impact of different setups on the end result, as well as finding an adequate measure, which will be the subject of future research.

V. CONCLUSION

In wide use, in a wide variety of applications, a variety of clustering methods exists, each with its advantages for a particular type of problem. In this paper, a new method of clustering is proposed, which has yet to be examined regarding the advantages and disadvantages, and possible fields of application. The approach based on the QQ-plot and the Fibonacci numbers proposed in this paper does not look like any of the other well-known clustering methods, leaving room for certain applications, in which the proposed algorithm could be pointed out in relation to the already familiar methods.

The aim of this paper was to show that clustering of multidimensional data can be performed using QQ-plot. Further research for improvement of the proposed steps of the algorithm remains an open question. Also, it is important to solve the issue of engaged setups, which is imposed as a necessary topic of further research.

Robust Object Tracking based on SURF in Thermal Images

Nataša Vlahović, *Member, IEEE,* Željko Đurović

***Abstract*—This paper describes the problem of single object tracking in thermal image by using SURF (Speeded Up Robust Features) feature descriptor and Kalman filter. Kalman filter is as good as its model, so the measurement and process noise matrices calculation for the specific problem are inevitable and important step in obtaining good tracking results. On the other hand, outliers - deviations from the assumed noise distributions (Gaussian in the case of Standard Kalman filter) can affect and compromise the tracking result of Standard Kalman filter. That is why robust statistics methods are used. In this paper, Robust Kalman filter is modelled using the Huber influence function. The designed Robust Kalman filter is than used along with SURF feature descriptor in the task of pedestrian tracking.**

***Index Terms*— object tracking, SURF descriptor, Kalman filter, Robust Kalman filter, robust statistics, thermal image.**

I. Introduction

Thermal imaging has been associated with military applications only for a long time. Today, thermal sensors are not as expensive as they used to be, their size is decreased, while image quality is significantly increased. With this recent development in the area, thermal imagery is now widely used in civil applications as well. Thermal sensors measure the reflected or emitted radiation of different objects in the scene, and that is why these sensors enable the same visibility in the darkness as in the day light. Thermal sensors are passive, since radiation is emitted by object itself, which is another important advantage of thermal imagery [1]. The infrared wavelength band is divided into: near infrared (NIR, wavelengths 0.7–1 μm), shortwave infrared (SWIR, 1–3 μm), midwave infrared (MWIR, 3–5 μm), and longwave infrared (LWIR, 7.5–12 μm). In this paper, noise characteristics are studied on MWIR thermal camera of the resolution 640x480.

In target tracking applications feature descriptors are often used for feature matching on successive frames. Not all feature descriptors used in images obtained from color cameras can be used in the same way in thermal images, since many image characteristics are different. So, it can be said that there are some misconceptions when talking about object tracking in thermal infrared. The first one is that thermal tracking is hotspot tracking only, but the situation is certainly more complex than that. The other misconception is that thermal infrared tracking is the same as grayscale visual imagery tracking [2]. Thermal images do not have shadows, they have different noise characteristics [3], [4] as well as patterns from variation in material and temperature, not from color such as in color images.

In this paper, the task of single object tracking is addressed. The selected method includes the object description with feature descriptors. SURF (Speeded Up Robust Features) features are found to be very successful in the thermal image domain [5], [6], and that is why these descriptors are chosen. The next step is using the Kalman filter to predict the position of the target in situations where SURF feature descriptor does not give correct results, or when features cannot be found at all. The first step is certainly using SURF detector and Standard Kalman filter for the tracking task. The process and measurement matrix are set according to calculated noise statistics for the observed thermal image.

Since Kalman filter implies a state space model made on some assumptions (measurement and process noise are Gaussian), these assumptions do not have to be true for the observed scenario. And often, this model does not fit the real situation. So minor deviations from the assumptions can affect results. That is why, in this paper, robust procedures are used to signify insensitivity to small deviations from assumptions [7].

II. SURF feature descriptor

Features are some specific structures in an image, which can be corners, or other shapes or blobs. The descriptor chosen for the task of object tracking in thermal image, in this paper, belongs to the family of Spectra Descriptors. SURF (Speeded-up Robust Features) descriptor is developed as a faster version of SIFT descriptor, and it balances the two important requirements in every system: computation speed and performance. SURF detector is scale and rotation invariant [8].

The SURF algorithm is based on the multi-scale space theory and Hessian matrix while it uses its basic approximation. SURF creates a stack, and results in images of the same dimension. Due to the use of integral images, SURF filters the stack using a box filter approximation of the second order Gaussian partial

derivatives. Integral images allow the computation of rectangular box filters in near constant time [5].

Feature descriptor SURF (Speeded-up Robust Features) is chosen from the family of feature descriptors for the task of object tracking in thermal image. Among descriptors from the other families, this detector has shown better performance than descriptors from the other families [5].

SURF features can distinguish light (foreground) and dark (background) patterns due to the gradient orientations used to describe a certain image region. This means that the descriptor of a light region on dark background does not match a dark region on light background and vice versa, which is very useful in the task of pedestrian tracking, since persons are typically lighter than the background objects [8], [6].

III. KALMAN FILTER IN OBJECT TRACKING

A. Standard Kalman filter

Kalman filter represents widely applied algorithm in the field of object tracking, while being one of the most important achievements of linear estimation field [10].

In this paper, Kalman filter models the dynamics of the center of the tracked object, while assuming constant object velocity. The system is represented by the state-space model:

$$x(k+1) = F(k)x(k) + G(k)w(k) \quad (3)$$

$$y(k) = H(k)x(k) + v(k) \quad (4)$$

where *x(k)* represents the state vector and *y(k)* represents observation vector, while *w(k)* is the state noise and *v(k)* is the measurement noise. The state noise *w(k)* and the measurement noise *v(k)* are assumed to be zero mean white noises:

$$E\{w(k)\} = 0; E\{w(k)w(k)^T\} = Q(k)\delta_{kj}; \quad (5)$$

$$E\{v(k)\} = 0; E\{v(k)v(k)^T\} = R(k)\delta_{kj}; \quad (6)$$

where δ_{kj} is the Kronecker's delta symbol and E{.} is the mathematical expectation. *F(k)* is the state transition matrix, and *H(k)* is the observation matrix. If $\hat{x}(k/k-1)$ is the linear least squares estimate of *x(k)* and *P(k/k-1)* denotes the corresponding error covariance matrix, then the standard Kalman filter recursions are:

$$\widehat{x_p}(k+1/k) = F(k)\hat{x}(k/k) \quad (7)$$

$$P_p(k+1/k) = F(k)P_p(k/k)F^T(k) + G(k)Q(k)G^T(k) \quad (8)$$

$$K(k) = P_p(k/k-1)H^T(k)[H(k)P_p(k/k-1)H^T(k) + R(k)]^{-1} \quad (9)$$

$$\hat{x}(k/k) = \widehat{x_p}(k/k-1) + K(k)(y(k) - H(k)\hat{x}(k/k-1)) \quad (10)$$

$$P_p(k/k) = [I - K(k)H(k)]P_p(k/k-1) \quad (11)$$

The initial state *x (0)* is a random value, independent of the future noises *w(k)* and *v(k)* with zero mean and covariance matrix *P (0)*. [11]

B. Robust Kalman filter

Standard Kalman filter, as a statistical method, relies on some assumptions. It gives good results when the initial assumptions are correct: the distribution of noise in observed data is Gaussian. This makes the resulting model more manageable, but, in real situations, these assumptions are usually not correct. The main reason for assuming a normal distribution is that it can be a good and convenient assumption, which enables using optimal statistical methods, such as Kalman filter, among many others. These classical statistics are quite easy for computation. But, the probability density function of noise in real applications deviates from Gaussian, thus making Standard Kalman filter sensitive to outliers in the data, and non-robust. Outliers are data that are atypical for the observed case, and in our case of single object tracking in thermal imagery outliers can be of various nature. Even a single outlier can have a great impact on Standard Kalman filter results.

On the other hand, when using the robust estimation theory, the effect of these outliers can be minimized. If the data contain no outliers the robust method gives approximately the same results as the classical method, while if a small proportion of outliers are present the robust method gives approximately the same results as the classical method applied to the "typical" data. That is why robust methods are reliable method of outlier detection [12].

In this paper, we use the following Robust Kalman filter method:

1) Initialization step:
   - The initial state *x (0)* is a random value, independent of the future noises *w(k)* and *v(k)* with zero mean and covariance matrix *P (0)*.
   - The state noise *w(k)* and the measurement noise *v(k)* are assumed to be zero mean white noises:

$$E\{w(k)\} = 0; E\{w(k)w(k)^T\} = Q(k)\delta_{kj}; \quad (12)$$

$$E\{v(k)\} = 0; E\{v(k)v(k)^T\} = R(k)\delta_{kj}; \quad (13)$$

   - Defining Huber influence function:

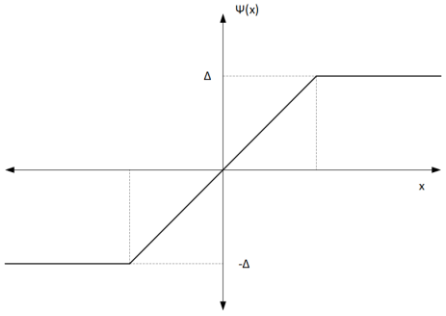

Fig. 1. Huber influence function

$$\psi(x) = \begin{cases} x & , |x| \le \Delta \\ \Delta\, sgn(x) & , |x| > \Delta \end{cases} \quad (14),$$

where Δ is any constant [13].

2) Prediction step:

$$\hat{x}_p(k) = F(k-1)\hat{x}(k-1) \quad (15)$$

$$P_p(k) = F(k-1)P(k-1)F^T(k-1) + G(k-1)Q(k-1)G^T(k-1) \quad (16)$$

3) Robust estimation step:

$$\varepsilon(k) = y(k) - H(k)\hat{x}_p(k) \quad (17)$$

$$S(k) = H(k)P(k)H(k)_k^T + R_k \quad (18)$$

$$d^2(k) = [S_{11}\ S_{22}\ \dots\ S_{nn}] \quad (19)$$

$$v_n(k) = \varepsilon(k) \oslash d(k)\,, \quad (20)$$

Where $\oslash$ is Hadamard division (element by element division)

$$\psi(k) = \psi\big(v_n(k)\big) = min(|v_n(k)|, \Delta) sgn(v_n(k)) \quad (21)$$

$$\omega(k) = \begin{cases} \frac{\psi(v_n(k))}{v_n(k)} & , v_n(k) \neq 0 \\ 1 & , v_n(k) = 0 \end{cases} \quad (22)$$

Based on Robust dynamic stochastic approximation estimator theory [12], an approach based on the definition of a time-varying functional, we can write:

$$K(k) = \omega(k)P_p(k/k-1)H^T(k) * [H(k)P_p(k/k-1)H^T(k) + R(k)]^{-1} \quad (23)$$

$$\hat{x}(k) = \hat{x}_p(k/k-1) + K(k)\varepsilon(k) \quad (24)$$

$$P(k) = [I - K(k)H(k)]P_p(k-1) \quad (25)$$

4) Increment k, the number of iterations, and repeat the procedure from the step 2.

IV. Experimental Results and Discussion

A. Standard Kalman filter results

A starting point in object tracking system design, in this paper, is using SURF features and Standard Kalman filter for the basic system setting. First, SURF features are extracted from the initially set object position region of interest (ROI). The next step is the center position calculation from matched features' locations. This position is Kalman filter measurement vector, with x and y coordinates of the center of the object. Kalman filter predicts the position of the bounding box in the next frame, in accordance with the adopted motion model. In the case where no matched points are found, Kalman filter prediction is used as the center of the object for the next iteration. When the measurement and process noise values are not properly set for the specific problem, Kalman filter cannot give good results [11]. In this case, Kalman filter is used to give predictions when no matched points are found.

Process noise statistics are calculated from the difference image, made from the first two frames of the sequence. The initial measurement noise is calculated from the ground truth data from the given dataset. A difference between ground truth and real measured positions obtained from SURF points matching is calculated. This way, mean values and variances of the measurement and process noise are set.

Standard Kalman filter tracking gives good results when SURF feature matching does not have any obstacles or situations where features are not properly found or matched. This situation is shown in Figure 2 and Figure 3, where the tracking error of x and y position is shown.

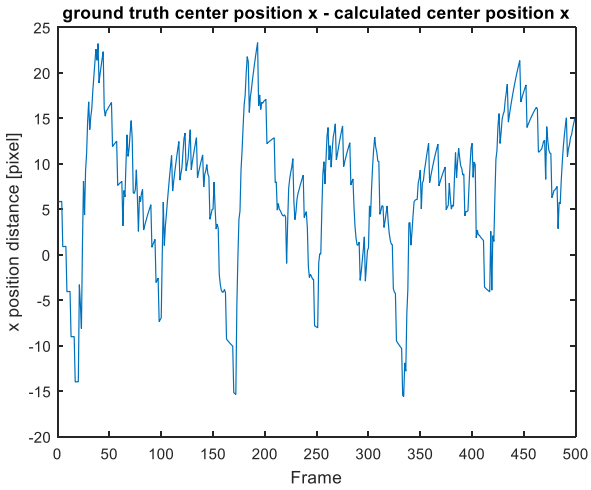

Fig. 2. Standard Kalman filter – dataset 1, error x coordinate

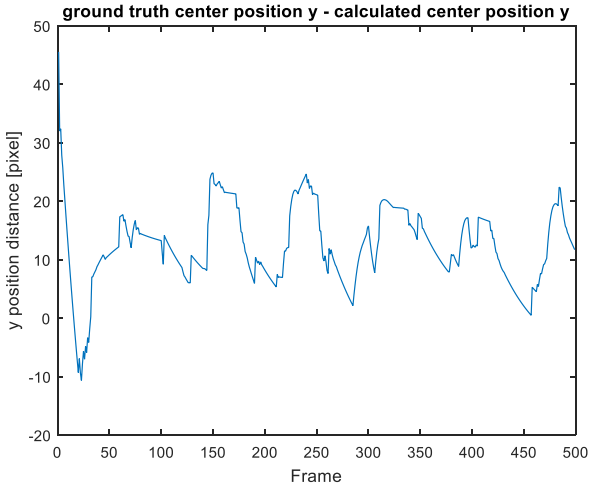

Fig. 3. Standard Kalman filter – dataset 1, error y coordinate

On the other hand, when outliers are present in the data, when SURF feature matching step gives results that step out of calculated noise statistics, Standard Kalman filter does not give good results. These are situations when SURF algorithm finds matching features on some other object in image, or when there

is an obstacle in the image that prevents good matching, as shown in Figure 4.

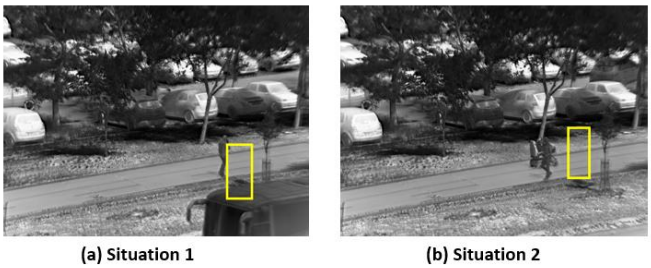

Fig. 4. Standard Kalman filter – estimation error because of an outlier, (a) situation 1 – wrong matching, (b) situation 2 – obstacle in the image

That is why, the next step is designing Robust Kalman filter that ignores outliers in the data.

B. Robust Kalman filter results

The next step, after the Standard Kalman filter design, is Robust Kalman filter design, with the Huber M-function as an influence function.

First, the results for the sequence 1 will be shown. This is a sequence where there are no obstacles, and the comparative results for Standard and Robust Kalman filter are shown. Figure 5 and Figure 6 show ground truth positions as well as Standard and Robust Kalman filter estimations for x and y coordinates, while Figure 7 and Figure 8 show the estimation error in pixels for both coordinates.

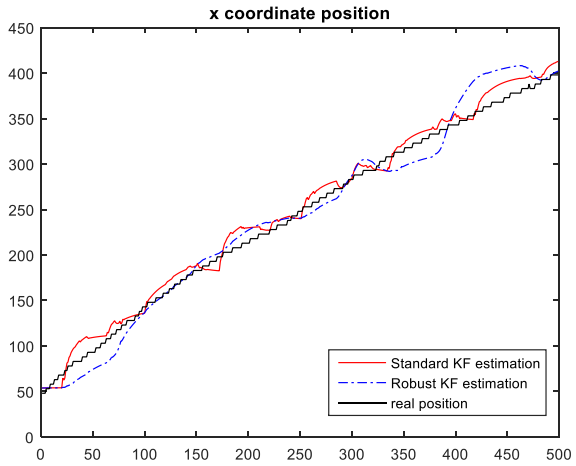

Fig. 5. Comparative representation of estimation results for x coordinate, Standard and Robust KF, sequence 1

SURF features used with Standard Kalman filter for the tracking problem give good performance in the case of expected noise statistics, which is shown in Figures 2 and 3. This is the situation where Robust Kalman filter gives the same or, in some parts, slightly larger error than Standard Kalman filter, but both filters continue tracking the target.

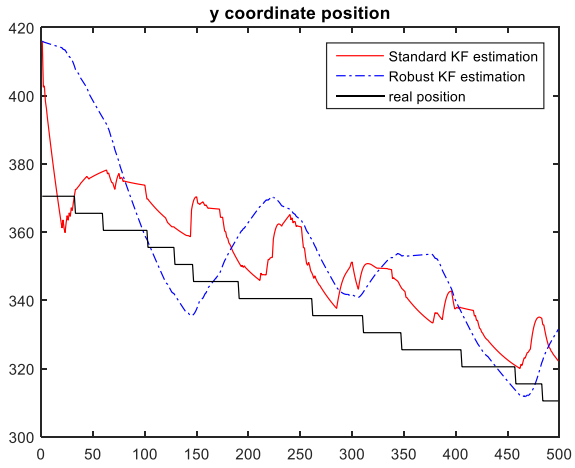

Fig. 6. Comparative representation of estimation results for y coordinate, Standard and Robust KF, sequence 1

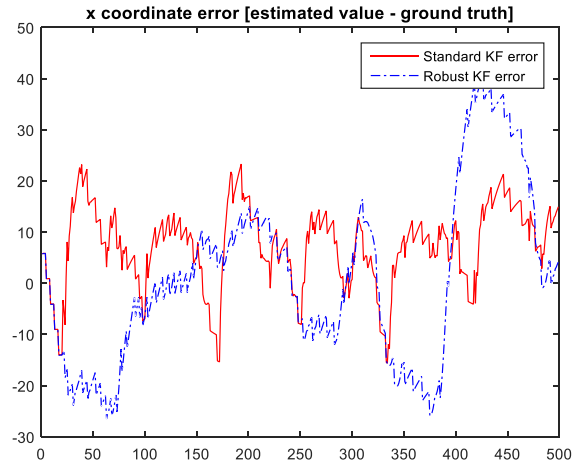

Fig. 7. Estimation error in pixels, results for x coordinate, Standard and Robust KF, sequence 1

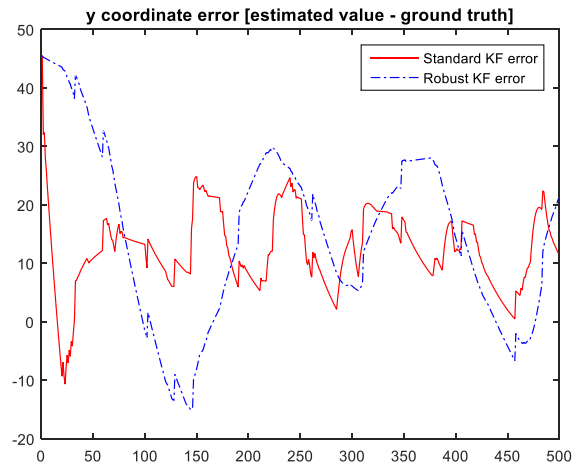

Fig. 8. Estimation error in pixels, results for y coordinate, Standard and Robust KF, sequence 1

As we already mentioned, Standard Kalman filter has problems when dealing with outliers in the data. That is why

for the sequence 2, where SURF algorithm gives imprecise measurements, Robust Kalman filter with Huber influence function gives good results. A few frames from the sequence are shown in Figure 9, Standard (upper three frames) and Robust KF.

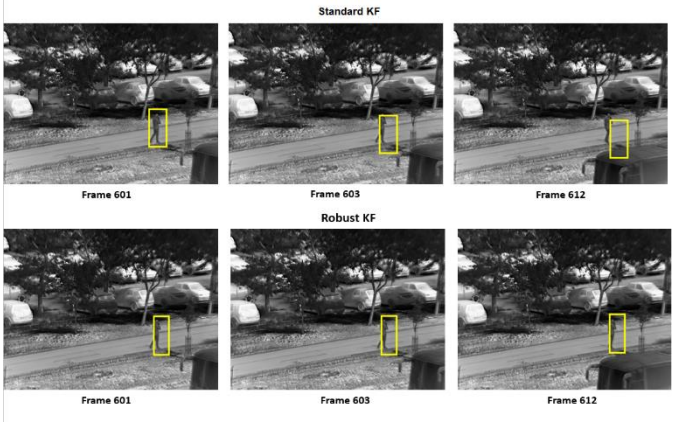

Fig. 9. Standard (upper frames) and Robust KF tracking results, sequence 2

As we can see from the Figure 9, y coordinate has the outlier in measurement data. Figure 10 shows comparative representation of the estimated position for Standard and Robust KF, along with the real coordinates. It points out that Robust Kalman filter does not react on this outlier like Standard Kalman filter does.

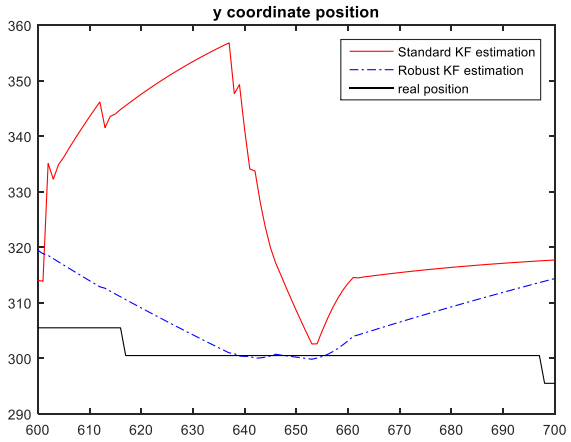

Fig. 10. Comparative representation of Standard and Robust KF, along with ground truth position for y coordinate, sequence 2

The estimation error (deviation of Standard and Robust KF estimation from real positions) for the y coordinate is shown in Figure 11. So, from the results presented in Figure 10 and Figure 11 it is obvious that Standard Kalman filter reacts to outliers in the measurement data poorly, while Robust Kalman filter ignores them while continuing tracking the object of interest.

In the next observed situation 3, there are outliers present in the x coordinate measurement data. This situation also shows that, in the presence of outliers in the data, Standard Kalman filter has lost the target completely, while Robust Kalman filter continues tracking the target.

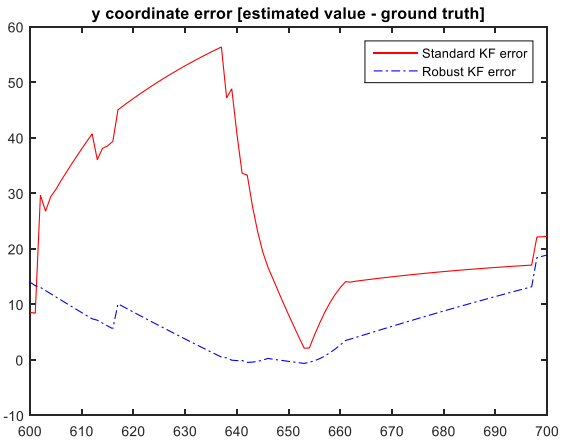

Fig. 11. Estimation error in pixels, results for y coordinate, Standard and Robust KF, sequence 2

For the situation 3, the results for x coordinate only are presented, since it contains outliers. In Figure 12 comparative representation of the estimated position for Standard and Robust KF, and real coordinates is shown (Figure 12), as well as estimation error (Figure 13).

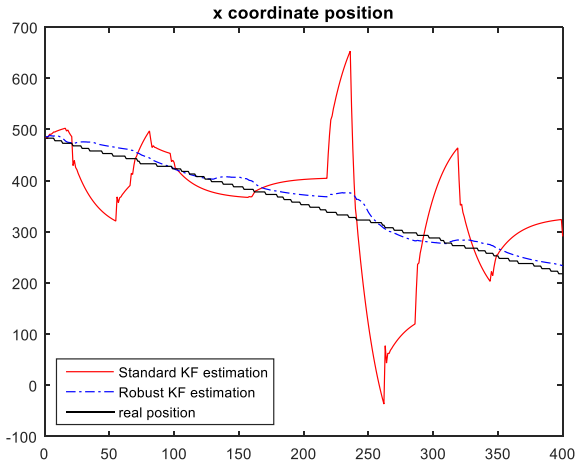

Fig. 12. Comparative representation, x coordinate, sequence 3

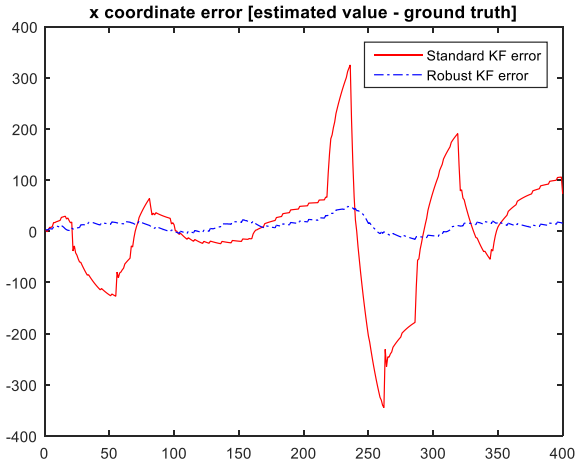

Fig. 13. Estimation error in pixels, results for x coordinate, Standard and Robust KF, sequence 3

In the Figure 14 frames from the real sequence are shown, with estimated position of bounding box in the case of Standard (left image) and Robust Kalman filter (right image).

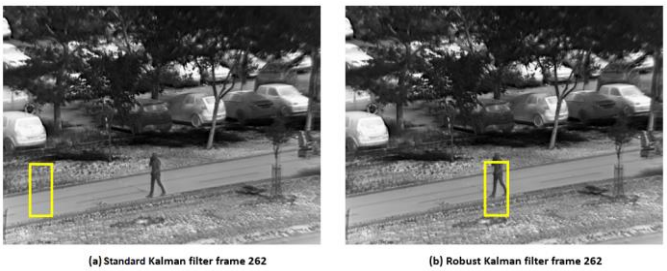

Fig. 14. (a) Standard KF result (left) and (b) Robust KF tracking result, sequence 3

C. Discussion

The situation 1 shows that in the case of the assumed noise distributions without outliers in the data, Standard Kalman filter used with SURF feature matching gives good results, even more precise than Robust Kalman filter.

On the other hand, in the real situations the existence of the outliers in the measurement data is inevitable. That is when the assumptions that Standard Kalman filter is built on are no longer true. Robust Kalman filter gives the solution to the outlier's problems, illustrated in Figure 4.

For the situation 2, the outlier is contained in the y coordinate SURF matching result, which is measurement data for the Kalman filter. SURF feature matching algorithm actually found features not contained in the tracked object. In figures 9, 10 and 11 it is shown that Robust Kalman filter can deal with this type of outliers.

For the situation 3, the outlier is contained in the x coordinate SURF matching result. This outlier is a result of an obstacle that covered the tracked object resulting in the loss of target. In figures 12, 13 and 14 it is shown that Robust Kalman filter can deal with this type of outliers also.

So, the actual tracking results in presence of outliers in the data show that Standard Kalman filter can easily lose the target, while Robust Kalman filter continues tracking the pedestrian as if nothing happened.

V. Conclusion

In this paper, a problem of single object tracking with SURF feature descriptor in thermal image is shown. Even though SURF descriptor can be good for the tracking problem in thermal imaging, it often happens that no feature is found in the image, or that some obstacles affect the matching results. That is why Kalman filter is used, to give object position predictions when the SURF algorithm fails.

In this step of Kalman filter design, it is important to emphasize that Kalman filter noise statistics need to be set for the specific problem, or Kalman filter cannot give good results. For that reason, noise statistics for the observed type of thermal image are calculated (measurement and process noise). SURF features and Standard Kalman filter give good results when there are no outliers in the data.

On the other hand, outliers can affect the results of Kalman filter estimation, therefore the whole tracking performance. This is the reason for using Robust Kalman filter with Huber influence function, in this paper. Robust Kalman filter ignores the influence of outliers in the measurement data in a way that great deviations from the previous position are considered as an outlier, therefore their influence is reduced.

Even though Robust Kalman filters are a good solution when dealing with outliers in the data, there are many situations where Huber influence function is not good enough as an influence function. So, in the future work, some other influence functions will be considered. Also, combination of Adaptive and Robust Kalman filters can be a good solution that can adapt dynamically to any different specific types of noise and outliers in the data, which is also a topic to consider in the future.

The CFAR Contribution on the Radar Target Tracking

Zvonko Radosavljević, Branko Kovačević and Dejan Ivković

***Abstract*—The different kinds of the constant false alarm rate (CFAR) detectors are used in radar receivers to detect targets in the surveillance zone where all of parameters of the statistical distribution of clutter are not known, or where they are nonstationary. In this time, the standard Integrated Track Splitting (ITS) filter is efficient target tracking algorithm, which is capable to integrates multiscan track with probability of target existence, which becomes the measure of track quality in ITS. We investigate the contribution of two used CFAR algorithms (CA-cell averaging and CATM-cell averaging-trimmed mean) to the quality of target tracking. After the theoretical analysis, this contribution was experimentally tested on the example of single target tracking. Preliminary results of numerical simulations are given in this paper.**

***Index Terms*—CFAR, target tracking, radar detection.**

I. Introduction

When the radar operates, they appear a different sources of noise [1]. There are unwanted signals from other sources of radiation, which can occupy the radar display fully and make targets very hard to see. Detector in radar receivers has to be a detector with the adaptive threshold because radars work always in an environment where there are different sources of noise. It must use the adaptive threshold detector, which has a feature that adjusts automatically its sensitivity according to a variety of interference power. Thus it maintains a constant probability of false alarm [2][3].

In radar receivers, most commonly used detector is the constant false alarm rate (CFAR) detector, which can be classified with algorithms that use the averaging technique, with algorithms that use ordering technique, with algorithms which are the combination of the above mentioned techniques and with algorithms that have some kind of a fusion center in their procedures [4]. They are used very often as a detectors of very close targets per azimuth and per range using the Linear and NonLinear Fusion Constant False Alarm Rate (LF-CFAR and NLF-CFAR) detectors and single CA-CFAR (Cell Averaging CFAR), OS-CFAR (Ordered Statistic CFAR) and TM-CFAR (Trimmed Mean CFAR) which are considered in [5].

When tracking targets in clutter, existence and position of targets in the surveillance are a-priori unknown. Unknown association of measurements with appropriate targets (unknown measurement source) is a common problem in multitarget tracking [6]. Automatic track initiation and termination under such conditions requires some knowledge about track existence. A track exists if it is based on measurements from a target (which follows specified dynamic and detection models), and is not a product of random clutter only. If a track follows a target, we shall call it a true track otherwise we shall call it a false track.

The ITS filter is a single target, multiscan tracking algorithm, where the track quality measure, used for false track discrimination, is the probability of target existence [2]. Each ITS track state estimate probability density function (PDF) is approximated by a Gaussian Mixture. ITS algorithm uses apriori clutter density information to discriminate clutter from target measurements [7]. Because of the uncertainties associated with the origins of the various sensor reports, it is impossible to ascertain precisely which measurement at each scan was the correct one. Further, since sensor detection probability is generally below unity, it is also possible that no measurement on the target was received on a given scan. Pruning [3] involves either removing measurement histories with low probability or removing whole subtrees of measurement histories. How different types of CFAR detectors influence of the quality of targets tracking is the subject of the theoretical and experimental analysis in this paper. However, this topic is not often processed in the literature. Mostly, the targets clutter is treat only in the sense of radar and CFAR thresholding [8], without review of tracking. This paper will be examined the effects of the two different CFAR detectors to the target tracking system.

The paper is organized as follows. After the introducing preamble, problem statements are presented in the Section 2. The cell averaging (CA) and cell averaging-trimmed mean (CATM) CFAR detectors are described at the beginning briefly, in the Section 3. The standard steps of known ITS algorithm is given by the Section IV. At the end of this Section, a probability of detection dependence on target tracking, followed by the results of simulation and final conclusions, from the Section V and Section VI, respectively.

II. Problem Statement

Any target tracking scenario is defined from at least two parameters: probability of detection and clutter density. Again, the clutter density is depending on target dynamics and

Zvonko Radosavljević (corresponding author) is with Military Technical institute, R.Resanovica 1, 11030 Belgrade, Serbia (zvonko.radosavljevic@gmail.com).

Branko Kovacević is with the School of Electrical Engineering, University of Belgrade, 73 Bulevar kralja Aleksandra, 11020 Belgrade, Serbia (e-mail: kovacevic_b@etf.rs).

Dejan Ivković is with Military Technical institute, R.Resanovica 1, 11030 Belgrade, Serbia (e-mail: ivkovic555@gmail.com).

characteristic of sensor. Generally, clutter is defined by number of selection measurement from size of selection gate. At begin, consider the target state $x_k \in R^{n_z}$ at time interval *k*, which evolves according to:

$$x_k = Fx_{k-1} + v_k \tag{1}$$

where *F* is the state propagation matrix and the process noise, v_k is a zero mean and white Gaussian sequence with covariance matrix Q_k. Originally, size of selection gate is depending on measurements matrix *R* and process noise matrix *Q*. False tracks are consumed at begin, whence true tracks are depending on matrix *Q*. Measurement merging is best modeled in the sensor measurement space, while tracking and data association issues are using more often converted measurements. Converted target measurement $y \in R^{n_y}$ is:

$$y_k = Hx_k + w_k \tag{2}$$

Clutter measurements follow the non-uniform Poisson distribution by clutter measurement density (Poisson intensity) ρ_y. Each track is a set of components. The number of components before processing the measurements at scan *k* will be denoted with $C_k \geq 1$. The sufficient statistic of each track is the union of the sufficient statistics of its components. The article is having a practical contribution while approve which optimal depth of component memory is needed for the specific tracking situation

III. Description of CA and CATM-CFAR

The basic parameters of each *CFAR* are the probability of false alarm rate P_{FA}, size of the window detection $N = 2n$, average signal value in cells *Z*, scaling factor of the detection threshold *T* and detection threshold *S*. Scaling factor of the detection threshold *T* is a constant which achieves a desired value of the probability of false alarm for a given size of the window detection *N*. The detection window consists of two groups with the same number of cells *n* that are located on the opposite sides with respect to the cell whose contents are tested. *CFAR* processes signals by averaging of signals in *2n* neighborhood range bins (X_i) and the resulting mean value compares with the signal in range bin which is under test (*Y*).

The cell averaging (*CA*) *CFAR* algorithm [4] consists of two collector for the leading and lagging windows (Fig. 1). Here, *Z* is simply the sum of Y_1 and Y_2. The cell *Y* in the middle of the reference window is a cell under test. Input samples are sent serially into the reference window. At begin, we calculate the mean clutter power level *Z* using the appropriate *CFAR* algorithm, and than we multiply *Z* by a scaling factor *T* which depends on the *CFAR* algorithm and the designed probability of the false alarm rate P_{fa}. Probability of detection P_{DCA} is given by [5]:

$$P_{DCA} = \left(1 + \frac{T}{1 + SNR}\right)^{-N} \tag{3}$$

where *SNR* is signal-to-noise ratio.

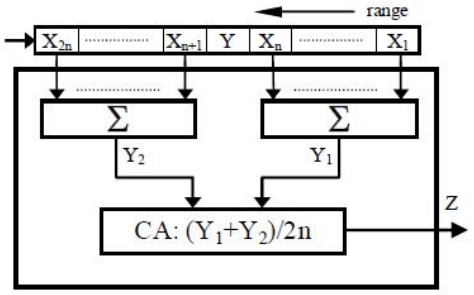

Figure 1 CA-CFAR algorithm

The *CATM-CFAR* [4][5] is cell-averaging-trimmed-mean detector which is optimizes features of some mentioned *CFAR* detectors from different groups depending on the characteristics of clutter and targets, and it is shown in Fig. 2. Main goal of *CATM-CFAR* modelling was increasing the probability of detection at a constant probability of false alarm rate. The cell *Y* in the middle of the reference window is a cell under test. Input samples are sent serially into the reference window.

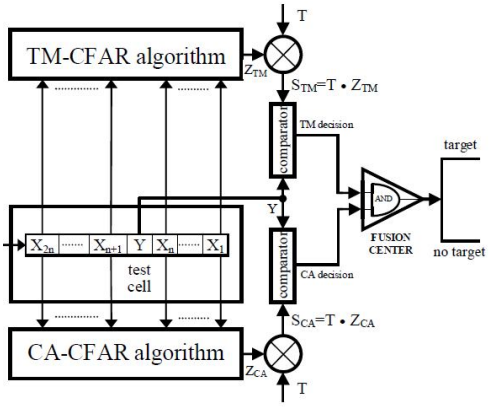

Figure 2 Block diagram of *CATM-CFAR* detector

The first step is to calculate the mean clutter power level *Z* using the appropriate *CFAR* algorithm. The second step is to multiply *Z* by a scaling factor *T* which depends on the *CFAR* algorithm and the designed probability of the false alarm rate P_{FA}. The product *TZ* is the detection threshold *S*. In this time, the *TM-CFAR* detector use first cells in the reference window to be sorted per amplitude. Then it trims T_1 smallest cells and T_2 cells with the highest amplitudes. After that, the summation of the content in the remaining cells is done to obtain *Z*. *CATM CFAR* algorithm is realized by the parallel. The *CA CFAR* detector and the *TM CFAR* detector work simultaneously and independently but with the same scaling factor of the detection threshold *T*. They produce their own mean clutter power level *Z* using the appropriate *CFAR*

algorithm. Next, they calculate their own detection thresholds S_{CA} and S_{TM}. After the comparison with the content in the cell under test *Y*, they decide about target presence independently. The finite decision about target presence is made in the fusion center composed of one"and" logic circuit. If both input single decisions in the fusion center are positive, the finite decision of the fusion center is the presence of the target in the cell under test. In other cases, the finite decision is negative and the target is not at the location which corresponds with the cell under test. Probability of detection P_{DCATM} is given by [5]:

$$P_{DCATM} = \left(1+\frac{T}{1+SNR}\right)^{-N}\prod_{i=1}^{N-T_1-T_2} M_{V_i}\left(\frac{T}{1+SNR}\right) \quad (4)$$

where M_V in (4) is defined as:

$$M_{V_1}(T) = \frac{N!}{T_1!(N-T_1-1)!(N-T_1-T_2)}\cdot\sum_{j=0}^{T_1}\frac{\binom{T_1}{j}(-1)^{T_1-j}}{\frac{N-j}{N-T_1-T_2}+T} \quad (5)$$

and

$$M_{V_i}(T) = \frac{a_i}{a_i+T}, \quad i = 2,3,...,N-T_1-T_2 \quad (6)$$

where a_i is defined as:

$$a_i = \frac{N-T_1-i+1}{N-T_1-T_2-i+1} \quad (7)$$

3.1 Probability of detection of optimal CFAR detector

In radar signals processing, is not possible to use an optimal detector with the fixed optimal threshold S_O to decide target existence, because is it a priori unknown background clutter. A solution is to use the *CFAR* detector which has a constant probability of false alarm. For the optimal detector with the fixed optimal threshold S_O, the probability of detection P_D is given by [4]:

$$P_D = P[Y > S_O \mid H_1 \mid] = \exp[-\frac{S_O}{2\mu(1+SNR)}] \quad (8)$$

where H_1 is the hypothesis the target is present in the radar cell, parameter *SNR* signal to noise ratio and μ background clutter power. The corresponding diagram of dependence of probability of detection versus $\hat{x}_{k|k}$ signal-to-noise ratio *SNR* is given in Fig. 3 according to (3), (4) and (8) for N=16 and P_{fa}=10^{-6}. Finally, we have *CFAR* probability of detection - P_D^{CFAR} as follows [9]:

$$P_D = P\{\chi_{k-1} \mid Z^{k-1}\} = \sum_{c=1}^{C_{k-1}} P\{\chi_{k-1}^c \mid Z^{k-1}\} = P_D^{CFAR} \quad (9)$$

IV. Integrated Track Splitting Algorithm

Assume that each track is the union of components. The estimation state of each component is the output of a filter which is given a single measurement at each scan. The *ITS* filter models each track as a set of components, where each component is defined with a unique measurement history which consists of zero or one measurement received each scan. For each component the state estimate and the a-posteriori probability of component existence are computed recursively. After each scan, a new component is formed from each pair of (existing component; associated measurement) [6]. The probability of the new component existence is the probability that the parent component exists and that the measurement used to create the new component is the target measurement. The probability of target existence, mean and covariance of the state estimate for the track are then calculated and used for track maintenance and track output. Thus each component represents a possible measurement-to-target association history, and components are mutually exclusive. Each component state consists of the probability of the component existence and the component state estimate PDF conditioned on the component existence

A. Target state propagation

Denote the number of components of a track at time *k* with C_k. Let the event that the target exists at time *k*, and therefore the track is a true track, will be denoted by χ_k. A selected set of measurements,z_k, is used to update the track state at scan *k*, with $Z^k = \{z_k; Z^{k-1}\}$ denoting the set of all selected measurements up to and including scan *k* [10]. Thus the a posteriori probability of target existence at time *k - 1* is given by:

$$P\{\chi_{k-1}\left|Z^{k-1}\right.\} = \sum_{c=1}^{C_{k-1}} P\{\chi_{k-1}^c\left|Z^{k-1}\right.\} \quad (10)$$

where $P\{\chi_{k-1}\left|Z^{k-1}\right.\}$ is the probability of existence of the cth component. The a priori probability of component existence is updated using the Markov Chain One for component c and track respectively:

$$P\{\chi_k^c\left|Z^{k-1}\right.\} = \pi_{11}P\{\chi_{k-1}^c \mid Z^{k-1}\} \quad (11)$$

$$P\{\chi_k\left|Z^{k-1}\right.\} = \pi_{11}P\{\chi_{k-1} \mid Z^{k-1}\} \quad (12)$$

where π_{11} denotes the probability that the true track remains a true track, e.g. the target will not disappear.

B. Track State Update

The *PDF* of the target state estimate is the mixture of mutually exclusive component state estimate *PDF*. The component state estimate *PDF* is conditioned on the target existence and component data association history being the correct one and the track state estimate PDF is conditioned on the target existence. Thus the a posteriori track state *PDF* is given by [11]:

$$P\{\chi_k \mid Z^k\} = \frac{\sum_{c=1}^{C_k} P\{\chi_k^c \mid Z^{k-1}\} p^c(x_k \mid Z^k)}{P\{\chi_k \mid Z^k\}} \quad (13)$$

where $p^c(x_k \mid Z^k)$ is the a posteriori component state estimate PDF. At the start of scan k, the ITS filter has Ck components. Associated with each component c is an a priori existence probability $P\{\chi_k^c \mid Z^{k-1}\}$ and an a priori component measurement PDF, $p\{z \mid Z^{k-1}\}$, which is derived from the filtered component state estimate PDF and sensor measurement model. Then the track measurement PDF is given by [12]:

$$p(z_k \mid Z^{k-1}) = \frac{\sum_{c=1}^{C_k} P\{\chi_k^c \mid Z^{k-1}\} p^c(x_k \mid Z^{k-1})}{P\{\chi_k \mid Z^{k-1}\}} \quad (14)$$

Each track selects a set zk of mk candidate measurements, in such a manner that the probability the target measurement is selected, assuming the target exists and is detected, is PW. Denote by zk;i the ith measurement in zk, and by:

$$p_{k,i} = p(z_{k,i} \mid Z^{k-1}) = \frac{\sum_{c=1}^{C_{k-1}} P\{\chi_k^c \mid Z^{k-1}\} p^c(x_k \mid Z^{k-1})}{P\{\chi_k \mid Z^{k-1}\}} \quad (15)$$

its likelihood, where $p^c(z_{k,i} \mid Z^{k-1})$ is likelihood of measurement zk,I with respect to component c. Denote by $\rho_{k,i} \cong \rho\{z_{k,i}\}$ clutter measurement density at zk,i. Define measurement likelihood ratio at time k by [13]:

$$\Lambda_k = 1 - P_D^{CFAR} P_W \sum_{i=1}^{m_k} \frac{p_{k,i}}{\rho_{k,i}} \quad (16)$$

Updated probability of target existence is:

$$P\{\chi_k \mid Z^k\} = \frac{\Lambda_k P\{\chi_k \mid Z^{k-1}]}{1-(1-\Lambda_k)P\{\chi_k \mid Z^{k-1}\}} \quad (17)$$

Each measurement outcome $i \geq 0$ is paired with each old track component *c* to create a new track component. The state estimate of new components is obtained by updating the state prediction pdf of the parent component c with the measurement $z_{k,i}$ (or not updating for *i = 0*). Denoted by k;ithe event that measurement outcome $i \geq 0$ is true. Posterior probability of new component existence is:

$$P\{\chi_k^c, \chi_{k,0}^c \mid Z^k\} = \frac{(1-P_D P_W)P\{\chi_k^c \mid Z^{k-1}\}}{1-(1-\Lambda_k)P\{\chi_k \mid Z^{k-1}\}} \quad (18)$$

$$P\{\chi_k^c, \chi_{k,i}^c \mid Z^k\} = \frac{P_D P_W P\{\chi_k^c \mid Z^{k-1}\}}{1-(1-\Lambda_k)P\{\chi_k \mid Z^{k-1}\}} \frac{p^{c}{}_{k,i}}{\rho_{k,i}} \quad (19)$$

C. Update Components

Each pair *(c, g)* generates a new component for the next scan, where measurement are *g = 1, 2, …G*. The probability of new component $c_n=(c,g)$ is obtained by applying the Bayes formula and is given by:

$$p(x_k \mid \chi_k, Z^k) = \sum_{c_n=1}^{C_k} \xi_k^{c_n} p(x_k \mid \chi_k, c_n, Z^k) \quad (20)$$

State estimate of new component c_n is defined by probability of component $\xi_k^{c_n}$, mean $\hat{x}_{k|k}^{c_n}$ and covariance $P_{k|k}^{c_n}$ of a posteriori state estimate of model *j*, by the following equations (for the *'nul'* mesurements):

$$\xi_k^{c_n} = \beta_{k,0} \xi_{k-1}^{c} \quad (21)$$

$$\hat{x}_{k|k}^{c_n} = \hat{x}_{k|k-1}^{c} \quad (22)$$

$$P_{k|k}^{c_n} = P_{k|k-1}^{c} \quad (23)$$

and apropos for the any other measurements:

$$\xi_k^{c_n} = \beta_{k,1} \xi_{k-1}^{c} p_k^{c_n} p_k \quad (24)$$

$$\hat{x}_{k|k}^{c_n} = \hat{x}_{k|k}^{c,g} \quad (25)$$

$$P_{k|k}^{c_n} = P_{k|k}^{c,g} \quad (26)$$

A new component c_n are obtained by applying Kalman filter state update on measurement with mean $z_k(g)$ and covariance $R_k(g)$ and apriori state estimate of model *j* of old component *c* with mean $\hat{x}_{k|k}^{c,j}$ and covariance $P_{k|k}^{c,j}$. They are standard Kalman filter formulae [1]. The preferred form of track output consists of the mean value and associated error covariance matrix of track trajectory estimate denoted by $\hat{x}_{k|k}$ and $P_{k|k}$, respectively. They are given:

$$\hat{x}_{k|k} = \sum_{c=1}^{C_{k+1}} \xi_k^c \hat{x}_{k|k|}^c \quad (27)$$

$$P_{k|k} = \sum_{c=1}^{C_{k+1}} \xi_k^c [P^c_{k|k} + \hat{x}^c_{k|k} \hat{x}^{c\ T}_{k|k}] - \hat{x}_{k|k} \hat{x}_{k|k}^{\ T} \quad (28)$$

D. Target Tracking Dependence on the CFAR Probability of Detection

In the standard ITS, each target may create one measurements with probability of detection P_D. In each scan the sensor also returns a random number of clutter measurements, parameterized by the clutter measurement density. Tracks are initialized in each scan using measurements from two consecutive scans. Taking into account eaquation (11) and (12) we have expression of the probability of detection for *CA-CFAR* is given as [4]:

$$P_D^{CA} = (1 + \frac{T}{1+SNR})^{-1} \quad (29)$$

According to the reference [5] we have probability of detection:

$$P_D^{CATM} = (1 + \frac{T}{1+SNR})^{-N} \prod_{i=1}^{n-T_1-T_2} M_{V_i}(\frac{T}{1+SNR}) \quad (30)$$

Now, we can define a new measurement likelihood ratio at time *k*, for the *CA* and *CATM CFAR* by the following equations:

$$\Lambda_k^{CA} = 1 - P_D^{CA} P_W \sum_{i=1}^{m_k} \frac{p_{k,i}}{\rho_{k,i}} \quad (31)$$

$$\Lambda_k^{CATM} = 1 - P_D^{CATM} P_W \sum_{i=1}^{m_k} \frac{p_{k,i}}{\rho_{k,i}} \quad (32)$$

respectively

V. Results of Simulations

The application selected for study was a two-dimensional (positions and velocities), four-state aircraft tracking problem in which the sensor observes both position coordinates. The area under surveillance was x = [0; 1000] [*m*] long and y = [0; 400] [*m*] wide. The false measurements satisfied a Poisson distribution with density $\rho = 10^{-4}[scan/m^2]$. Both dimensions were assumed independent, and the sensor measurement errors, target maneuver state excitation errors, and the equations of motion were assumed identical in each dimension.

The ITS parameters are calculated on-line according to the appropriate equations. Period of scanning is *T=1s*. Consider a target motion scenario with non-maneuvering constant velocity (CV) flight mode. Speed is constant 311[*m/s*]. For initialization of tracks we use a 'two point differencing' methodology. The target moves and can appear or disappear in the scene at any time, according to the linear and Gaussian target dynamics. The system input is modeled as follows: vector state $x_k = [x\ \dot{x}\ y\ \dot{y}]$ where x; y are the Cartesian coordinates of the target position, $\dot{x}; \dot{y}$ are the appropriate velocities. Initial target state x0 = [100 12 100 4]. Transition matrix and process noise matrix are given by:

$$\mathbf{F}_1 = \begin{bmatrix} 1 & T & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & T \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (33)$$

$$\mathbf{Q} = q \begin{bmatrix} T^4/4 & T^3/2 & 0 & 0 \\ T^3/2 & T & 0 & 0 \\ 0 & 0 & T^4/4 & T^3/2 \\ 0 & 0 & T^2/2 & T \end{bmatrix} \quad (34)$$

respectively, where *q = 0:252* is a maneuver coefficient. The ITS simulation process is governed by a Markov chain one. Probability of detection, for the CA CFAR and CATM CFAR and given signal to noise ratio (SNR) is 15[dB], is 0,54 and 0,66 [4], respectively [5] .

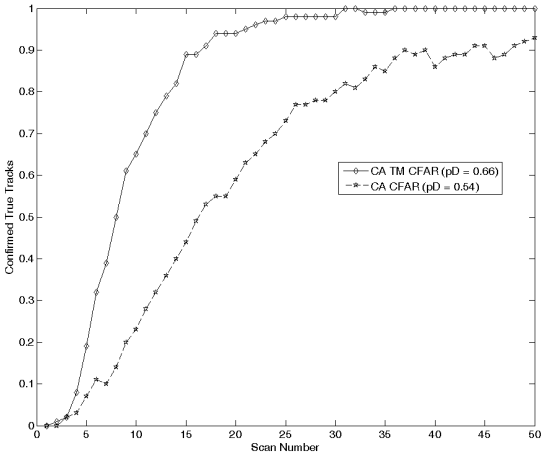

Fig. 3.Comparative confirmed true tracks diagram.

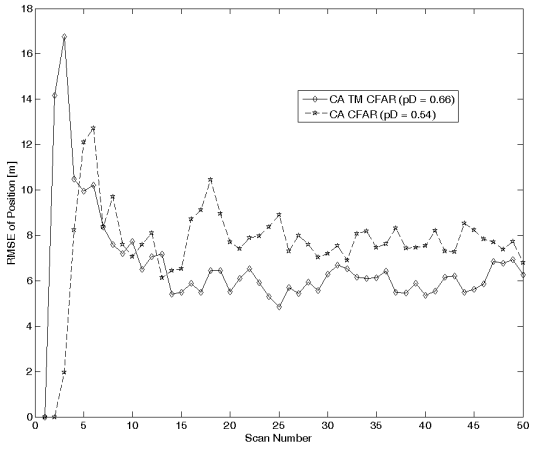

Fig. 4. Comparative RMSE of position diagram.

Respective diagrams of confirmed true tracks and root mean square error are given by the Fig: 3. and Fig: 4. On them is shown influence of two different CFAR algorithms to the target tracking quality. This analysis shows significant improvement of the tracking characteristics by using CATM CFAR algorithms, instead CA CFAR algorithms.

VI. CONCLUSION

The preliminary results of the study of the contribution of different types of CFAR detectors on the characteristics of the single target tracking were given in the paper. The application of the CA CFAR and CATM CFAR algorithms in the radar pre-processing phase and their influence on the distribution of the clatter were examined, through the scattering of the actual confirmed traces in known Integrated Track Splitting algorithm.

The result of single target tracking simulations are showed better tracking performance by the use CATM-CFAR algorithm, related to CA CFAR algorithm. In the future work, the multitarget cases will be considered.

Probability of Detection and False Alarm Density Estimation in Target Tracking Systems With Unknown Measurement Noise Statistics

Asem Elhasaeri, Aleksandra Marjanović, Sanja Vujnović, Goran Kvaščev, and Željko Đurović

***Abstract*—Successful implementation of any moving target detection system depends on precise knowledge of several statistical quantities such as the probability of target detection and false alarms density. These parameters are usually unknown as well as variable and, even though algorithms exist which are able to estimate them, they are further dependent on the knowledge of model parameters. This paper analyzes the effect the unknown measurement noise covariance has on probability of detection and clutter rate estimation in target tracking systems and proposes improvement in a form of noise covariance estimation.**

***Index Terms*—Target Tracking System, Probability of Detection, False Alarms Rate, Covariance Estimation.**

I. Introduction

During the past several decades the scientific community has shown great interest in moving target tracking systems [1]. At first, the motivation for developing these algorithms has been solely for military purposes, but later their applicability has significantly increased to areas such as traffic surveillance systems [2] and biological systems [3]. Currently in the literature many different structures are proposed for moving target tracking systems and among them there are various solutions for target state estimation filters and measurement-to-track association algorithms. Usually successful implementation of these structures heavily depends on precise knowledge of parameters such as the probability of target detection and density of false alarms. This can be quite a drawback due to the fact that these statistical parameters are usually unknown and it is difficult to estimate them because they are non-stationary in time and space. The importance of this problem has been described by [4] where it is stated that the exact knowledge of probability of target detection and density of false alarms is crucial for good behavior of modern target tracking filters such as Probability Hypothesis Density (PHD) and Cardinalized Probability Hypothesis Density (CPHD) filters.

There are several solutions presented in the literature for the problem of probability of target detection and false alarm rate estimation. In [5] Expectation Maximization (EM) algorithm is used to estimate several parameters of Gaussian Multiple Target Tracking Model (MTT), among which are probability of target detection and density of false alarms. Even though this algorithm showed great promise for offline patch procedure, in online setting it was shown to have bias. On the other hand [6] used Joint Probabilistic Data Association (JDPA) filter for estimation of both of these parameters and in [7] further complicated the problem by assuming non-homogeneous false alarm density background. The complexity of aforementioned solutions leaves much to be desired in terms of practical implementation. Recently a new approach for probability of target detection and density of false alarms estimation is proposed [8] which is based on a two-step generalized maximum likelihood (GML) approach and which is numerically simpler due to the fact that each scan generates a maximum number of two hypotheses which need to be tested. Also, this algorithm does not require any specific data association technique which further simplifies things.

Common feature among all of these algorithms is the assumption that the kinematic model parameters are known. This is not always justified, especially when the measurement error covariance is concerned. Within this paper the sensitivity of a two-step GML approach algorithm to the possible errors in measurement noise covariance matrix are analyzed in detail. Furthermore, a Kalman filter is implemented to estimate the correct value of the noise covariance matrix. This simultaneous estimation of probability of target detection and density of false alarms as well as the unknown measurement noise statistics is tested and the results with such corrected parameters are analyzed as well.

This paper is structured as follows. In Section II a detailed description of a moving target tracking system using two-step GML approach is presented. After that, in Section III the sensitivity of this algorithm to changes in measurement noise covariance matrix is analyzed and in Section IV the estimator of the noise covariance is implemented and tested. Finally, the conclusion is presented in Section V.

II. System description

Let us assume that there is a trace whose kinematic characteristics are monitored using Kalman filter model:

$$X[k+1] = \Phi X[k] + \Gamma w[k], \tag{1}$$

$$Y[k] = HX[k] + v[k]. \tag{2}$$

Here $X[k]$ is a trace state vector, $w[k]$ is a stochastic process of a model error, matrices Φ and Γ are state and input matrices, $Y[k]$ is a measurement vector and $v[k]$ is a stochastic process of a measurement noise at k-th scan. By applying Kalman filter state vector predictions can be obtained from one scan to another. The prediction will be denoted as $\hat{X}[k|k-1]$ and covariance error prediction matrix as $S[k|k-1]$.

After the prediction step, an association technique needs to be performed by forming a rectangular gate around the track prediction $\hat{X}[k|k-1]$ with dimensions $K_g\sigma_{ii}, i = 1, \ldots, n$. Here K_g is a gate parameter, σ_{ii} is the i-th diagonal element of covariance matrix $S[k|k-1]$ and n denotes spatial dimension in which the gate is applied. In each scan, in the area encompassed by the gate there can be zero, one or more observations. In an effort to construct a hypothesis whose likelihood maximization will give the estimate of unknown parameters two different cases are analyzed. In the first case the number of observations in k-th scan is $M_k = 0$ and there is only one partial hypothesis:

- H_k^0: target is not detected and the number of false alarms is zero.

In the second case the number of observations in the k-th scan is $M_k \geq 1$ and there are two partial hypotheses:

- H_k^0: target is not detected and the number of false alarms is M_k.
- H_k^1: target is detected and the number of false alarms is $M_k - 1$.

Combination of partial hypotheses in the last N scans produces integral hypotheses and there are $N_h = 2^{v(k-N+1)} \cdot 2^{v(k-N+2)} \cdots 2^{v(k)}$ of them, where $v(l) = \text{sgn}(M_l)$. Note that there is significantly smaller number of hypotheses here than in other multiple hypothesis testing approaches due to the fact that in the case when several observations are detected within a gate, only the one with the smallest statistical distance from the predicted position is analyzed for association purposes. Each integral hypothesis is associated with a likelihood function $L(H^i), i = 1, \ldots, N_h$ and the parameter pair (P_d^i, λ_{fa}^i) is computed which maximizes the likelihood of each integral hypothesis $L^{opt}(H^i) = \max_{P_d, \lambda_{fa}} L(H^i)$. Here P_d is the probability of detection, while λ_{fa} is false alarm density. After that, among all the optimal values of likelihood, the highest one is selected $L^{opt}(H^j) = \max_{i=1,\ldots,N_h} L^{opt}(H^i)$ and optimal estimations (P_d^j, λ_{fa}^j) are obtained from the chosen hypothesis.

Assuming that all the necessary conditions are satisfied [8] (i.e. $\hat{X}[k|k-1]$ is unbiased estimate of $X[k]$ and a Gaussian process, the frequency of false alarms is a Poisson process with mean $\lambda_{fa}V_g$, where V_g is an area of the gate, P_d can be considered constant, etc.), then i-th integral hypothesis can be calculated as

$$L(H^i) = \prod_{j=k-N+1}^{k} L(H_j^{p_j}), \;\; i = 1, \ldots, N_h. \tag{3}$$

Here $L(H_j^{p_j})$ is the likelihood of partial hypothesis in the j-th scan

$$L(H_j^{p_j}) = \begin{cases} (1-P_d)\frac{(\lambda_{fa}V_g)^{M_j} e^{-\lambda_{fa}V_g}}{M_j!(V_g)^{M_j}} & p_j = 0 \\ P_d \frac{(\lambda_{fa}V_g)^{M_j-1} e^{-\lambda_{fa}V_g}}{(M_j-1)!(V_g)^{M_j-1}} f_j & p_j = 1 \end{cases}, \tag{4}$$

with

$$f_j = \frac{1}{(2\pi)^{n/2}\left|S[j|j-1]\right|^{1/2}} e^{-\frac{d(j)^2}{2}}. \tag{5}$$

Here $d^2(j)$ denotes statistical distance between prediction position $X[j|j-1]$ and statistically closest observation Z_j in scan j.

Each integral hypothesis from the last N scans can be represented as a sequance of N binary digits $H^i = [p_1\, p_2 \cdots p_N]$, where p_j takes value 0 if there is no associated observation in scan $k-N+j$ and value of 1 if there is statistically closest observation associated with the trace in that scan. Then, the likelihood of integral hypothesis H^i becomes

$$\begin{aligned} L(H^i) = (1-P_d)^{N-\sum_{j=k-N+1}^{k} p_j} P_d^{\sum_{j=k-N+1}^{k} p_j} \cdot \\ \cdot \frac{\lambda_{fa}^{\sum_{j=k-N+1}^{k} M_j - p_j} e^{N\lambda_{fa}}}{\prod_{j=k-N+1}^{k}(M_j - p_j)!} \prod_{j=k-N+1}^{k} f_j(Z_j)^{p_j}, \end{aligned} \tag{6}$$

where $f_j(Z_j)$ is the probability density function

$$\begin{aligned} f_j(Z_j) = \frac{1}{(2\pi)^{n/2}\left|S[j|j-1]\right|^{1/2}} \cdot \\ \cdot e^{-0.5(Z_j - \hat{X}[j|j-1])^T S^{-1}[j|j-1](Z_j - \hat{X}[j|j-1])}. \end{aligned} \tag{7}$$

Maximization of likelihood as a function of unknown parameters is obtained by solving

$$\frac{\partial L(H^i)}{\partial P_d} = 0, \;\; \frac{\partial L(H^i)}{\partial \lambda_{fa}} = 0, \tag{8}$$

and the results are simple estimates of probability of detection ($\hat{P}_d$) and the density of false alarms ($\hat{\lambda}_{fa}$)

$$\hat{P}_d = \frac{\sum_{j=k-N+1}^{k} p_j}{N}, \hat{\lambda}_{fa} = \frac{\sum_{j=k-N+1}^{k} M_j - p_j}{NV_g}. \tag{9}$$

Further analysis of this estimator [8] shows that there is an estimation bias for both $\hat{P}_d$ and $\hat{\lambda}_{fa}$ which is smaller as the probability of detection increases. For this reason additional steps are implemented in order to reduce this bias.

The first step is estimator bias reduction and it relies on the assumption of nearly deterministic dependency among three parameters: K_g, $\hat{P}_d$ and $\hat{\lambda}_{fa}$. Corrected estimates $\hat{P}_d^c$ and $\hat{\lambda}_{fa}^c$ are obtained as:

$$\begin{aligned} \hat{P}_d^c &= \hat{P}_d + a_P K_g + b_P \hat{P}_d + c_P \hat{\lambda}_{fa} + d_P, \\ \hat{\lambda}_{fa}^c &= \hat{\lambda}_{fa} + a_\lambda K_g + b_\lambda \hat{P}_d + c_\lambda \hat{\lambda}_{fa} + d_\lambda. \end{aligned} \tag{10}$$

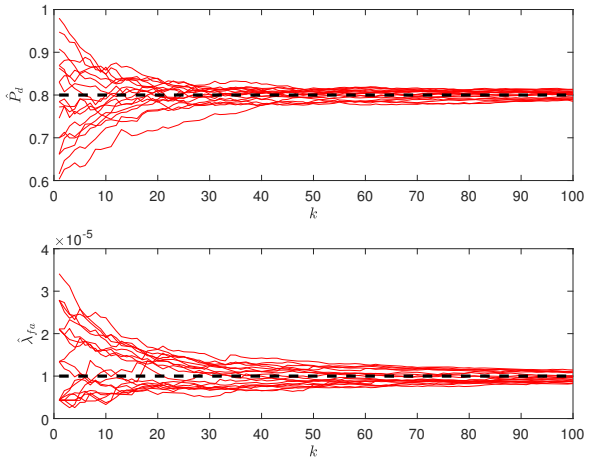

Fig. 1: Estimation results for probability of detection (up) and false alarm density (down) when all the kinematic parameters are known. Red lines represent the output of the algorithm for different initial conditions, while the black line is the correct value.

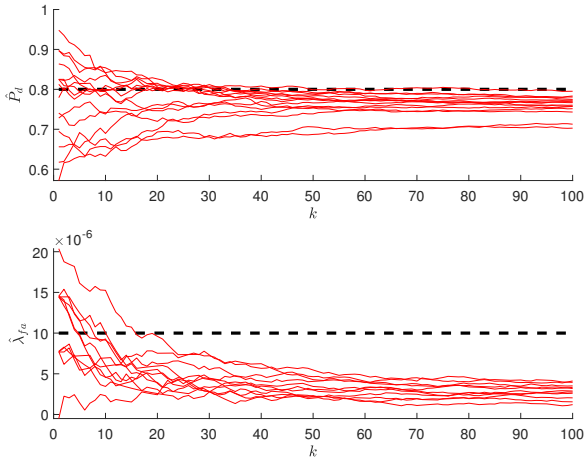

Fig. 2: Estimation results for probability of detection (up) and false alarm density (down) when measurement noise covariance matrix is unknown. Red lines represent the output of the algorithm for different initial conditions, while the black line is the correct value.

The correction parameters a_P, b_P, c_P, d_P and a_λ, b_λ, c_λ, d_λ are obtained by least squares method

$$\phi_i = (XX^T)^{-1}XY_i. \tag{11}$$

Here $\phi_i = [a_i\ b_i\ c_i\ d_i]^T, i \in \{P, \lambda\}$ are unknown correction parameters, $X = [K_g\ \hat{P}_d\ \hat{\lambda}_{fa}\ 1]^T$ is the regression vector and Y_i is the model output. These parameters are estimated for different values of gate width, detection probability and false alarm density.

The second step is estimator variance reduction using a recursive estimator with a variable forgetting factor

$$\begin{aligned}\hat{P}_d^r[k+1] &= \alpha[k]\hat{P}_d^r[k] + (1-\alpha[k])\hat{P}_d^c[k],\\ \hat{\lambda}_{fa}^r[k+1] &= \alpha[k]\hat{\lambda}_{fa}^r[k] + (1-\alpha[k])\hat{\lambda}_{fa}^c[k].\end{aligned} \tag{12}$$

Here $\hat{P}_d^r$ and $\hat{\lambda}_{fa}^r$ are the recursive estimates of probability of detection and false alarm density, and $\alpha[k] = \alpha[\infty] - e^{-k/\tau}(\alpha[\infty] - \alpha[0])$ is the variable forgetting factor with τ as a time constant representing the rate of change, and $\alpha[\infty]$ and $\alpha[0]$ its final and initial values. With these corrections the system for estimating parameters P_d and λ_{fa} is computationally simple with satisfactory performance, under the conditions that all the other parameters are known.

III. Sensitivity analysis

The system for probability of target detection and false alarm density estimation described in the previous section is highly effective and much simpler than other techniques available in the literature; however it does require the complete knowledge of the initial kinematic model from Eq. (1) and (2). Figure 1 shows the behavior of the algorithm for different initial conditions when all the necessary kinematic parameters are known. For fixed probability of detection ($P_d = 0.8$), false alarm density ($\lambda_{fa} = 10^{-5}$) and gate size ($K_g = 2.6$) it is evident that the estimation converges to correct values as the number of scans increases.

It would be interesting to analyze how possible errors in prediction covariance matrix influence the performance of the estimation algorithm. These errors are usually caused by unknown or erroneous information about the measurement noise covariance matrix R. Figure 2 shows how the algorithm behaves when it has erroneous information about the value of R. Fixed parameters are the same as in Fig. 1 and, in this case, the algorithm converges as well, but it has a significant bias. Naturally, the size of this bias depends on the magnitude of misinformation the algorithm has about measurement noise covariance matrix.

IV. Estimator adaptation

Previous chapter demonstrates high sensitivity of a two-step GML approach estimator to unknown measurement noise statistics and, therefore, erroneous covariance error prediction matrix of a model described in Eq. (1) and (2). Since a priori knowledge about the measurement noise is not known, the goal is to estimate it simultaneously with tracking parameters [9]. If we use Eq. (2) to define residual as

$$r[k] = Y[k] - H\hat{X}[k|k-1], \tag{13}$$

then the covariance matrix of this residual vector is

$$E\{r[k]r^T[k]\} = R + HS[k|k-1]H^T. \tag{14}$$

Bearing this in mind, measurement noise covariance matrix can be estimated as

$$\hat{R} = \hat{C}_r - H\hat{S}[k|k-1]H^T, \tag{15}$$

where $\hat{C}_r$ is estimated residual covariance matrix which can be obtained by generating trajectories using kinematic model from Eq. (1) and (2) with the following values:

$$\Phi = \begin{bmatrix}1 & 1 & 0 & 0\\ 0 & 1 & 0 & 0\\ 0 & 0 & 1 & 1\\ 0 & 0 & 0 & 1\end{bmatrix},\ \Gamma = \begin{bmatrix}0 & 0\\ 1 & 0\\ 0 & 0\\ 0 & 1\end{bmatrix},\ H = \begin{bmatrix}1 & 0 & 0 & 0\\ 0 & 0 & 1 & 0\end{bmatrix}. \tag{16}$$

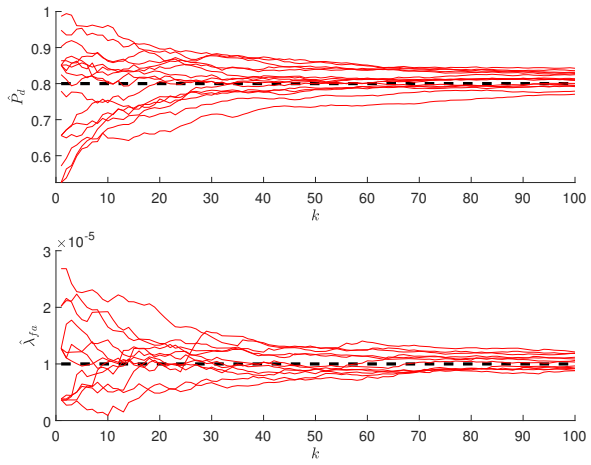

Fig. 3: Estimation results for probability of detection (up) and false alarm density (down) when measurement noise covariance matrix is estimated. Red lines represent the output of the algorithm for different initial conditions, while the black line is the correct value.

Here there are 4 states in vector $X[k]$ which are spatial coordinate x and its velocity, and spatial coordinate y, and its velocity, respectively. In each scan measurement is updated in this way, measurement noise covariance is estimated ($\hat{R}$) and then it is used to estimate parameters $\hat{P}_d$ and $\hat{\lambda}_{fa}$.

By implementing this adaptation to the existing algorithm from Section II, an augmented system is obtained which simultaneously estimates measurement noise covariance matrix ($\hat{R}$) as well as probability of detection ($\hat{P}_d$) and false alarm density estimation ($\hat{\lambda}_{fa}$) in each scan. Results of the algorithm augmented in this way can be seen in Fig. 3.

It is obvious from the figure that performance is significantly better than in the previous case when there was no a priori knowledge about parameter R. For all the initial conditions parameter estimates converge to the exact value of P_d and λ_{fa}. The dynamic of the convergence is similar to the first case in Fig. 1 when there is a priori knowledge about measurement noise, i.e. after as little as 30 scans parameter estimates approach a reasonable vicinity of the exact values. What is also noticeable is that the standard deviation of the estimate error of these parameters is somewhat larger in the case when R is estimated than when the correct values are known.

V. Conclusion

This paper investigates the sensitivity of a two-step GML approach to probability of detection and false alarm density estimation on an unknown measurement noise statistics. The algorithm itself was shown to have satisfactory performance when a priori knowledge about the measurement noise is available, but it has a significant bias when that knowledge is incorrect. For this reason an adaptation to the original approach was proposed which estimates measurement noise covariance matrix in each scan while simultaneously estimating the probability of detection and false alarm density as well. This augmentation of the algorithm was shown to remove the bias and enhance the convergence of the algorithm with respect to the case when estimation is lacking and a priori knowledge about noise statistics is erroneous.

In further research it would be interesting to investigate the case in which knowledge about a model noise is unavailable as well. This case is somewhat more complicated and will probably require more complex noise statistics estimator structure. Also, the existing augmentation of the algorithm can be further improved by introducing adaptive estimation of measurement noise covariance matrix.

On the Performance of the PHD Filter

Predrag Vasilić, Sanja Vujnović, Aleksandra Marjanović, Nikola Popović, and Željko Đurović

***Abstract*—The Gaussian Mixture Probability Hypothesis Density (GMPHD) filter represents a closed form solution to the Probability Hypothesis Density (PHD) filter which solves the problem of multi-target tracking (MTT), namely the tracking of multiple targets using the collection of measurements at each time sample. Each target has a certain probability of detection. Besides the target-caused observations, there are others which represent clutters. The paper examines the performance of the GMPHD filter in a scenario with many false alarms and deviations in the initial assumptions of the filter model parameters. The performance is measured using the Optimal Subpattern Assignment Metric (OSPA), which is broadly used as a standard metric in the estimation of the distance between two sets of vectors.**

I. Introduction

Single-target filters such as Kalman filter, assume the presence of only one target and only one noise-contaminated measurement originating from the target at each time sample [1], [2]. Multi-target tracking implies the possibility of more targets in the observation area. Each of these targets has its own time of appearance (birth) and disappearance (death) [3], [4]. Such targets are observed using one or more sensors which provide a collection of observations which does not necessarily include the information about all the targets. Furthermore, it can include some false detections due to various environmental influences and sensor noise. The goal of multi-target filtering methods is to estimate the number of targets and their state at each time sample.

One of the major issues of standard MTT approaches is the association of available measurements to certain targets [4]. Due to the combinatorial nature of the problem, data association implies significant computer resources. Random Finite Set (RFS) theory provides an elegant formulation of MTT problem by avoiding the explicit association of data [5], [6]. The idea is to represent the unknown target state collection as a set of states and the collection of measurements as a set of measurements and to formulate a mathematical tool similar to the Bayesian filtering in a single-target case. RFS theory falls under the field of Point Process theory, which represent the basis for derivation of Mahler's Finite-set statistics (FISST) [6]–[8]. Bayes RFS filter works in the space of sets which limits the application of this algorithm to a small number of targets. Therefore, the approximations of this filter were made in the form of the PHD filter, which operates in the space of vectors of individual targets, and its extension, the Cardinalized Probability Hypothesis Density (CPHD) filter [9], [10]. Even though these filters represent considerably simpler approximations, they contain integrals which do not have a closed-form solution. Different approaches to solving such equations led to many versions of these filters. Special attention was paid to the derivation of the GMPHD filter, whose final equations are analog to those of Kalman's [11].

This paper investigates the robustness of the GMPHD filter in the case of deviation in initial filter parameter estimations. We used the example which is the benchmark for testing of this type of filters, characterized with a high density of false alarms [12] and we provided performance results using the OSPA metric [13]. The robustness was tested in terms of the a prior knowledge about the appearance of targets, the changes in the state transition and measurement covariance matrices, as well as the change in the probability of detection.

The paper is organized as follows. Section II provides a brief overview of the basic concepts of RFS theory, as well as the definitions of the GMPHD filter and the OSPA metric. Section III contains the description of the commonly used test example and the testing of robustness, together with the results. Section IV concludes the paper and points out directions for further research.

II. Filtering formulation

This section gives a formulation of the multi-target filtering problem with the RFS approach. First we introduce the basic concepts of the RFS theory. Then we describe the idea and the properties of the PHD filter. Finally, we provide an overview of the GMPHD filter whose performances are examined in this paper.

A. Multi-target Filtering with Random Finite Sets

Unlike the single-target filtration problems which include only one target, the multi-target case assumes more than one target at each time. Let us assume that there are N_k targets from the space $\mathcal{X} \subseteq \mathbb{R}^{n_x}$ with states $x_{k,1}, x_{k,2}, ..., x_{k,N_k}$ and M_k observations from the space $\mathcal{Z} \subseteq \mathbb{R}^{n_z}$ with measurements $z_{k,1}, z_{k,2}, ..., z_{k,M_k}$ at time k. The ordering of states and observations has no significance, because we do not know

Sanja Vujnović is with the School of Electrical Engineering, University of Belgrade, 73 Bulevar kralja Aleksandra, 11020 Belgrade, Serbia (e-mail: svujnovic@etf.bg.ac.rs).

Aleksandra Marjanović is with the School of Electrical Engineering, University of Belgrade, 73 Bulevar kralja Aleksandra, 11020 Belgrade, Serbia (e-mail: amarjanovic@etf.bg.ac.rs).

Nikola Popović is with the School of Electrical Engineering, University of Belgrade, 73 Bulevar kralja Aleksandra, 11020 Belgrade, Serbia (e-mail: amarjanovic@etf.bg.ac.rs).

Željko Đurović is with the School of Electrical Engineering, University of Belgrade, 73 Bulevar kralja Aleksandra, 11020 Belgrade, Serbia (e-mail: zdjurovic@etf.bg.ac.rs).

which observation comes from which target, so it is natural to represent these collections as sets

$$X_k = \{x_{k,1}, x_{k,2}, ..., x_{k,N_k}\} \in \mathcal{F}(\mathcal{X}), \quad (1)$$

$$Z_k = \{z_{k,1}, z_{k,2}, ..., z_{k,M_k}\} \in \mathcal{F}(\mathcal{Z}). \quad (2)$$

Single-target filtering methods deal with the state of only one target x from the space $\mathcal{X} \subseteq \mathbb{R}^{n_x}$ and its observation z from $\mathcal{Z} \subseteq \mathbb{R}^{n_z}$. Therefore, the set X_k is in the collection $\mathcal{F}(\mathcal{X})$ of all finite subsets of $\mathcal{X}$. Similarly, the measurement space is the collection $\mathcal{F}(\mathcal{Z})$ of all finite subsets of $\mathcal{Z}$.

The goal of multi-target filtering methods is to estimate the current target set X_k using the observation sets $Z_{1:k} = (Z_1, Z_2, ..., Z_k)$ [6], [9]. The idea is to create such a mathematical tool which would have the form of the Bayesian filtering, appropriate for sets instead of vectors. This implies the formulation of random statistical set description, which leads to the Random Finite Set theory [6]. Rigorous mathematical definitions of random sets are given by the Point Process theory [5], [14]. Here, we provide only the most important, necessary results [7], [8], [12].

The random set $\mathbf{X}$ is described with a so-called multi-target probability density function

$$\pi(X) = \pi(\{x_1, x_2, ..., x_n\}), \quad (3)$$

which is a function of a set of vectors. The finite set has a random cardinality and each set element represents a random vector variable. The set integral in the region $S \subseteq \mathbb{R}^{n_x}$ is defined to be

$$\int_S \pi(X)\delta X = \pi(\varnothing) + \sum_{n\geq 1}^{\infty} \frac{1}{n!} \times \int_{S^n} \pi(\{x_1, x_2, ..., x_n\}) dx_1 dx_2 ... dx_n \quad (4)$$

and represents the possibility of set elements belonging to S.

Multi-target transition model is defined as follows. Let the multi-target state at time $k-1$ be described with a set X_{k-1}. The random finite set $\mathbf{X}_k$ which is formed using X_{k-1} is equal to

$$\mathbf{X}_k = T_{k|k-1}(X_{k-1}) \bigcup \mathbf{\Gamma}_k, \quad (5)$$

where the random set $T_{k|k-1}(X_{k-1})$ is created from all the targets $x_{k-1} \in X_{k-1}$ with the survival probabilities $p_{S,k|k-1}(x_{k-1})$ and state transition equations

$$f_{k|k-1}(x_k|x_{k-1}). \quad (6)$$

Besides the targets that survived time $k-1$, time k can include some completely new, independent targets. These new targets form the random set $\mathbf{\Gamma}_k$ which can be assigned with a different probability density function depending on the specific problem. The random set $\mathbf{X}_k$ is associated with a multi-target transition model with density function $f_{k|k-1}(X_k|X_{k-1})$.

The observation model is constructed in the similar way. Let us assume that each target $x_k \in X_k$ has the probability of detection $p_{D,k}(x_k)$. The observation set $\mathbf{Z}_k$ represents a union

$$\mathbf{Z}_k = \Theta_k(X_k) \bigcup \mathbf{K}_k, \quad (7)$$

where the random set $\Theta_k(X_k)$ is formed by adding a new observation vector in the event of target detection, which is related to the sensor observation law

$$g_k(z_k|x_k). \quad (8)$$

The random set $\mathbf{K}_k$ represents a set of false alarms and it is described using a certain problem-related distribution [5], [12]. The multi-target density function $g_k(Z_k|X_k)$ is defined for the random set $\mathbf{Z}_k$.

Following the aforementioned transition and observation models, let us define the recursive multi-target Bayes filter

$$p_{k|k-1}(X_k|Z_{1:k-1}) = \int f_{k|k-1}(X_k|X_{k-1}) p_{k-1|k-1}(X_{k-1}|Z_{1:k-1}) \delta X_{k-1}, \quad (9)$$

$$p_{k|k}(X_k|Z_{1:k}) = \frac{g_k(Z_k|X_k) p_{k|k-1}(X_k|Z_{1:k-1})}{\int g_k(Z_k|X) p_{k|k-1}(X|Z_{1:k-1}) \delta X}. \quad (10)$$

The advantage of the Bayesian RFS approach in solving multi-target tracking problems lies in the lack of need for direct data association, which can be observed from the derived prediction and correction equations. The main disadvantage is the complexity and computational intractability of the integrals defined by (9) and (10). Therefore, this filter is applicable only in the case of few targets. Over the years, some of its approximations have been derived, such as the PHD filter.

B. The Probability Hypothesis Density filter

PHD filter relies on the statistical moment of the random finite set [9]. The first statistical moment $v(x)$, also called the Probability Hypothesis Density function, has the following property

$$E\{|\mathbf{X} \cap S|\} = \int_S v(x)dx. \quad (11)$$

In other words, the integral over the area $S \subseteq \mathbb{R}^{n_x}$ gives the expected number of targets in that area. Therefore, the PHD function represents the density of target appearance in the area. Since the PHD function at one point is directly proportional to the expected number of targets at that point, the peak in the PHD function represents an area with the highest expected number of targets. Consequently, it is proportional to the probability of target being at that point. Hence, the idea of the PHD filter is to recursively propagate the corresponding density function $v_{k|k}(x|Z_{1:k})$, instead of the multi-target posterior density function $p_{k|k}(X_k|Z_{1:k})$ [14], [15]. The PHD filter was originally presented in [9], where it was derived using the FISST mathematical tool from Point Process theory [7], [8]. Let us denote the posterior PHD function at time $k-1$ as $v_{k-1|k-1}(x)$ and assume that:

- Each target evolves and generates observations independently of one another.
- The birth RFS and the surviving RFSs are independent of each other.
- The clutter RFS is Poisson and independent of target-originated measurements.
- The prior and predicted multi-target RFS are Poisson.

Consequently, the PHD functions of prediction $v_{k|k-1}(x)$ and correction $v_{k|k}(x)$ are equal to

$$v_{k|k-1}(x) = \int p_{S,k|k-1}(x_{k-1}) v_{k-1|k-1}(x_{k-1}) \times f_{k|k-1}(x|x_{k-1}) dx_{k-1} + \gamma_k(x), \tag{12}$$

$$v_{k|k}(x) = (1 - p_{D,k}(x)) v_{k|k-1}(x) + p_{D,k}(x) v_{k|k-1}(x) \times \sum_{z \in Z_k} \frac{g_k(z|x)}{\kappa_k(z) + \int p_{D,k}(x) v_{k|k-1}(x) g_k(z|x) dx}, \tag{13}$$

where

$p_{S,k|k-1}(x_{k-1})$ =probability of target existence at time k given previous state x_{k-1},
$\gamma_k(x)$ =PHD of the birth RFS $\mathbf{\Gamma}_k$ at time k.
$p_{D,k}(x)$ =probability of detection given a state x at time k,
$\kappa_k(z)$ =PHD of the clutter RFS $\mathbf{K}_k$ at time k.

Functions $f_{k|k-1}(x|x_{k-1})$ and $g_k(z|x)$ are the aforementioned models of transition and observation. The advantage of the PHD filter over the Bayes multi-target filter is the employment of vector space $\mathcal{X}$ instead of the set space $\mathcal{F}(\mathcal{X})$. However, the propagation of the first moment only carries part of the information about the distribution of the random set. The integrals in (12) and (13) generally do not have a closed-form solution, hence some additional assumptions are required. The most popular version of the PHD filter is the Gaussian Mixture Probability Hypothesis Density filter (GMPHD), which introduces following assumptions.

- Each target follows a linear Gaussian dynamical model and the sensor has a linear Gaussian measurement model,

$$f_{k|k-1}(x_k|x_{k-1}) = \mathcal{N}(x_k; F_{k-1}x_{k-1}, Q_{k-1}), \tag{14}$$
$$g_k(z_k|x_k) = \mathcal{N}(z_k; H_k x_k, R_k), \tag{15}$$

- The survival and detection probabilities are state independent

$$p_{S,k|k-1}(x_{k-1}) = p_{S,k|k-1}, \tag{16}$$
$$p_{D,k}(x_k) = p_{D,k}. \tag{17}$$

- The intensity of the birth RFS is Gaussian mixture of the form

$$\gamma_k(x) = \sum_{i=1}^{J_{\gamma,k}} w_{\gamma,k}^{(i)} \mathcal{N}(x; m_{\gamma,k}^{(i)}, P_{\gamma,k}^{(i)}), \tag{18}$$

where $J_{\gamma,k}, w_{\gamma,k}^{(i)}, m_{\gamma,k}^{(i)}, P_{\gamma,k}^{(i)}, i = 1, 2, ..., J_{\gamma,k}$ represent the model parameters of the PHD function of newborn targets. The function $\mathcal{N}(x; m, P)$ denotes a Gaussian density with mean value m and covariance P.

Apart from these assumptions, derivation relies on the two identities of the Gaussian distribution which are used in Bayesian formulation of the Kalman filter [6]. If all previous assumptions stand and if the posterior PDH function at time $k-1$ is equal to

$$v_{k-1|k-1}(x) = \sum_{i=1}^{J_{k-1}} w_{k-1}^{(i)} \mathcal{N}(x; m_{k-1}^{(i)}, P_{k-1}^{(i)}) \tag{19}$$

then the PHD prediction function is given as

$$v_{k|k-1}(x) = v_{S,k|k-1}(x) + \gamma_k(x), \tag{20}$$

where

$$v_{S,k|k-1}(x) = p_{S,k|k-1} \sum_{j=1}^{J_{k-1}} w_{k-1}^{(j)} \mathcal{N}(x; m_{S,k|k-1}^{(j)}, P_{S,k|k-1}^{(j)}), \tag{21}$$

$$m_{S,k|k-1}^{(j)} = F_{k-1} m_{k-1}^{(j)}, \tag{22}$$
$$P_{S,k|k-1}^{(j)} = Q_{k-1} + F_{k-1} P_{k-1}^{(j)} F_{k-1}^T, \tag{23}$$

and $\gamma_k(x)$ is defined by (18). These equations represent the prediction step of the GMPHD filter.

Let PHD prediction function at time k be a polymodal Gaussian function

$$v_{k|k-1}(x) = \sum_{i=1}^{J_{k|k-1}} w_{k|k-1}^{(i)} \mathcal{N}(x; m_{k|k-1}^{(i)}, P_{k|k-1}^{(i)}). \tag{24}$$

Then the posterior PHD function $v_{k|k}(x)$ is also polymodal Gaussian function in the form

$$v_{k|k}(x) = (1 - p_{D,k}) v_{k|k-1}(x) + \sum_{z \in Z_k} v_{D,k}(x; z), \tag{25}$$

where

$$v_{D,k}(x; z) = \sum_{j=1}^{J_{k|k-1}} w_k^{(j)}(z) \mathcal{N}(x; m_{k|k}^{(j)}(z), P_{k|k}^{(j)}), \tag{26}$$

$$w_k^{(j)}(z) = \frac{p_{D,k} w_{k|k-1}^{(j)} q_k^{(j)}(z)}{\kappa_k(z) + p_{D,k} \sum_{l=1}^{J_{k|k-1}} w_{k|k-1}^{(l)} q_k^{(l)}(z)}, \tag{27}$$

$$q_k^{(j)}(z) = \mathcal{N}(z; H_k m_{k|k-1}^{(j)}, R_k + H_k P_{k|k-1}^{(j)} H_k^T), \tag{28}$$

$$m_{k|k}^{(j)}(z) = m_{k|k-1}^{(j)} + K_k^{(j)}(z - H_k m_{k|k-1}^{(j)}), \tag{29}$$

$$P_{k|k}^{(j)}) = (I - K_k^{(j)} H_k) P_{k|k-1}^{(j)}, \tag{30}$$

$$K_k^{(j)} = P_{k|k-1}^{(j)} H_k^T (H_k P_{k|k-1}^{(j)} H_k^T + R_k)^{-1}. \tag{31}$$

Previous equations represent the correction step of the GMPHD filter. The analogy with the Kalman filter equations is direct, due to the Bayesian formulation of the Kalman filter. Let us emphasize that the GMPHD filter has a closed-form solution, which is suitable for implementation. The drawback of the filter is the polynomial increase in the number of Gaussian components through iterations, demanding the heuristics for their pruning which can be found together with set estimation procedure in [11].

Testing of the RFS-based filtering methods requires a metric different then the classic Euclidean, which compares the sets of solutions. The standard metric for these methods is the Optimal Subpattern Assignment Metric (OSPA) [13]. Let $d^{(c)}(x, y) := min(c, |x - y|)$ represent the distance between

vectors x and y bounded by the cut off parameter $c > 0$, then the OSPA metric is defined as

$$\bar{d}_p^{(c)}(X,Y) = \left(\frac{1}{n}\left(\min_{\pi\in\Pi_n}\sum_{i=1}^{m} d^{(c)}(x_i, y_{\pi(i)})^p + c^p(n-m)\right)\right)^{\frac{1}{p}}, \tag{32}$$

if $m \leq n$; $\bar{d}_p^{(c)}(Y,X)$ if $m \geq n$; $\bar{d}_p^{(c)}(X,Y) = 0$ if $m = n = 0$. Set Π_n represents the set of all permutations of n elements. The order parameter p determines the sensitivity of the metric to the outliers, and the cut-off parameter c determines the relative weighting of the penalties assigned to the cardinality and localization errors. Expression (32) includes two factors, which represent the localization and cardinality error. These errors are often in simulations observed separately [12]:

$$\bar{e}_{p,loc}^{(c)}(X,Y) = \left(\frac{1}{n}\left(\min_{\pi\in\Pi_n}\sum_{i=1}^{m} d^{(c)}(x_i, y_{\pi(i)})^p\right)\right)^{1/p}, \tag{33}$$

$$\bar{e}_{p,card}^{(c)}(X,Y) = \left(\frac{c^p(n-m)}{n}\right)^{1/p}, \tag{34}$$

if $m \leq n$,, and $\bar{e}_{p,loc}^{(c)}(X,Y) = \bar{e}_{p,loc}^{(c)}(Y,X), \bar{e}_{p,card}^{(c)}(X,Y) = \bar{e}_{p,card}^{(c)}(Y,X)$ if $m > n$.

III. Perfomance robustness of the GMPHD filter

Previous section defines the prediction and correction parts of the GMPHD filter. Even in the single-target filtering case, there are very few a priori information, namely the parameters that need to be known during the initialization of the algorithm. This includes the parameters of the transition and observation models, target detection probability, process and measurement noise covariance matrices, etc. The quality of the filtration certainly depends on the robustness in terms of parameter changes, because some of the assumptions will not be met in the real-life scenario. Therefore, this is the next thing we should examine.

We used the implementation of the GMPHD algorithm suggested by its author as stated in [11]. Specifically, we used the filter implementation for the example given in [12]. The simulation scenario is the following. The number of targets in a 2D space is unknown. The sensor is collecting the data from the surveillance region $[-1000, 1000] \times [-1000, 1000]m$. The state of each target $x_k = [p_{x,k}, p_{y,k}, \dot{p}_{x,k}, \dot{p}_{y,k}]^T$ consists of position $(p_{x,k}, p_{y,k})$ avd velocity $(\dot{p}_{x,k}, \dot{p}_{y,k})$. The measurement vector $z = [z_{x,k}, z_{y,k}]^T$ received by the algorithm can be a noisy position of the target in the case of detection, or a clutter measurement. The transition and observation models are given by (14) and (15). Let us assume a linear Gaussian model with constant velocity

$$F_k = \begin{bmatrix} I_2 & T_s I_2 \\ 0_2 & I_2 \end{bmatrix}, \qquad Q_k = \sigma_v^2 \begin{bmatrix} \frac{T_s^4}{4} I_2 & \frac{T_s^3}{2} I_2 \\ \frac{T_s^3}{2} I_2 & T_s^2 I_2 \end{bmatrix},$$

where F_k i Q_k are the transition and process covariance matrices, respectively. The sampling period is $T_s = 1s$, and the process noise standard deviation is $\sigma_v = 5\frac{m}{s^2}$. The matrix I_n is an $n \times n$ identity matrix and 0_n is an $n \times n$ zero matrix. The survival probability of each target is $p_{S,k} = 0.99$. The birth of new targets is described using a

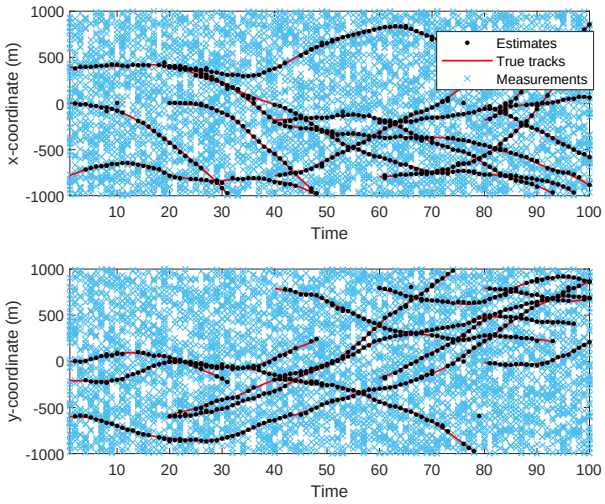

Fig. 1: Simulation results in the case of equivalent filter and model parameters. The scenario includes 12 targets which appear and disappear at different times.

PHD function $\gamma_k(x) = \sum_{i=1}^{4} w_\gamma \mathcal{N}(x; m_\gamma^{(i)}, P_\gamma)$, where $w_\gamma = 0.03, m_\gamma^{(1)} = [0,0,0,0]^T, m_\gamma^{(2)} = [400,-600,0,0]^T, m_\gamma^{(3)} = [-800,-200,0,0]^T, m_\gamma^{(4)} = [-200,800,0,0]^T$ i $P_\gamma = diag([10,10,10,10])^2$. The probability of detection is $p_{D,k} = 0.98$ and the measurement equation satisfies (15). Further on

$$H_k = [I_2 \quad 0_2], \qquad R_k = \sigma_\epsilon^2 I_2,$$

where $\sigma_\epsilon = 10m$ is the standard deviation of the measurement noise. Also, the false alarms are described using a PHD function

$$\kappa_k(z) = \lambda_c V u(z),$$

where $V = 4 \times 10^6 m^2$ is the volume of the surveillance region, and $\lambda_c = 12.5 \times 10^{-6} m^{-2}$ is the average number of false detections in a unit volume, resulting in around 50 false detections in the sensor surveillance area. The function $u(z)$ is a uniform probability density function in the sensor surveillance area.

The other parameters of the implemented GMPHD filter are $T = 10^{-5}, U = 4$ i $J_{max} = 100$, determining the parameters of the pruning and state set estimation algorithms described in [11]. The example of movement and algorithm performance is shown in Fig. 1. In this case the model parameters used for generation of targets, their measurements and clutter measurements are the same as the parameters of the GMPHD filter used for observation. The performance of the algorithm in the case of this many target is obvious. However a more detailed look shows an often error in cardinality. Namely, some of the targets are left out during the estimation process, because the algorithm sets the target states equal to the mean values of the components of the Gaussian PHD function that exceed a preset threshold (typically around 0.5 [11])

The scenario proposed by the authors is interesting because the targets appear at the positions of peaks in the birth intensity function $\gamma_k(x)$, namely these peaks are the mean values of

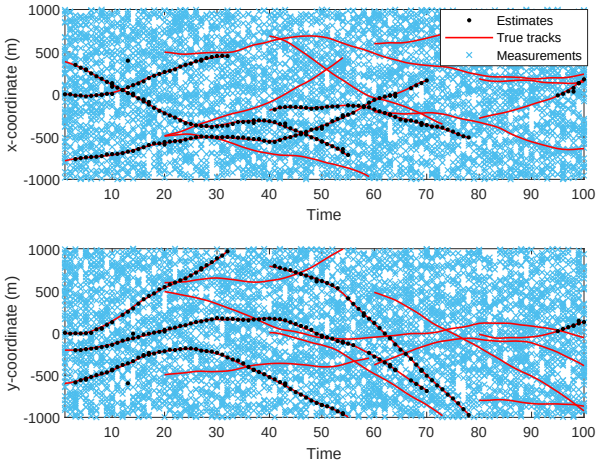

Fig. 2: Simulation results when the target appearance differs from the peak of birth intensity function $\gamma_k(x)$.

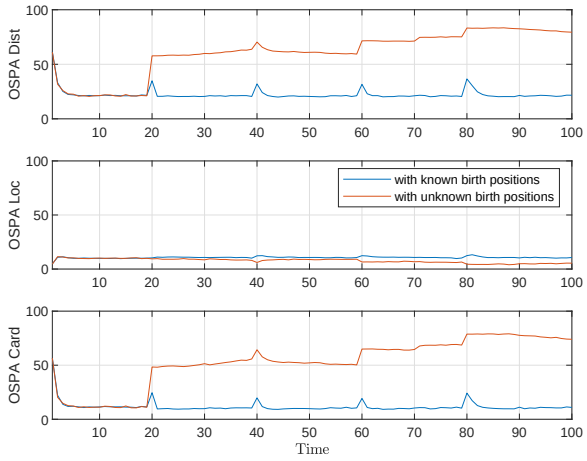

Fig. 3: The average OSPA metric over 1000 MC simulations, when some targets appear at the peaks of birth intensity function, and some of them appear in other locations.

Gaussian components. The constant positions throughout the simulation can represent the airports in a real-life problem in airplane tracking. We tested this algorithm in the case of arbitrary positions of targets' appearance within the sensor surveillance area. The results of the simulation are given in Fig. 2. Four targets are born in the peaks of intensity function and the algorithm tracks them successfully. The other targets are not even recognized. Only in some cases, like the one in the end of the simulation, the algorithm manages to detect and follow the target. The performance of the algorithm, besides the visual inspection, can be perceived using the OSPA metric for comparison of two sets of solutions. We did not consider the target velocity during evaluation, only its position. Due to stochastic noise properties and common errors in cardinality estimation, the OSPA metric during one simulation has many fluctuations and it is not informative. Therefore, we ran 1000 Monte Carlo (MC) simulations and obtained the average OSPA metric. The parameters of the OSPA metric were set to $c = 100$, i $p = 1$. Each MC simulation contained targets born at the same position and the same time as in Fig. 2. The only difference in the trajectories comes from the process noise. We also ran 1000 MC and calculated the average OSPA metric for the scenario shown in Fig. 1, where the targets were born at the same time at the positions of peaks in the intensity function $\gamma_k(x)$. Fig. 3 shows the average OSPA metric together with the localization and cardinality errors for the two mentioned cases. Let us examine the average OSPA metric in the case of known target birth locations. We see the characteristic metric peaks at times $0, 20, 40, ...$, which correspond to the birth of new targets in Fig. 1. The analysis of localization and cardinality errors suggests that those peaks are caused by the cardinality error, because the algorithm needs a few samples before detecting the new target. Let us look at the case of targets being born in arbitrary locations. The cardinality error is the same during the first 20s, because the first three targets appear at the expected positions. Later on the cardinality error increases, since the algorithm does not recognize the unexpected targets. The localization error seems

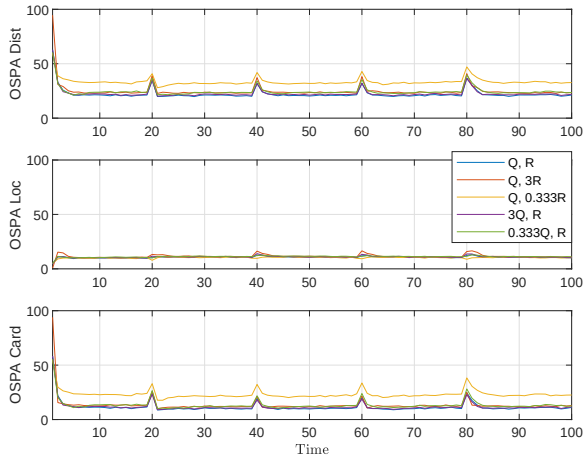

Fig. 4: The average OSPA metric over 1000 MC simulations, when the assumed transition and measurement covariance matrices differ from Q_k i R_k.

to be even smaller when compared to the standard case. The reason for this effect is the small number of detected targets resulting in the small number of elements in the summation (33). The figure shows no significant peaks, suggesting that the algorithm does not make many mistakes. Although Fig. 3 shows the average behavior over 1000 MC simulations, it provides a reliable description of the estimation quality of the simulations from Figs. 1 and 2. The obvious conclusion states that knowing the expected target birth position is of the essential importance to the algorithm performance in the case of a large number of false alarms.

The robustness testing included other parameters as well. For instance, we examined the influence of the underestimated and overestimated process or noise covariance matrix. In other words we ran 1000 MC simulations for four different cases in which the trajectories were generated using the exact matrices Q_k and R_k, while the matrices used by the algorithm

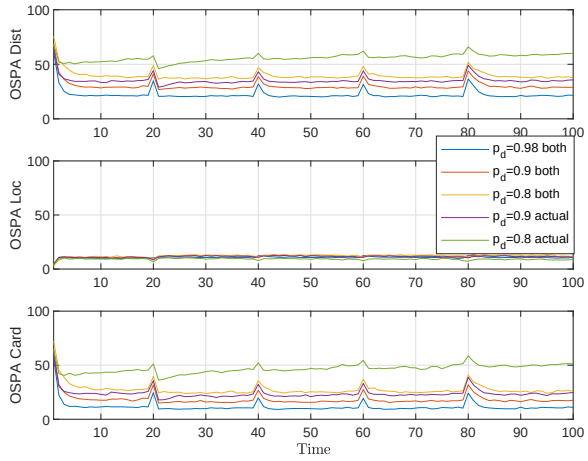

Fig. 5: The average OSPA metric over 1000 MC simulations for different values of probability of detection; *both* means that the assumed and exact probabilities are the same, while *actual* implies that the assumed probability is 0.98, and the exact is smaller.

were changed within some reasonable boundaries. The average OSPA metric with the appropriate legend of covariance matrices is shown in Fig. 4. The scaling of covariance matrix in the range of 0.333 to 3 (the variance is three times smaller or bigger) caused no significant deviations in the OSPA metric. A slight indication of a greater degradation can be observed only for the three times underestimated R_k. This implies that the algorithm is not too sensitive to minor variance changes.

Let us note that the probability of detection $p_{D,k} = 0.98$ is quite large. What if this probability is smaller or the algorithm assumes this large probability in the case when the exact probability is in fact smaller? Again, we ran 1000 MC simulations when the exact probability of detection is equal to the assumed one. We tested two cases: $p_{D,k} = 0.9$ and $p_{D,k} = 0.8$. Next, we analyzed the case when the algorithm assumes high probability of detection $p_{D,k} = 0.98$, and it is actually $p_{D,k} = 0.9$ or $p_{D,k} = 0.8$. All the results are shown in Fig. 5. A degradation in performance quality is expected for the decreasing probability of detection. However, if the algorithm is aware of this fact, the metric increases but the performance is still satisfactory. On the other hand, if a decrease in probability of detection is unknown to the algorithm, there is a significant degradation in performance. This is confirmed by the metric in Fig. 5, when the exact probability of detection is equal to 0.8. Poor filter robustness in terms of cardinality once again shows the need for an improved version of the filter with better estimation of set cardinality, which leads us to the CPHD filter [10].

IV. Conclusion

The paper examines the robustness of the PHD filter in terms of an error in a prior filter parameter estimations. The standard example for RFS-based filter testing is explored. This example is significant because it assumes a large density of false alarms. We obtained satisfactory robustness in the case of changes in process and measurement noise variances. It also allows the change in the probability of detection up to a certain level. The significant drawback of the filter is poor detection in the case when the approximate target birth location is not known in advance. The results of OSPA metrics for error estimation suggest that the biggest performance degradation is caused by a poor set cardinality estimation, because the algorithm is unable to detect the target. Once the targets are detected, the localization error remains small enough, in all of our examples. Future work on performance estimation would include comparative analysis with standard algorithms for target tracking, robustness testing in terms of changes in transition and observation models, etc.

Robust Control Design for a 3D Crane System

Anja Buljević, Miloš Miletić, Aleksandra Mitrović, Mirna N. Kapetina, Milan R. Rapaić

***Abstract*—This paper presents an example of controlling complex electromehanical system of 3D crane. Parameters of simplified 3D crane model are estimated using Recursive Least Squares (RLS) algorithm. After that two different control algorithms are applied. The first is fractional-order PI controller which parameters are tuned by Symmetrical Optimum Method, and second one is optimal PI controller which parameters are obtained to satisfy certain measures of the system performance and robustness. Performance of both algorithm are illustrated on the model and real system.**

Keywords: 3D Crane, RLS algorithm, PI control, FOPI control, PSO algorithm, Symmetrical Optimum Method (SOM), Robust control.

I. Introduction

Cranes are used in many industries, factories and warehouses to transfer heavy loads from one place to another. Although, they are generally controlled by human operators, automated systems are able to obtain more precise control. In many papers 3D crane models are considered and various control techniques solving the position control to track desired trajectories and to reduce the load swing have been widely studied in the literature [1], [2], [3].

This paper concerns the time control of 3D crane, based on a simple linear mathematical model. The idea is to realize online parameters estimation for laboratory model of 3D crane and controlling that crane by using different controllers. Recursive least squares algorithm is used for parameters estimation. Depending on what we want to achieve, two types of proportional–integral(PI) controller are used for controlling the 3D crane. Parameters that should be obtained for both controllers are K_p(proportional gain) and K_i(integral gain). Main task is to determine parameters that satisfies some performance and robustness measures of the system. Regulator must follow the reference, eliminate the disturbance and decrease noise impact. Also, regulator must be resistant on the process variations, ie it should be as robust as possible in that sense. Of course, it is almost impossible to satisfy all requirements in the same time, so it is necessary to find some compromise between them.

After Introduction, the paper is organized in the following manner: description of the 3D crane system, process model and parameter estimation procedure are explained in Section II, optimal design method for conventional PI controllers was introduced in Section III, while symmetrical optimum procedure for fractional order PI controllers is introduced in Section IV. The two controllers were compared in Section V, and the concluding remarks are given in the final Section VI.

II. Online parameters estimation

Inteco® 3DCrane [4] is laboratory model of 3D crane and it is controlled from a PC. The 3D crane is nonlinear electromechanical system having a complex dynamic behaviour and creating challenging control problems. Its hardware and software can be easily mounted and installed in a laboratory.

3D crane (Fig. 1) consists of a payload hanging on pendulum which length can be changed. The payload can move freely in 3 dimensions (x, y and z-axis). Therefore, 3D crane is driven by 3 DC motors. The payload is lifted and lowered in the z direction. The rail and the cart are capable of horizontal motion along the rail in x direction. The cart is capable of horizontal motion along the rail in the y direction.

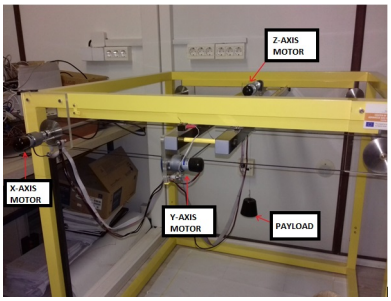

Fig. 1. 3DCrane

Mathematical model of 3D crane has ten differential equations and because of this complexity, it is necessary to linearize the system. For design controllers is enough to use simple linear models which assumed that the oscillations of the payload are so small that the trigonometric relations may be neglected. In this way, we get the transfer function from digital control signal in MATLAB to the measured position. Also, in order to obtain a simpler transfer function, the behavior of the system is observed individually in each axis. The input of transfer function is digital control signal in interval [-1,1](which later transforms by electronics and motors into a pulling force) and output is distance in meters. The simple linear model of the crane dynamics in the X-axis and Y-axis are assumed:

$$G_x(s) = \frac{K_x}{s(T_x s + 1)}$$
$$G_y(s) = \frac{K_y}{s(T_y s + 1)} \quad (1)$$

Generally, linear model can be described by

$$G(s) = \frac{K}{s(Ts+1)} = \frac{K}{Ts(s+\frac{1}{T})} = \frac{K_n}{s(s+p)} \tag{2}$$

where K is K_x or K_y, T is T_x or T_y. Unknown parameters that have been determined are gain K and time constant T. In this paper, we performed online estimation of unknown parameters.

Online estimation algorithm estimates parameters when new data is available during the operation of the physical system. Online parameter estimation is typically performed using a recursive algorithm [5], i.e. model parameters values are determined by recursive least squares algorithm. The results of estimation are compared with parameters obtained from the MATLAB Toolbox.

Recursive least squares algorithm

Recursive least squares algorithm [6], [7], [8] represents mathematical procedure for solving a problems of parameter identification (estimation) in the adopted structure of the model. The appropriate model structure can be written in the following form:

$$y(t) = \varphi_1\theta_1 + \varphi_2\theta_2 + ... + \varphi_n\theta_n \tag{3}$$

$$y(t) = \varphi(t)^T\theta \tag{4}$$

where $y(t)$ is measured output value, φ is vector of known values and θ is vector of unknown values. $y(t)$ is called regressand, elements of vector $\varphi(t)$ are called regressors and variable t represents time.

The basic problem is finding the estimated values of the parameters from the measurements $y(1)$, $y(2)$,..., $y(N)$ and $\varphi(1)$, $\varphi(2)$,...,$\varphi(N)$ where N is number of measurements. A linear equation system can be formed:

$$\begin{aligned} y(1) &= \varphi^T(1)\theta \\ y(2) &= \varphi^T(2)\theta \\ &\vdots \\ y(N) &= \varphi^T(N)\theta \end{aligned} \tag{5}$$

The matrix form is obtained:

$$y = \Phi\theta \tag{6}$$

The linear equation system is solvable by θ if the number of measurement N is equal to the number of variables n. In that case, Φ is square matrix and if it is nonsingular matrix, values of parameter θ can be determined.

However, in practice, the number of measurements is greater than the number of variables ($N > n$) because of the existing of a disturbance and mistakes in model. That means that the linear equation system becomes predetermined and the solution does not exist.

This problem can be solved as a problem of the smallest squares:

$$J = \sum_{k=1}^{N}(y_k - \hat{y}_k)^2 = \sum_{k=1}^{N}(y_k - \sum_{k=1}^{n}\varphi_{k,i}\hat{\theta}_i)^2 \tag{7}$$

In order to minimize criteria function (7) it is necessary to equalize the first derivate with zero:

$$\frac{\partial J}{\partial \hat{\theta}_j} = 0 \quad (\forall j \in 1...n) \tag{8}$$

After that, the following equation was obtained:

$$\Phi^T\Phi\hat{\theta} = \Phi^T y \tag{9}$$

The equation (9) in the literature is called *"normal equation"* [5]. Recursive least squares algorithm is applied to the following mathematical model:

$$\begin{aligned} G(s) = \frac{Y(s)}{U(s)} &= \frac{K}{s(Ts+1)} \\ s^2TY &= -sY + KU \\ \ddot{y}T &= -\dot{y} + Ku \\ \ddot{y} &= -\frac{1}{T}\dot{y} + \frac{K}{T}u \end{aligned} \tag{10}$$

The last equation from (10) represents the general form of the transfer function of all axes of the 3D crane and linear model can be formed:

$$\ddot{y}_f = \begin{bmatrix} -\frac{1}{T} & \frac{K}{T} \end{bmatrix} \begin{bmatrix} \dot{y}_f \\ u_f \end{bmatrix} \tag{11}$$

We can adopt the following relations: $p_1 = -\frac{1}{T}$ and $p_2 = \frac{K}{T}$ and get the mathematical model linear by parameters:

$$\ddot{y}_f = \begin{bmatrix} p_1 & p_2 \end{bmatrix} \begin{bmatrix} \dot{y}_f \\ u_f \end{bmatrix} \tag{12}$$

where $\ddot{y}_f$ is filtered output, $\begin{bmatrix} p_1 & p_2 \end{bmatrix}$ is model linear by parameters (matrix of unknown parameters) and $\begin{bmatrix} \dot{y}_f \\ u_f \end{bmatrix}$ is matrix of known parameters. A transfer function of a filter that was used is $H(s) = \frac{1}{(T_f s+1)^2}$, where T_f is time constant. If noise exists in system, it will have a big impact on parameters, so it is necessary to do filtering. T_f is chosen so that it doesn't cut anything from input signal. In order to obtain unknown values of gain and time constant, it is necessary to perform the following transformation:

$$T = -\frac{1}{p_1} \tag{13}$$

$$K = p_2 T \tag{14}$$

Criteria function that represents deviation of the estimated model from the measurement was minimize in order to obtain unknown values of parameters:

$$J_r = \hat{\ddot{y}}_f - \ddot{y}_f \tag{15}$$

Obtained values of unknown parameters are given in Table I.

The form of input signal was $u(t) = 0.2\sin(\pi t + 0.23) + 0.3\sin(\pi t)$. Comparative view of the crane and model response are shown at Fig. 2a and 2b.

It can be noticed from Fig. 2a and 2b that due to the nonlinearity and imperfection of the system, there are disagreements between the linearised model and the real system. However, it will be shown that linearised model will be sufficient for robust control design.

0.3075	0.1906	0.3176	0.1066

III. Optimal PI Control Design

PI controller [9] is given in form

$$G_c(s) = K_p + \frac{K_i}{s}.$$

The focus of this section is on the system response on the disturbance, which is slow changing variable in time domain, so we can assume that it is constant. In that case, its transfer function is $D(s) = \frac{k}{s}$. Disturbance elimination is the main requirement in most process control loops because it relates to system behaviour in the steady state. Requirements are mathematically formulated by some optimality criterion and accompanying constraints. Before defining measures of system performance and robustness it is necessary to define some characteristic transfer functions. Transfer functions that are used are known as "gang of four" [10], [11]. One of the most common system performance indicator is integral of absolute error(IAE) [10]. Secondly, very similar is integral of error(IE) [10]. Measure of the system performance called Q [10], [11] limits resonant peak of the frequency characteristic. By the limiting Q it is possible to get acceptable values of the IAE. Q is limited by 1.01 [10]. That value was obtained experimentally through a large number of simulations. This measure is defined by

$$Q = \frac{\max_{\omega\geq 0} Q_v(j\omega)}{Q_v(0)} = \max_{\omega\geq 0} \left| \frac{k_i \frac{G_p(s)}{j\omega}}{1 + G_c(j\omega)G_p(j\omega)} \right|_{\omega=\omega_g}$$

Also, it is necessary to define some systems robustness measures. In that purpose most often used is maximal sensitivity M_s [10], defined by

$$M_s = \max_{\omega\geq 0} \left| \frac{1}{1 + G_c(j\omega)G_p(j\omega)} \right|.$$

Measure M_s represents minimal inverse distance of the Nyquist curve from the critical point(-1,0j). Often measure M_s is taken as the main systems robustness criterion. For example, system can have big gain and phase margin, but small maximal sensitivity, so it is easy to destabilize it. Best results are gained if maximal sensitivity is between 1.7 and 2 [10]. Maximal complementary sensitivity M_p [11] is another one systems robustness measure which will be explained. Application of this measure relates to examination of systems robustness in the medium-frequency band. It is used to get bigger damping or bigger phase margin without getting system response slower. The main application of this measure is in unstable processes with integral component. Maximal complementary sensitivity is defined by

$$M_p = \max_{\omega\geq 0} \left| \frac{G_c(j\omega)G_p(j\omega)}{1 + G_c(j\omega)G_p(j\omega)} \right|_{\omega=\omega_p}$$

Next step is to optimize the parameters of PI controller for each axis separately, ie mutual impact between axes is ignored in the optimization. In first section Optimality criterion is the integral of absolute error (IAE) while constraints are Q(limit on resonant peak of frequency characteristic), maximal sensitivity and maximal complementary sensitivity. Optimization was done with the Particle Swarm Optimization (PSO) algorithm [12], [13], [14].

Minimal and maximal allowed value for the M_s and M_p are shown in Table II. Maximal allowed value for Q is 1.01 as it was mentioned earlier. At both cases, the recommended values for the M_s were not used because in that case system response is too fast and it produces intensive swinging of the payload. The regulator has a task to eliminate disturbance. Disturbance is step signal with amplitude 0.3. After optimization, parameters are obtained for each axis. Parameters and corresponding values of the constraint are shown in Table III. This controller will be called *Optimal PI*. Model responses will be shown in Section V where they will be compared with FOPI controller.

Table II
Optimization constraints

	Q^{max}	M_s^{min}	M_s^{max}	M_p^{min}	M_p^{max}
x	1.01	1.3	1.5	1.2	1.4
y	1.01	1.4	1.6	1.2	1.4

Table III
Obtained regulator parameters with corresponding constraints

	k_p	k_i	Q	M_s	M_p
x	25.32	31.1	1	1.5	1.31
y	31.45	28	1	1.6	1.35

IV. Fractional Order PI Control

The PID controller is the most common solution to practical control problems due to its robust performance and simplicity to get the tuning parameters. However, it is sometimes necessary to provide better controller performance, flexibility and more adequate methods for tuning controllers. As a result, fractional-order(FO) controllers were proposed by Podlubny [15] as a generalization of the PID controller with integrator of real order α and differentiator of real order η. FOPI controller [16] is used for controlling 3D crane and it can be described using this formula:

$$G_c(s) = K_p(1 + \frac{1}{(T_i s)^\alpha}), 0 < \alpha < 1. \tag{16}$$

Symmetrical Optimum Method

After parameters identification is done, it makes sense to start controlling the 3D crane. Linear model of the crane dynamics is generally described by (2). There are many methods for tuning parameters for controllers, but we chose to set parameters using Symmetrical Optimum Method(SOM) as it is mentioned in section I. This concept was presented by Kessler [17] in 1958. Later, in 1995. it was modified by Voda and Landau whose modified method ensures obtaining a maximum phase margin in closed loop system [18]. SOM has a few advantages over other methods in aspect of phase and gain margins and sensitivity of system.

In this paper, we use SOM which is explained in [19]. The main principle is based on designing the regulator in order to meet requirements, so that phase margin is as close as it is possible to 37°. That phase margin should be obtained at frequency $\omega_{max} \equiv \omega_{gc}$, where ω_{max} is the frequency at which maximum margin can be reached and ω_{gc} is the gain crossover frequency. Further more, $|W_{sp}| = 1$ should be obtained in the largest possible frequency range, especially in low frequencies. This method also reduces disturbance effects.

The controller design is mainly based on shaping asymptotic gain and choosing the slope of the segment crossing the frequency axis. The gain diagram must maintain this slope in a wide frequency interval around the crossover frequency. The phase margin is constant in that interval and robust stability is guaranteed even for high gain variations.

$$G_{bode}(s) = (\frac{\omega_{gc}}{s})^\alpha.$$

If FO controllers are used, slopes can be $\alpha \cdot 20dB/dec$ (α can be non-integer number, e.g. $\alpha = 0.5 \Rightarrow slope = -10dB/dec$) unlike classic controllers where α has to be integer number. Basic idea for tuning FO controllers parameters using SOM is to choose gain crossover frequency so that phase is maximized. Phase margin is maximum if

$$\frac{d}{d\omega} arg W(j\omega) = 0.$$

If it is not possible to achieve this, then it is possible to analytically solve non-linear minimization function to obtain the tuning formulas for controllers parameters. It is possible to make compromise between dynamic performance and robust stability using α (16). Solution to this problem is given in [19]:

$$C = 1 + \cos(0.5\pi\alpha), S = \sin(0.5\pi\alpha)$$
$$\theta_a = \tan(0.5\pi - 0.5\pi\alpha), \theta_b = \tan(PM_\alpha)$$
$$a = \sqrt{\frac{C(1 + \theta_a\theta_b) - S(\theta_a - \theta_b)}{C(\theta_a - \theta_b) + S(1 + \theta_a\theta_b)}}.$$

Formula for a comes from minimization of a non-linear function that depends on determining the frequency for which the phase is maximum.

Tuning parameters that are obtained are:

$$T_i = a^2 T$$
$$K_p = \frac{1}{KT_i}\sqrt{\frac{1 + a^4}{2a^4 C}}$$
$$PM_\alpha = \arctan\frac{S}{C} - \arctan(a^{-2}) + 0.5\pi(1 - \alpha).$$

PM_α is the maximum achieved phase margin, T_i and K_p are the parameters we were looking for. Obtained parameters using SOM for FOPI controller with $\alpha = 0.7$ by axis are:

1) x-axis: $K_{px} = 6.0389, K_{ix} = 11.9823$
2) y-axis: $K_{py} = 4.9848, K_{iy} = 9.7343$,

and their responses, also by axes, are given in Section V where they are compared with Optimal PI.

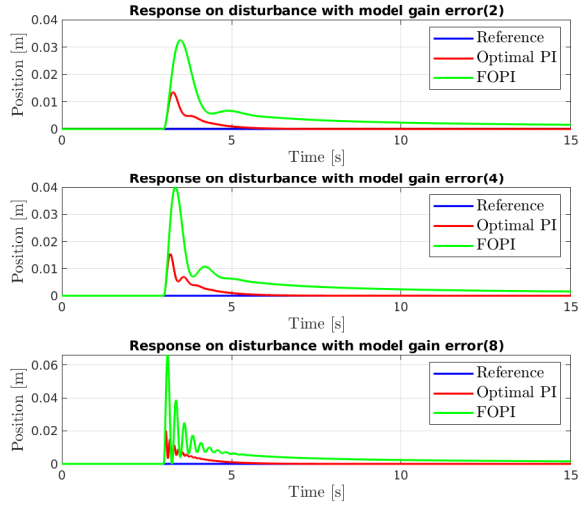
V. Simulation results

In this section, simulations are done on model and real system and their results are shown below.

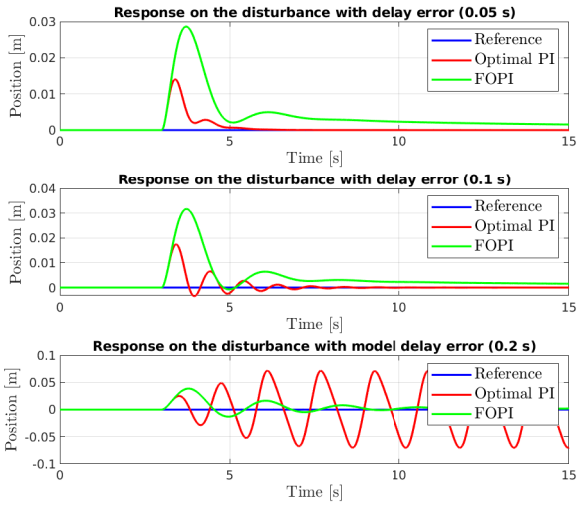
Model results

In this subsection, model responses will be compared when it is controlled by FOPI controller and PI controller described in Section III. Responses will be presented when there is constant disturbance with amplitude 0.3. To test controllers robustness, we will include some errors in modelling (gain error, delay, time constant error).

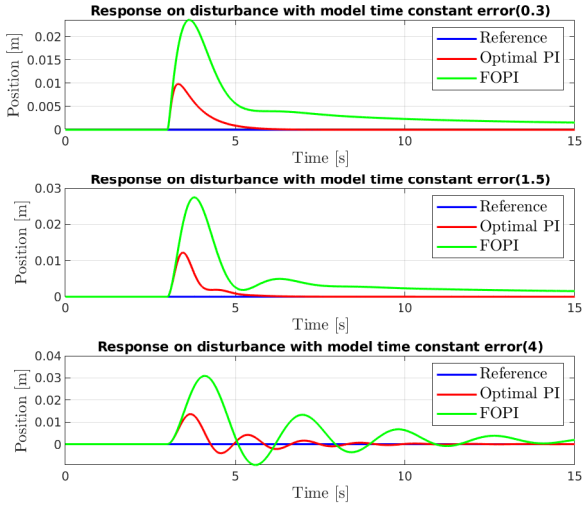
Results will be presented only for x-axis because similar results are obtained for y-axis.



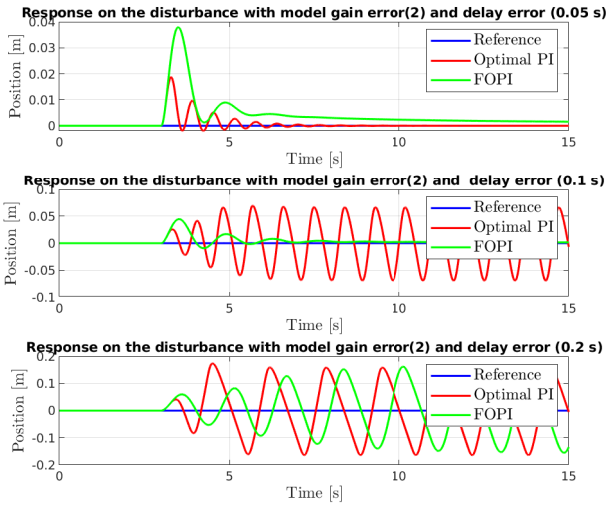
(a) Model responses with gain error



(b) Model responses with delay included in model



(c) Model responses when time constant is not estimated correctly



(d) Model responses with gain error and delay included

Fig. 3. Comparison of model results obtained with Optimal PI and FOPI

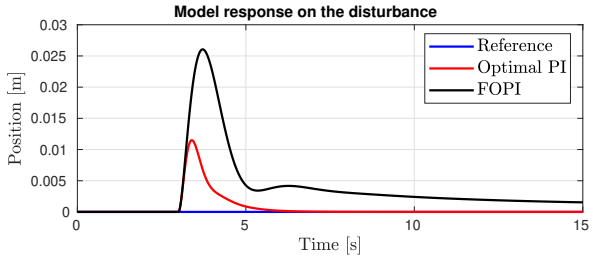


Fig. 4. Model responses on disturbance which starts after 3 (s) with amplitude 0.3

Fig. 4 shows model responses when only disturbance is included. It is obvious that Optimal PI faster eliminates disturbance impact.

Fig. 3a shows responses if there is gain error. Both controllers keep system stable and successfully eliminate disturbance because gain margin is big enough what can be seen at Fig. 5.

Fig. 3b shows responses if there is delay in system model. It is obvious that FOPI controller is more robust in this aspect because it tolerates more delays. Optimal controller can tolerate delay by some time, and after that system becomes unstable. Their delay margins are shown at Fig. 5.

Fig. 3c shows responses when time constant is not estimated correctly. Both controllers are very robust, but Optimal PI has better performance.

Fig. 3d shows responses when there is combined gain error and delay in system model. It is obvious that FOPI has better performance.

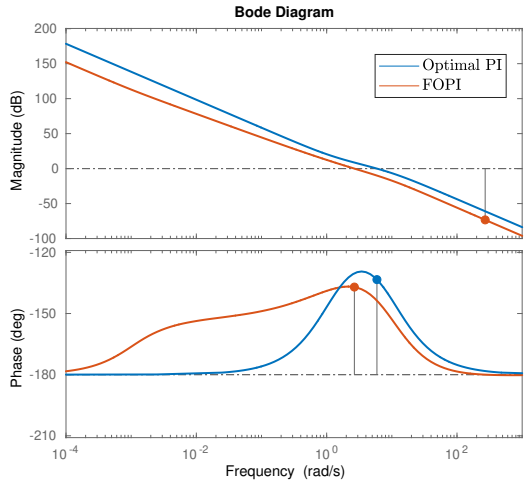

Fig. 5. Bode diagrams for model controlled by FOPI and Optimal PI. FOPI: gain margin is 73.3 (dB), phase margin is 43 (deg), delay margin is 0.282 (s); Optimal PI: phase margin is 46.6 (deg), delay margin is 0.138 (s).

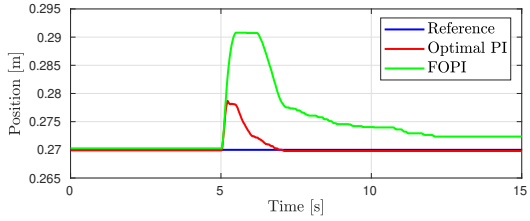
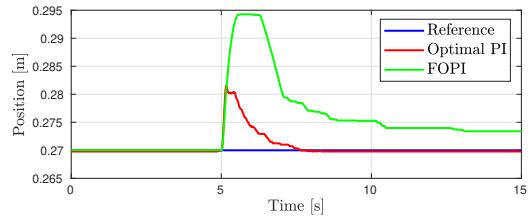


(a) x-axis



(b) y-axis

Fig. 6. Crane responses on disturbance which starts after 5 (s) with amplitude 0.3

Real system results

Obtained parameters for Optimal PI and FOPI regulator are used on real 3D crane. Fig. 6a and 6b show system responses. Disturbance is simulated with step signal with amplitude 0.3, which is added to control signal.

VI. Conclusion

This paper presents one approach of modelling the 3D crane. Original model of 3D crane is very complex, so linearization was done to make model simpler. Obtained model is second-order system. Online parameters estimation was done using recursive least square method. Comparative analysis shows that obtained results for x and y-axis are acceptable. Fractional-order PI regulator was used for controlling the crane and its parameters were tuned by Symmetrical Optimum Method. This method reduces disturbance effects and can tolerate more delays which is proved on the real system. Optimal PI controller was designed to satisfy certain measures of the system performance and robustness. Controller is applied at the real 3D crane and behaviour of system satisfies criteria. Finally, both controllers were compared. It is proved that Optimal PI has better performances, but FOPI is much better if there is bigger delay in system. Although there are reasonable deviations in system model, both controllers fulfill their tasks, so we can conclude that they are robust enough.

Incident simulator for ADMS performance testing

Nedeljko Stojaković, Marina Stanojević, Darko Čapko, Tatjana Grbić

***Abstract* — The Advanced Distribution Management System (ADMS) is an Industrial Control System specifically designed and developed for the Smart Grid industry. One of the important components of this system is Outage Management Service (OMS) which is responsible for handling unexpected outages or planned maintenance. The most critical time for ADMS, when its response and durability are of exceptional importance, is when a storm occurs. In this paper, we analyze actual storm data, build storm model and propose a simulation of a storm. It is imagined that the utilities could use such simulator in order to test and verify their ADMS according to the real storm conditions.**

***Keywords* — Advanced Distribution Management System; Smart Grid; storm modeling; simulation;**

I. Introduction

THE electric power system is one of the biggest and most important technical system nowadays. Its main goal is to provide customers with electric energy with minimal downtime. Because of this, many electric utilities spend significant amount of money in developing systems such as Advanced Distribution Management System (ADMS). ADMS is used for monitoring, controlling and optimizing electric power distribution system with millions of customers. Outages in electric power system are inevitable, but it is very important to react quickly in order to eliminate their consequences. Component in ADMS that is in charge of outages is called Outage Management System (OMS).

When it comes to closing outage, there is a procedure with a few steps that needs to be executed. Firstly, the dispatcher in control room takes over the incident and makes the Work Order plan for it. In that plan, he needs to specify which field crew is going to be responsible for resolving the incident. The best solution is to find crew which is the nearest to the location of the incident. After this, a crew is notified and they need time to find actual location of the incident and to fix it. Only when crew finishes with all the work, incident can be closed. For ADMS the most critical time is when the storm occurs because then several outages which need to be handled as soon as possible, could be created at the same time. Utility usually needs to send out many crews to restore services during a storm. In this paper, we analyze actual storm data to provide statistical distributions. A storm is modeled as a group of incidents that appear at the same time. As there are several incident types, we analyze them separately. For the analysis, times between arrivals of the same incident type are used and as a result distribution for those times are obtained. After that, the response of the system to the incident, as well as the assessment of the time system to close the incident, is being examined. These distributions can be used in incident generation and later in testing ADMS.

Authors in [1] investigate about impact which natural disasters have on electric power grid and review progress of research field towards methods and tools of forecasting natural disasters, pre-storm operations, and restoration models. One example of model used to predict power interruptions is developed in [2]. It is based on common weather conditions and refined using statistical and deterministic simulations of the model. In [3] automated analysis of distribution systems are presented using cloud-based architecture. Several storm models are evaluated in [4] and authors suggested framework that can be used for predicting outages for emergency-preparedness functions. Literature survey on models and algorithms used to predict hazards and on restoration strategies are presented in [5].

In the next section outage types are described. Section III gives a description of the problem discussed in this paper. Section IV contains information about system architecture. Also, in this section, the statistical distributions of the given input as the results of the research is presented. Section V contains information about data used as an input in storm modeling. And finally, these distributions are used in testing of the system which is described in Section VI.

II. Outages and Incidents in Power Grid

In OMS, outages are modeled as incidents. There are several possible ways to detect outages which lead to several different outage types: Phone Call Created, Supervisory Control And Data Acquisition (SCADA) Created, Work Order and User Created.

A. Phone Call Created incident type

Phone call received from customers is one type of the incident. In this case, it is still unknown what caused outage, where its root is and how many customers are affected. Dispatcher in the control room models incident from the

Nedeljko Stojaković is with the Faculty of Technical Sciences, University of Novi Sad, Trg Dositeja Obradovića 6, 21101 Novi Sad, Serbia (phone: 381-66-9382181; e-mail: nedeljko.stojakovic@uns.ac.rs).

Marina Stanojević is with Faculty of Technical Sciences, University of Novi Sad, Trg Dositeja Obradovića 6, 21101 Novi Sad, Serbia (phone: 381-63-686827, e-mail: marina.stanojevic@uns.ac.rs).

Darko Čapko is with Faculty of Technical Sciences, University of Novi Sad, Trg Dositeja Obradovića 6, 21101 Novi Sad, Serbia (phone: 381-21-4852451; e-mail: dcapko@uns.ac.rs).

Tatjana Grbić is with Faculty of Technical Sciences, University of Novi Sad, Trg Dositeja Obradovića 6, 21101 Novi Sad, Serbia (phone: 381-21-4852275; e-mail: tatjana@uns.ac.rs).

information he received from customer and marks it on the network view. If more than one call came from the same area, incidents are grouped and observed as one. The most important in this step is to find outage root.

B. SCADA Created incident type

SCADA incident occurs when the voltage drop is detected on a breaker. ADMS records the event through the SCADA system. With this type, the exact location of the fault is known.

C. Work Order incident type

Work Order incident type is used for modeling planned maintenance. In this case dispatcher knows exact position of the maintenance and models incident to match that position.

D. User Created incident type

Generic type of incident, and it is used when the actual type is not specified.

III. Problem Definition

Conceptual model of the system is presented in Fig. 1.

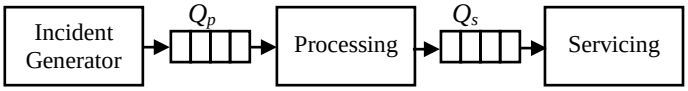

Fig. 1. Conceptual model

The complete process can be treated as a queuing system and multiphase servicing. Waiting is caused by the inability of parallel service in certain service stages.

Incident Generator is used to generate events - incidents at certain times that are determined based on the collected data from the system.

Processing is process from reporting an incident to its acceptance by a dispatcher and assigning to the specific field crew.

Servicing refers to the process from the moment of accepting the incident to its resolution.

The aim of the paper is to simulate the system based on the collected data from the real system. The analysis of the obtained results should determine the number of dispatchers and crews. Criteria for the selection of optimal parameters are minimization of waiting in queues (Q_p and Q_s), utilization of dispatchers and utilization of crews.

IV. System Architecture

In order to obtain the correct results of the simulation, it is necessary to use adequate input data.

Since it analyzes the behavior of the system during incidents in the network, it is first of all necessary to determine the incident events during the simulation. Since data on incidents are stored in the historical database in the ADMS system, the idea is to use this data when estimating the dynamics of generating incidents - input data into the simulation.

In view of this, the process of analyzing the behavior of the system could be divided into 4 phases, as shown in Fig. 2:

1. Extraction incident data from a historical database.
2. Filtering and processing data.
3. Input Modeling - occurrence time of incidents.
4. System simulation and analysis of results.

Fig. 2. System architecture

A. Historical Database

Data related to the incidents that are reported, registered and processed in the ADMS system are stored in a historical database. Data such as moment of occurrence, incident type and location, the time of incident registration, the time of assignment of the incident to the specific team in the field, the time of completion of the incident processing, etc., are kept.

The data recorded in the database can be stored with certain deficiencies and errors, and therefore it is necessary to filter them for further use. For example, SCADA and Phone Call incident could be reported separately while referring to the same outage and thus should be treated as one incident.

B. EFC Process (extraction, filtering, calculations)

The EFC process consists of the following three phases:

1. Data Extraction from the database.
2. Data filtering.
3. Data processing.

During data extraction, raw incident data from the database for the given time period are obtained.

The data filtering process consists of two phases. The first stage identifies information about the same incident (multiple application - idempotence) and eliminates data with possible errors (incident processing time missing or any other significant data). After that, data from the significance of the system behavior analysis (the data are shown in Table I) are extracted from the set of filtered incidents.

TABLE I
DATA OF INTEREST

Symbol	***Data***	***Description***
IT_{ID}	INCIDENT_TYPE_ID	Identification of incident type. e.g. Phone Call, SCADA
t_o	OUTAGE_TIME	Time of occurrence - this represents time when incident happened (e.g. phone call received)
t_c	CREATE_TIME	Time of processing - time when dispatcher confirmed the incident.
t_a	ASSIGNED_TIME	Time of start servicing
t_e	ACTUAL_END_TIME	Close time - when all steps are finished and incident is closed

After data filtering, the data processing phase is next. At this stage, the input data values for each incident are calculated. Input data are:

- The time of occurrence of the incident after the previous incident - the so-called interarrival time – t_d,

- Time of the incident processing (processing time) – t_p,
- Service time of the solving incident – t_s.

These parameters are calculated as follows:

$$t_d(i) = t_o(i) - t_o(i-1), \quad t_o(0) = 0 \tag{1}$$

$$t_p(i) = t_a(i) - t_o(i) \tag{2}$$

$$t_s(i) = t_e(i) - t_a(i), \quad i = 1,2,..., n \tag{3}$$

where i is an ordinal number of incident and n is the total number of incidents.

C. Data modeling

After calculating the parameters given by (1), (2) and (3), it is necessary to model the interarrival times, the processing time and the time of servicing by certain random distributions. The obtained distributions are given as parameters of the simulation model and they are used in the simulation process.

D. Simulation

Simulation model, created in Arena simulation software [6], is presented on Fig. 3. Input blocks represent the generators of incidents divided by type. The next four blocks are Assign modules of Arena Simulation software that are used to define certain attributes and variables in the simulation. Next block presents part of simulation that describes time needed from modeling to incident acceptance.

In the *Servicing* - service time is the time system needs to solve an incident. The last block presents stock which is used for closed incidents that got through the system. Processing and servicing components can have multiple instances.

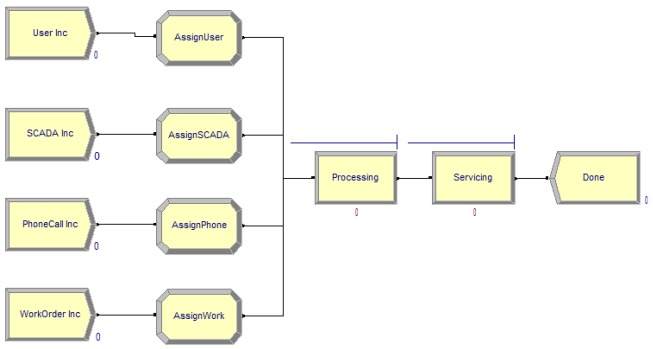

Fig. 3. Simulation model for *Incident Simulator*

V. Simulation Input Data

The incidents on a smaller segment of a typical European network are recorded in period from June 2015 to November 2016. In given period total of 17057 incidents occurred. Table II presents number of incidents per type.

TABLE II
NUMBER OF INCIDENTS PER TYPE

Name	User	SCADA	Phone Call	Work order
Count	1237	4793	8424	2603

After the data filtering, an estimation of the processing time of the servicing time was performed. The distribution and parameters were evaluated using Arena and the following estimates were obtained:

- Processing time - exponential distribution *Exp* (λ=167.214).
- Servicing time - *Gamma* (β=0.397, α=149.546).

In Table III, the months with the most frequent occurrence of incidents by a certain type are given. The idea is to estimate the statistical distribution in the most frequent months for certain incidents and to maximize the system's response time during the simulation in one month. In this way, an assessment could be made of the maximum requirements of the dispatchers and the field crews.

TABLE III
MONTHS IN WHICH CERTAIN INCIDENTS WERE MOST NUMEROUS

Incident Name	***Month/Year***	***Count***	***Distribution***
User	Nov/2016	106	*Exp* (405.32)
SCADA	Dec/2015	429	*Exp* (104.22)
Phone Call	Jan/2016	673	*Exp* (65.30)
Work Order	Dec/2015	127	*Exp* (292.90)

Statistical distribution for processing time, servicing time and incident arrivals (Table III and IV) was estimated using Arena software. Corresponding p-value for Chi-Square test is less than 0.005 and for Kolmogorov-Smirnov test less than 0.01 which means that the distributions are acceptable.

TABLE IV
NUMBER OF INCIDENTS PER TYPE AFTER FILTERING

Incident Name	***Count***	***Distribution***
User	858	*Exp* (898.29)
SCADA	3338	*Exp* (350.44)
Phone Call	6654	*Exp* (306.81)
Work Order	1141	*Exp* (667.44)

VI.

VI. Incident Simulation Results

Two types of simulations are executed:

- Simulated with aggregate statistical parameters - simulation time T_{sim} = 2 years,
- Simulation with maximum occurrences for all types of incidents - T_{sim} =1 month.

The number of service channels is changed:

- Processing - p = 1,2,5,6,7,8,9.
- Servicing - s = 1,2,3,4,5.

The following output parameters are observed:

- Utilization of incident processing (dispatchers) - δ_i,
- Field utilization (field crew) - σ_i,
- Average waiting time in Q_p - W_p and percent of the total number of incidents that waited for processing x%
- Average waiting time in Q_s - W_s, and percent of the total number of incidents that waited for servicing y%.

Results obtained by repeating the simulations 500 times are shown in Tables V and VI.

TABLE V
SIMULATION RESULT FOR MONTH PERIOD

Test no		Utilization				W_s [min] (x%)	W_p [min] (y%)
		Servicing		Processing			
s	p	σ_{min}	σ_{max}	δ_{min}	δ_{max}		
2	5	0.86	0.91	0.97	0.99	361.73 (0.8%)	1170.06 (2.8%)
3		0.45	0.71	0.97	0.99	23.07 (0.05%)	1112.53 (2.7%)
4		0.22	0.65	0.98	0.99	4.03 (0.01%)	1261.60 (3.02%)
5		0.08	0.65	0.93	0.97	**0.92 (0.002%)**	**288.71 (0.67%)**
2	6	0.88	0.91	0.76	0.93	415.56 (0.99%)	115.65 (0.28%)
3		0.48	0.72	0.76	0.93	**28.90 (0.07%)**	**118.43 (0.28%)**
4		0.24	0.66	0.76	0.93	5.50 (0.01%)	119.03 (0.28%)
5		0.10	0.65	0.76	0.93	1.13 (0.003%)	120.69 (0.29%)
2	7	0.88	0.91	0.53	0.88	406.31 (0.96%)	31.25 (0.07%)
3		0.48	0.72	0.54	0.88	**29.02 (0.07%)**	**31.77 (0.07%)**
4		0.25	0.65	0.54	0.88	5.59 (0.01%)	31.44 (0.08%)
5		0.11	0.65	0.53	0.88	1.14 (0.003%)	31.14 (0.07%)
2	8	0.88	0.92	0.36	0.86	405.78 (0.97%)	11.16 (0.03%)
3		0.49	0.72	0.36	0.86	**30.09 (0.07%)**	**10.95 (0.03%)**
4		0.24	0.67	0.36	0.86	5.53 (0.01%)	11.09 (0.03%)
5		0.11	0.65	0.36	0.86	1.15 (0.003%)	11.42 (0.03%)
2	9	0.88	0.92	0.22	0.85	451.40 (1.07%)	4.25 (0.01%)
3		0.49	0.72	0.22	0.85	**29.56 (0.07%)**	**4.18 (0.01%)**
4		0.24	0.66	0.22	0.85	5.67 (0.01%)	4.17 (0.01%)
5		0.11	0.65	0.22	0.85	1.15 (0.003%)	3.94 (0.01%)

The results are shown in Table V (only the minimum and maximum values for service utilization are shown) present the behavior of the system in the case of maximum stress. The total number of incidents in all simulations is ~1350 incidents per simulation. Based on the results shown, it can be concluded that there is a need for minimum $p = 7$ processing services (due to W_p values and Processing utilization) and minimum $s = 3$ servicing services.

TABLE VI
SIMULATION RESULT FOR PERIOD OF TWO YEARS

Utilization						W_s [min]	W_p[min]
Servicing		Processing					
σ_1	σ_2	δ_1	δ_2	δ_3	δ_4		
0.52	*	**0.78**	**0.68**	*	*	**110.7**	**189.5**
0.52	*	0.64	0.49	0.34	*	110.35	24.22
0.52	*	0.60	0.44	0.27	0.14	110.01	4.49
0.38	**0.16**	**0.60**	**0.44**	**0.27**	**0.14**	**6.74**	**4.49**

Based on the obtained results, it can be concluded that, in the case of the first simulation (Table VI), if $s = 1$ servicing service and $p = 2$ processing services are used, the service utilization is correct, but the average waiting time for the incidents to be processed (W_p) and resolved (W_s) is approximately 5 hours in total (average total number of incidents in queues is less than 2 incidents per queue). Increasing the number of processing services to $p = 3$ significantly reduces the waiting time for processing, while increasing the number of servicing services at $s = 2$, reducing the waiting time for servicing, but also reducing their productivity (38% and 16%).

VII. CONCLUSION

During the management of the distribution network, it is necessary to review the need for engaging dispatchers and field crews to timely correct the incidents in the network. In this paper, a simulation and analysis procedure are described that allow the estimation of the necessary resources to effectively solve the problem in the network.

Some of the incidents from different types could have mutual dependence and priority which is not taken into consideration in this paper. For the future work authors plan to give more attention on grouping incidents.

Comparative analysis of the usage of different image descriptors in object's video tracking

Abdalgalil Alsagair Abdulla and Stevica Graovac

***Abstract*—In this paper we tested a feature-based tracking algorithm for object tracking in video sequences, using different image descriptors (based on color, edge and texture) and particle filtering as a concept. A histogram-based framework is used to describe the object's features, where the object is a window consisting from a tracked vehicle and local background around it. Particle filtering has been proven as very robust one for non-linear and non-Gaussian estimation problems and performs well when clutter and occlusions are present. However, tracker based on single feature may lose the track easily or may start to track the wrong object. One popular remedy for this problem is usage of multiple features. In our approach, we develop the feature based particle filter tracker that relies on the search for the window, whose feature histogram matches a reference feature histogram model as much as possible. This work includes a comparison of tracking performances obtained by usage of different image descriptors separately; showing that some kind of fusion of partial results should be a reasonable solution in the context of analyzed traffic scenarios**

***Key Terms*— object tracking, particle filter, video tracking, image processing, color features, edge features, texture feature, histograms.**

I. Introduction

Tracking of moving objects is required in many applications such as surveillance systems, human-computer interfaces, target tracking, aircraft and car traffic monitoring, security and control. For the most of these tasks, a visual tracking based on processing of video sequences is used [1].

We focused our attention in this work toward visual tracking applications in the area of Intelligent Transportation Systems (ITS) where there are a number of algorithms and systems developed for automatic analysis and/or monitoring of traffic activities. Robust vehicle tracking is essential in traffic monitoring because it is the groundwork to higher level tasks such as traffic control, event detection and tracking [2]. Generally, visual tracking of moving objects is basically realized using object's visual features (e.g. color, texture, and shape) or motion information [3]. For the purpose of reliable vehicle tracking in the sequence of traffic images, typical problems are: variable background and shadows, variable existence of other close objects (moving or stationary), partial or even full occlusion by elements of scene, variable size of a tracked object during the sequence, etc [4], [5], [6]. Moreover, the visual tracking is affected by the problems caused by camera vibration due to wind, and lighting transitions between night/day and day/night.

There are a number of successful results in video tracking based on single or multiple features [4], [5], [7], [8]. Most of the problems encountered in video tracking can be addressed to the modeling of non-linear, non-Gaussian, multi-modal systems or any combination of these. To model accurately the underlying dynamics of a physical system, it is important to include elements of non-linearity and non-Gaussian noise distributions in many application areas. Speaking about of tracking algorithm concept, we have been motivated by the fact that a *Particle Filter* (PF) is very robust for non-linear and non-Gaussian dynamic state estimation problems and performs well when clutter and occlusions are present. PF uses *sequential Monte Carlo methods* based on point mass representations of probability densities that are applied to any state model.

While the color histogram-based particle filtering is the most common method used for object tracking, the existing R&D experiences as well as our analyses, have shown that in these ('single feature') cases tracker may lose the track easily or may start to track the wrong object. That was the reason why we focused our attention toward other features as are orientation of gradients and texture, in order to make the comparison between candidate features.

Tracking problem is specified in Section II, while particular image descriptors are the subject of Section III. In Section IV we have presented the results of usage different descriptors in specified set of test sequences. Concluding remarks are given in Section V.

II. Tracking Problem Formulation

The main task here was to design an algorithm for vehicle tracking using different features in the context of PF, for generated synthetic video sequences as well as for some typical real-world video sequences. Different techniques exist in the literature for video tracking tasks related to traffic monitoring and control. The tracking approach for video data that we apply is based on window-matching techniques consisting in the assessment of the degree of similarity among regions in sequential images. This way, an object may be recognized, and its position inferred in subsequent frames. For the synthetic video sequence, relatively small windows of size equal to 32×32 pixels are used for window matching purposes with the criterion to maximize the proper similarity function, as it was used in [1]. The similarity measure is based on the Euclidian distance between relevant histograms. The proposed approach uses three different types of matching: **color** (RGB)-based matching, **gradient** based matching, and **texture** based matching.

Stevica Graovac is retired professor of the School of Electrical Engineering, University of Belgrade, 73 Bulevar kralja Aleksandra, 11020 Belgrade, Serbia (e-mail:graovac@etf.rs).

This work addresses the problem of tracking single target in video sequences and discusses the obtained results in the presence of typical disturbances.

Particle Filter

Particle Filter is a hypothesis tracker that approximates the filtered posterior distribution by a set of weighted particles. It weights particles based on a likelihood score and then propagates these particles according to a motion model. The basic key idea of particle filters is that, one can find an approximate representation of a complex model (any arbitrary probability distribution function – PDF) rather than an exact representation of a simplified mode (Gaussians). PF is a promising technique because it is concerned with the problem of tracking single and multiple moving objects in video sequences [1], [9], [10] in typical traffic scenes characterized by non-linear motion model and non-Gaussian nature of disturbances. For testing of the tracking of single moving object using PF, we developed a synthetic video sequences and selected some typical real world street video sequences.

Steps in general PF algorithm are:

1. Initialize the state x_1 for the first frame and calculate the reference histogram on proposed features (color, edge and texture) for the target window.
2. Generate a particle set of N particles $\{X^m\}$, m=1: N, around the target point.
3. Predict the new state for each particle using transition model.
4. Compute a histogram distance (Euclidian distances for chosen feature) for each particle.
5. Weight each particle based on histogram distance and normalize the weights.
6. Select the location of target as a particle with minimum histogram distance (maximum weight).
7. Update the target location and particles' positions.
8. Resample the particles for the next iteration
9. Increase the time step and go to step 3.

III. FEATURES BASED TRACKING METHODS

Instead of tracking the entire objects (i.e. pattern of light intensities of pixels inside the tracking window), this approach tracks only the proposed features representing the window around moving objects, from frame to frame. The advantage of this approach is that, even in the presence of partial occlusion, some of the features of the moving object remain visible/recognizable [11]. Several features can be used for this purpose. We have analyzed the application of tracking PF using the features based on:

- Color measurement cue.
- Gradient measurements cue.
- Texture measurements cue.

In all three cases the feature/image descriptor is a particular type of histogram, representing the distribution of color components, gradient orientations, or texture/spatial relationships.

A. Color Feature

Color-based trackers have been proven to be robust. These trackers rely on the deterministic search of a window, whose color content matches a reference histogram. The target object to be tracked is the window initially formed manually around the moving vehicle. Color histogram (RGB) of this window is calculated and used for the purpose of a deterministic search for a matching window [12]. Color histograms have been widely used for tracking problems, because they are relatively robust in the presence of partial occlusion, rotation, and changes in size. They have limits in areas where the background has a similar color as the target object and they have poor performance when the illumination varies.

Tracking the window of interest consists in the context of PF in comparing its histogram with the histograms of the sample positions of particles, using the Euclidian distance as a measure [13]. In this work the histograms are typically calculated in the RGB space using 20 bins for each of color channels (60 bins, in sequence, together).

Fig. 1 shows a typical RGB color histograms for both, the reference window (frame number 4) and the best candidate window (frame number 35).

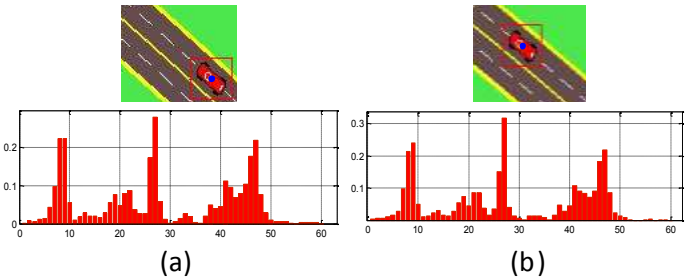

Fig. 1 a) Reference window histogram (k=4), b) Best candidate window histogram (k=35)

The predicted position of the tracked window could be chosen as the position of the particle where the matching of histograms is the best (as in our case) or at the position obtained by weighted averaging of positions of all particles, with the partial influence proportional to the distance between color histogram of the window on particle's position and the reference color window [6]. The smaller the discrepancy between the candidate and the reference models, the higher the likelihood that the object is located inside the candidate region. This discrepancy is measured by calculating the histogram distance. In this work we used Euclidean distance (EC_{dist}) as given in Eq. 1.

$$EC^{i}_{dist}(k) = \sqrt{\sum_{j=1}^{m}(C\_H\_part(j) - C\_H\_ref)^2} \qquad (1)$$

Where: 'i' is the particle index, 'k' is the Frame number, 'j' is bin number, 'm', is total number of bins, 'C_H_ref', is the extracted color histogram of reference window, and 'C_H_part', is the extracted color histogram of a particular particle window to be compared.

The observation likelihood model is used to assign a weight associated to a specific particle (new observation) depending on how similar the reference window histogram and the

particle's histogram are in the case of i^{th} particle [4].To evaluate the similarity between the reference histogram, and the particle's histogram, the similarity criteria based on Euclidian distance is used as in Eq. 2:

$$\mathrm{SIM}^{i}(k) = 1 - \mathrm{EC}^{i}_{\mathrm{dist}}(k) \quad (2)$$

B. Edge Feature

Object edges play a very important role in computer vision/pattern recognition and their orientations describe an important feature specifying the shape of the object of interest. The edge in image is the continuous set of pixels with high intensities of gradient. The edge feature used here is formed as a histogram of gradient orientations for the pixels where the magnitude of gradient is above some specified threshold. Edges are detected using horizontal and vertical Sobel operators K_x and K_y on the gray-scale image. The horizontal gradient G_x and vertical gradient G_y have magnitudes given by:

$$\left.\begin{aligned} G_x(x,y) &= K_x * I(x,y) \\ G_y(x,y) &= K_y * I(x,y) \end{aligned}\right\} \quad (3)$$

Where $K_x = \begin{bmatrix} -1 & 0 & 1 \\ -2 & 0 & 2 \\ -1 & 0 & 1 \end{bmatrix}$, $K_y = \begin{bmatrix} -1 & -2 & -1 \\ 0 & 0 & 0 \\ 1 & 2 & 1 \end{bmatrix}$

and *I(x,y)* is the candidate window.

The magnitude (G) and phase (θ) of the edges are determined as:

$$\left.\begin{aligned} G(x,y) &= \sqrt{G_x(x,y)^2 + G_y(x,y)^2} \\ \theta(x,y) &= \tan^{-1}\left(\frac{G_y(x,y)}{G_x(x,y)}\right) \end{aligned}\right\} \quad (4)$$

The basic idea in histogram of edge orientation of gradients is that an object shape can be characterized by the specific distribution of gradient orientations along its edges. The histogram bins are equally spaced over the interval -180 ^{o} to +180^{o} for unsigned gradient. There are three steps to find the histogram of edge gradient orientations:

- Find the positions (pixels) where the magnitude (G) is determined to be above some specified threshold (e.g. 80% of maximal magnitude in this window).
- Obtain the phases (θ) of the gradients corresponding to the pixels extracted in previous step;
- Calculate the edge orientation gradients histogram (using 40 bins in this particular case)

C. Texture Cues

Despite there is no unique definition of texture, it is generally agreed that texture provides information about the spatial arrangements of pixel color or grey levels in an image [1], which may be stochastic or periodic, or both. Texture descriptor provides measures of properties such as smoothness, coarseness, and regularity. There are many approaches used for describing the texture such as statistical approach described in [14].

There are various methods for statistical texture description:

- Local Binary Partition
- Histogram and Features
- Co-occurrence Matrices and Features
- Autocorrelation and Power Spectrum

In this work we used a histogram of *Grey Level Co-occurrence Matrix* (GLCM) values at a given offset over an image as texture descriptor.

The GLCM is a tabulation of how often different combinations of pixel brightness values (grey levels) occur in an image. In summary, there are four necessary steps in generating a GLCM matrix:

- Create a framework matrix;
- Decide on the spatial relation between the reference and neighbor pixel (give offset), in our work we use offsets=[0 1].
- Count the occurrences and fill in the framework matrix;
- Normalize the matrix to turn it into probabilities.

The obtained GLCM matrix size is 8x8 (eight classes of gray level), it is converted to a vector of size 64, and probabilities of occurrence being the elements of GLCM, now form the histogram with 64 bins as the texture descriptor.

IV. SIMULATION RESULTS AND DISCUSSION

There are five supposed scenarios for vehicle tracking tests. These are:

Case-I: Tracking the non-maneuvering target car without disturbance (synthetic sequence of images).

Case-II: Tracking a target car with disturbance (car shadow and shadow produced by road environment-(synthetic sequence of images).

Case-III: Tracking a maneuvering target car without disturbance (synthetic sequence of images).

Case-IV: Tracking the car with car ego-shadow and trees' shadow (real video sequence).

Case-V: Tracking the maneuvering car with partial occlusion and full occlusion (real video sequence).

The assumed parameters for synthetic video sequence simulation are:

- Velocity of the target vehicle in all cases is 90 km/h.
- Time interval between frames 50 ms.
- The number of particles used in PF was 150 in Case-I and Case-II, and 200 particles in Case-III.
- The spreading radius of the particles was 10 pixels in Case-I and Case-II, and 15 pixels in Case-III.
- Framework window size is 32×32 pixels
- 1 meter ≈ 7 pixels

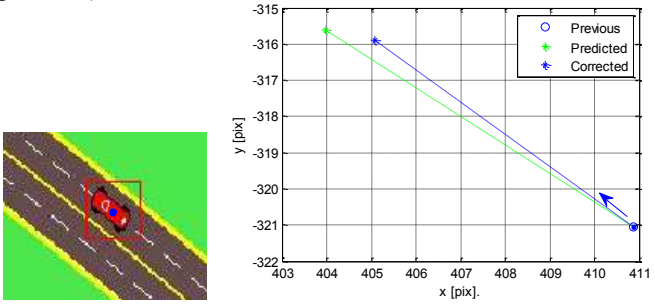
Simulation parameters for the selected real video sequences are:

- Interval between frames - 10.
- The number of particles used in PF was 150 particles for both cases.
- The spreading radius of the particles was 20 pixels in Case-IV and 15 pixels for Case-V.

- Framework window size is 50×50 and 80×70 pixels for Case-IV and Case-V, respectively.
- 1 meter ≈ 63 pixels for Case-IV and 1 meter ≈ 16 pixels for Case-V.

*A. **Case-I:** Tracking the non-maneuvering target car without disturbance.*

This case is verifying the tracking situation where there are no disturbances and no obstacles on the road, as shown in Fig.2a below. Fig.2b shows the tracked trajectory between frame 34 (previous) and frame 35.



(a) (b)

Fig.2 a) target car in the road, b) tracked trajectory between 2-frames

Fig.3 below shows the average similarity (for all particles) and the deviation between the estimated (updated) target positions using the proposed descriptors and the actual vehicle position respectively.

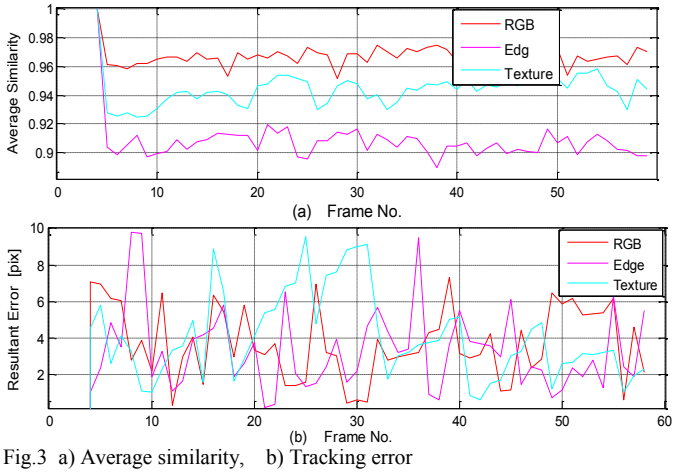


Fig.3 a) Average similarity, b) Tracking error

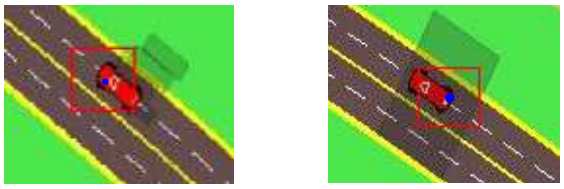
From Fig.3 we can see that the errors are approximately the same for all three descriptors (root mean square error are 4.18, 3.94 and 4.61 pixels, respectively for color, edge and texture). Average similarity slightly gives the preference to color descriptor.

*B. **Case-II:** Tracking a target car with disturbance (ego-car shadow and shadow produced by road environment)*

The disturbances such as ego-car shadow and tree shadow are inserted in this scenario and they appear abruptly at different intervals. Fig.4a illustrates the target car with shadow produced by itself (k=15), and Fig.4b shows the target car when it is affected by tree shadow (k=45). The obtained average similarity and deviation between the actual and estimated position of the target vehicle respectively can be seen in Fig.5 below.



(a) (b)

Fig.4 a) Target car with its shadow (k=15), b) Target car within Tree shadow (k=45)

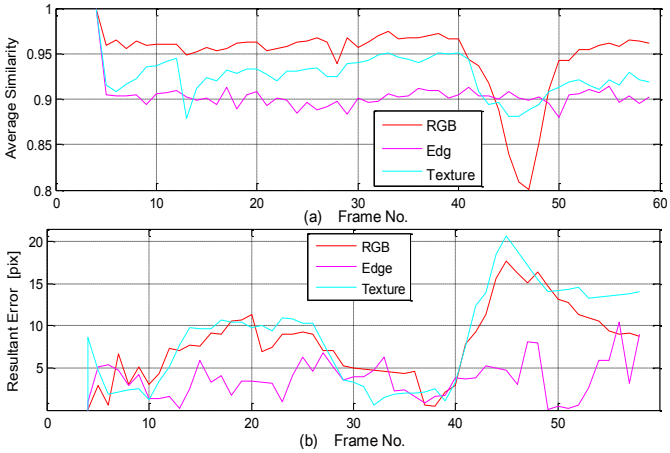


Fig.5 a) Average similarity, b) Tracking error

The error diagram shows that the color and texture descriptors are more sensitive to the shadow in both cases. The Average similarity for color descriptor is dropped to 0.80 at tree shadow interval and the root mean square error is 8.89, 4.32 and 10.10 pixels respectively for color, edge, and texture (giving the preference to edge descriptor).

*C. **Case-III:** Tracking a maneuvering target car without disturbance*

Fig.6 illustrates the tracking situation for maneuvering car bypassing the others: before over-taking (k=25), two cars in parallel (k=39), and after over-taking (k= 55).

(a) (b) (c)

Fig.6 Different status intervals frame (k=25), a) before over taking, b) 2-cars in parallel (k=39), c) after over taking (k=55).

Average similarity and the deviation between the actual and estimated position of the target vehicle respectively, can be seen in Fig.7. The maneuvering stage is occurring between the 4th frame and 70th frame.

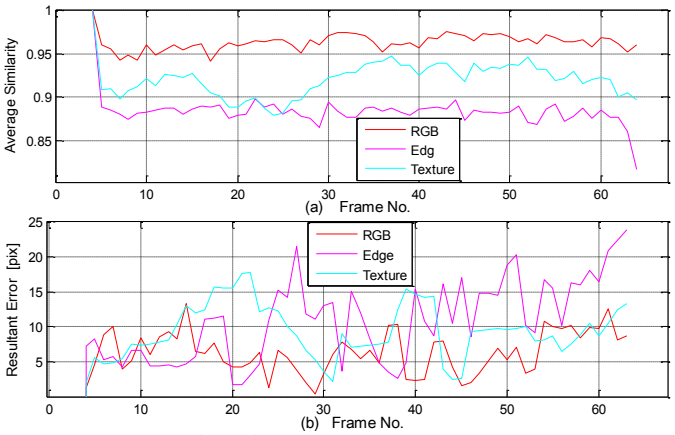

Fig.7 a) Average Similarity, b) Tracking error

We can see from Fig.7 that the color is favorable compared with other descriptors; and the root mean square error is 6.93, 12.14 and 10.05 pixels respectively for color, edge, and texture.

D. ***Case-IV:*** *Tracking the target car in real video sequence with disturbances of car and tree shadow*

This case describes the tracking situation in the existence of car shadow and tree shadow. Fig.8 shows the target window and color histogram respectively for the reference frame (k=235), first frame (k=242), car at tree's shadow frame (k=263) and car after tree shadow frame (k=291).

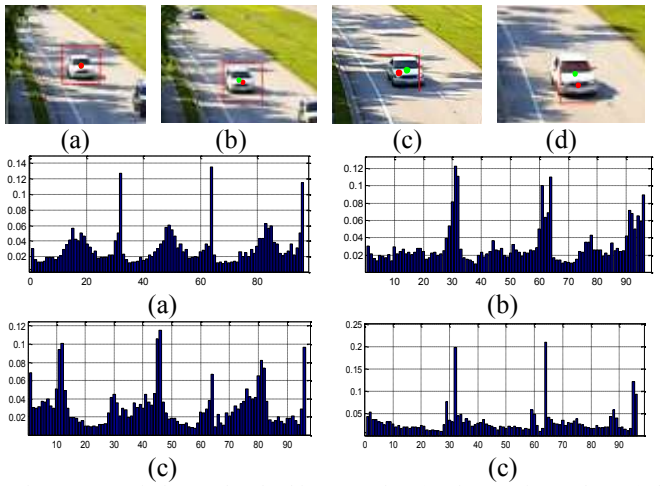

Fig.8 Target window and Color histogram for, a) reference frame (k=235), b) first frame (k=242), c) car at tree shadow frame (k=263), d) car after tree shadow frame (k=291).

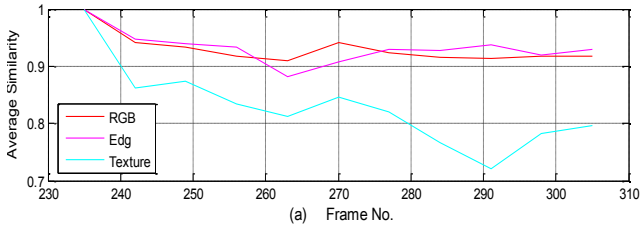
The average similarity and the deviation between the actual and estimated position of the target vehicle respectively can be seen in Fig.9.



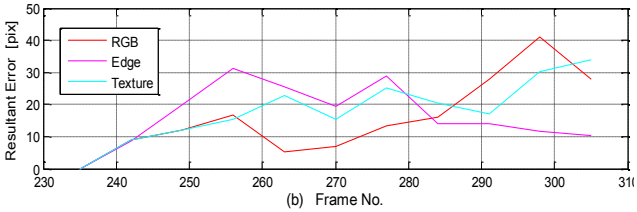


Fig.9 a) Average Similarity, b) Tracking error

We can see from the average similarity in Fig.9 that the color and edge are favorable descriptors; while the root mean square error is 19.65, 18.87 and 20.47 pixels respectively for color, edge, and texture. One should note that there are some differences in comparison to synthetic sequence of this type:

1. Size of the Frame – larger than before
2. Variable shadow all the time
3. Both types of shadows simultaneously
4. Correlation between pixels and meters is different (1 meter = 64 pixels).

E. Case-V: Tracking of maneuvering target car in real video sequence with partial and full occlusion

This case describes the tracking situation of the target vehicle exposed to partial and full occlusions due to the tree beside the road. One may say that this case is the most complex scenario because of:

1. Decreasing the size of car.
2. Partial and even full occlusion.
3. Maneuver during the full occlusion phase.

Fig.10 illustrates some important frames and corresponding color histograms representing these situations.

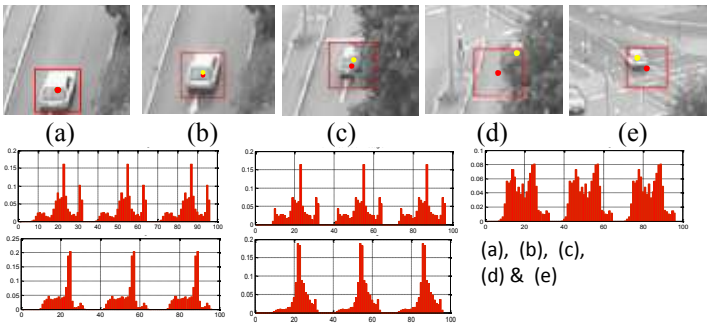

Fig.10 Frame and color histogram for a) Reference (k = 448), b) first frame (k = 460), c) partial occlusion (k = 580), d) full occlusion (k = 628), e) after occlusion (k = 700).

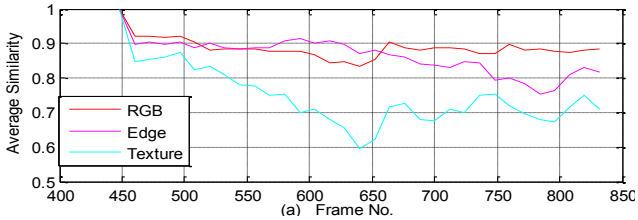
Fig.11 below shows the average similarity and the deviation between the actual and the estimated (updated) target positions using the three descriptors respectively.



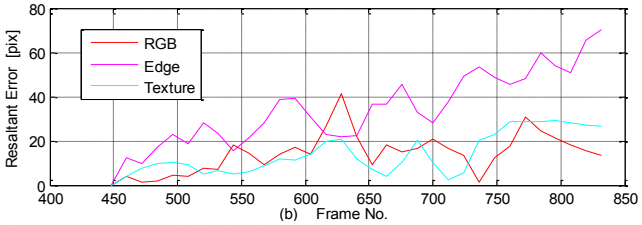


Fig.11 a) Average similarity, b) Tracking error

The root mean square error is 16.91, 38.16 and 16.65 pixels respectively for color, edge and texture; Correlation between pixels and meters is 1 meter ≈16 pixels. We can see in Fig.11 that according to the average similarity, color and edge are favorable descriptors. On the other hand, looking onto error histories, one can see that edge descriptor is practically not useful at all, because tracking based on it lost the tracked car completely after the full occlusion during the interval of k = 544 to k = 664.

Table-I below illustrates the RMS error in meter for all five cases.

TABLE I
RMS OF TRACKING ERRORS IN METERS FOR ALL CASES

	Case I	Case II	Case III	Case IV	Case V
RGB	0.597	1.270	0.990	0.307	1.057
Edge	0.563	0.617	1.734	0.295	2.385
Texture	0.659	1.443	1.436	0.320	1.041

V. CONCLUSION

In this paper, we have presented a comparative analysis of application of object tracking PF algorithm based on three features/image descriptors. From the studded cases, for a single object in synthetic video sequences and in real video, we can conclude the following:

- In the case of non-maneuvering target vehicle without disturbance, the tracking errors are mostly the same for all three descriptors.
- The case of tracking of a target car with its shadow and shadow produced by road environment has shown that the color and texture descriptors are more sensitive in comparison to edge descriptor.
- The maneuvering of undisturbed target case shows the edge descriptor is the most sensitive to rotation as illustrated in Fig.6, and the color cue gives the best accuracy compared to the others.
- In the case of tracking the target car (real video) with its shadow and tree, one can conclude that the color is favorable descriptor.
- The situation of the maneuvering target vehicle with partial and full occlusions has shown in the last case, being the most complex scenario, that the preference should be given to color and texture descriptors in comparison to edge based.

As a final conclusion, it could be said that according to different scenarios tested here, none of analyzed descriptors can be declared as the best one for all cases. To overcome this ambiguity, some fusion of all three tracking results obtained by different descriptors should be made in one integral tracking algorithm based on all three analyzed descriptors.

Gaussian Process Domain Experts for Prediction of Alzheimer's Disease-Related Cognitive Scores

Nikola Popović, Ognjen Rudović, Predrag Vasilić and Predrag Tadić

***Abstract*—We address the problem of predicting Alzheimer's Disease (AD) progression, taking data from past visits as inputs. This is important for timely monitoring of a subjects' cognitive performance, and, consequently, for improving the selection of subjects for new clinical trials. To this end, we introduce a novel prediction model based on the notion of domain adaptive Gaussian Processes (GP). Specifically, in contrast to previous works that employed GPs for this task, here we formulate a mixture of domain-specific GPs, where each GP is trained on a subpopulation with different clinical status (cognitively normal (CN), mild-cognitive impairment (MCI) and AD). Furthermore, by using the probabilistic formulation of GPs, we personalized our model to the target subject (not used to train the model) using his/her previous visits' data, in order to reduce the estimation bias, which is typically pronounced when applying the population-level GP models to the target task. The proposed method was compared to several state-of-the-art GP-based models on a sub-cohort of subjects who participated in the Alzheimer's Disease Neuroimaging Initiative (ADNI) [1]. The models were train to predict the patient's future score on the standard Alzheimer's Disease Assessment Scale–Cognitive Subscale (ADAS-Cog13). We show in the experiments presented here that the proposed domain-specific mixture of adaptive GPs does not lead to large improvements in terms of the point estimate of the ADAS-Cog13 scores compared to existing GP models trained on the whole training population. However, it provides much better uncertainty estimates for its predictions. This is an important advantage of our model as it allows to encode the model's prediction confidence more accurately than the single expert model (i.e. when a GP is trained on all three sub-groups together). We also show that the proposed approach has much lower computational complexity, as the necessary matrix inversions can efficiently be performed on the data-subsets corresponding to the target sub-populations.**

***Index Terms*—Gaussian processes, Alzheimers disease, Personalized models, Gaussian process experts, Machine Learning.**

I. Introduction

RECENTLY, view on Alzheimer's Disease (AD) diagnosis has shifted towards a more dynamic process in which clinical and pathological markers evolve gradually before diagnostic criteria are met [2]. Achieving accurate predictions of AD progression is a significant and difficult challenge. There is wide variability in data available per subject, inherent per-person differences, and the disease has a slowly changing nature. The most widely used general cognitive measure in clinical trials is the Alzheimer's Disease Assessment Scale-cognition sub-scale (ADAS-Cog) [3], which assesses multiple cognitive domains including language, memory, orientation and praxis [4]. The ADAS-Cog has proven important for target clinical assessments, so in this article we focus on a machine learning method for predicting the future values of this score based on previously seen subjects. We specifically use the modified ADAS-Cog 13-item scale [3], which includes all original ADAS-cog items, with the addition of a number of cancellation tasks and a delayed free recall task, for a total of 85 points. Higher scores mean greater severity. These additional items were added to increase the number of cognitive domains and range of symptom severity without a substantial increase in the time required for administration.

One of the main challenges in a clinical assessment of a subject at risk of developing AD is the ability to accurately predict the future cognitive scores of interest for clinical trials, which for instance aim to find the most effective treatments for AD. An algorithm that could predict future cognitive scores such as ADAS-Cog13 would bring great value to the assessment procedure, and would have a potential to improve the efficiency of clinical trials, which are typically expensive and lengthy. For example, out of hundreds of clinical trials, costing billions of dollars, fewer than 1% have proceeded to the regulatory approval stage and non have managed to prove a disease-modifying effect [5], [6]. Improvement in the ability to accurately identify subjects at early stages of the disease, where the treatment has a bigger chance to be effective, promises more success. Thus, having models that can make accurate predictions of the progression of cognitive scores such as ADAS-Cog13 is of great importance.

In this paper, we use data from the Alzheimer's Disease Neuroimaging Initiative (ADNI) [1], which was processed for the TADPOLE Challenge [5], to evaluate models which predict the ADAS-Cog13 score for the next doctor visit. The dataset is very sparse, with different combinations of features missing for different subjects. For about 80% of the subjects, partial records are missing from the dataset. Accurate forecasting of cognitive decline and related measures of disease progression is a very difficult challenge given the wide variability in available data per subject, slowly changing nature of the disease and inherent per-person differences.

We use various Gaussian Process (GP) models for predicting the ADAS-Cog13 score for the next doctor visit based on the current visit. GP are nonparametric, probabilistic models which also offer the predictive uncertainty in the form of the predictive distribution variance [7]. The uncertainty enables better quantification of the prediction performance. We first evaluate the results achieved using regular and personalized

O. Rudović – MIT Media Lab, 75 Amherst St, 02139 Cambridge, MA, USA (e-mail: orudovic@mit.edu).

GP which have been used to tackle this challenge [2], [8]. We then propose a novel GP domain-expert approach that is based on the notion of domain-adaptive and distributed GPs [9], [10]. While previous GP-based approaches use a single GP expert to model the whole population under the study, here we use the domain knowledge to derive the GP expert models for each subpopulation (the subjects diagnosed as CN, MCI and AD), as we expect different dynamics in the data of these subjects. Specifically, we build a mixture of three domain-specific GP experts (CN, MCI and AD) as well as the target expert (a GP applied to the target subject's data only), using the variance-based weighting scheme, as in [10]. As in the previous works [2], [8], we also show the effects of the model personalization on the prediction performance. We show that the proposed GP expert approach achieves relatively good predictions with much better uncertainty estimates, while being much more computationally efficient.

The rest of the paper is structured as follows: in Section II, we provide a theoretical overview of GPs, personalized GPs and GP expert models. Section III describes the dataset used, and provides further details about the models, their evaluation, and shows the experimental results. Finally, Section IV concludes the paper.

II. Gaussian Processes

Gaussian processes are very flexible probabilistic, non-parametric models. Unlike classical Machine Learning algorithms, their output is not a point estimate, but a distribution. This is a good property since besides the point estimate, the model also expresses how certain it is in the prediction. For example, if the predictive distribution is tightly concentrated around some value it means that the model is confident in that prediction.

First, we will look at classical Gaussian processes for regression as described in [7]. Then, an overview of Gaussian process adaptation technique [2], [10] which makes personalized predictions will be given. Finally, we will look at Gaussian process domain experts technique [9], [10].

A. Gaussian Processes for Regression

Strictly speaking, a Gaussian process is a collection of random variables, any finite number of which have a joint Gaussian distribution [7]. A Gaussian process $f(\mathbf{x})$ is completely specified by its mean $m(\mathbf{x})$ and covariance function $k(\mathbf{x}, \mathbf{x}')$ which are defined as

$$m(\mathbf{x}) = \mathbb{E}[f(\mathbf{x})], \tag{1}$$

$$k(\mathbf{x}, \mathbf{x}') = \mathbb{E}[(f(\mathbf{x}) - m(\mathbf{x}))(f(\mathbf{x}') - m(\mathbf{x}'))], \tag{2}$$

and it is denoted as

$$f(\mathbf{x}) \sim \mathcal{GP}(m(\mathbf{x}), k(\mathbf{x}, \mathbf{x}')), \tag{3}$$

where the mean function is usually taken to be zero.

The usual setting is that only noisy measurements of the function value are obtained at some input locations

$$y = f(\mathbf{x}) + \varepsilon. \tag{4}$$

The noise ε is assumed to be independent and identically distributed Gaussian noise with zero mean and variance σ_n^2. We will denote the training set inputs with $\mathbf{X}^{(v)} = \{\mathbf{x}_{n_v}^{(v)}\}_{n_v=1}^{N_v}$ and outputs with $\mathbf{Y}^{(v)} = \{\mathbf{y}_{n_v}^{(v)}\}_{n_v=1}^{N_v}$. The joint distribution of all the training measurements along with one test function value is

$$\begin{bmatrix} \mathbf{Y}^{(v)} \\ f_* \end{bmatrix} \sim \mathcal{N}\left(\mathbf{0}, \begin{bmatrix} \mathbf{K} + \sigma_n^2\mathbf{I} & \mathbf{k}_* \\ \mathbf{k}_*^{\mathrm{T}} & k_{**} \end{bmatrix}\right), \tag{5}$$

where $\mathbf{K} = \mathbf{K}(\mathbf{X}^{(v)}, \mathbf{X}^{(v)})$, $\mathbf{k}_* = \mathbf{k}(\mathbf{X}^{(v)}, \mathbf{x}_*)$ and $k_{**} = k(\mathbf{x}_*, \mathbf{x}_*)$. We can then condition this joint Gaussian distribution on the observations to obtain a posterior Gaussian distribution

$$p(f_*|\mathbf{X}^{(v)}, \mathbf{Y}^{(v)}, \mathbf{x}_*, \boldsymbol{\theta}) \sim \mathcal{N}(\mu_*, \sigma_*^2), \tag{6}$$

with the mean μ_* and variance $V_* = \sigma_*^2$

$$\mu_* = \mathbf{k}_*^{\mathrm{T}} \left(\mathbf{K} + \sigma_n^2\mathbf{I}\right)^{-1} \mathbf{Y}^{(v)}, \tag{7}$$

$$V_* = k_{**} - \mathbf{k}_*^{\mathrm{T}} \left[\mathbf{K} + \sigma_n^2\mathbf{I}\right]^{-1} \mathbf{k}_*, \tag{8}$$

where $\boldsymbol{\theta}$ are the hyper-parameters of the Gaussian process—parameters of the prior covariance function and the variance of the noise σ_n^2. When using Gaussian processes for regression, we first specify a prior distribution with (1) and (2). The prior should be based on our belief about the underlying function. We then use the training data $\left(\mathbf{X}^{(v)}, \mathbf{Y}^{(v)}\right)$ to obtain the posterior predictive distribution (7) and (8), at inputs $\mathbf{x}_*$ that are of interest.

One of the most commonly used covariance functions is the squared-exponential kernel

$$k_{\mathrm{SE}}(\mathbf{x}, \mathbf{x}') = \sigma_f^2 \exp\left(-\frac{\|\mathbf{x} - \mathbf{x}'\|^2}{2l^2}\right), \tag{9}$$

where σ_f^2 represents the variance of the process and l represent the characteristic length-scale—how much $\mathbf{x}$ and $\mathbf{x}'$ have to be far apart to become uncorrelated. The parameters σ_f^2 and l are the hyper-parameters of the squared-exponential covariance function.

The hyper-parameters $\boldsymbol{\theta}$ will be learned by maximizing the log-likelihood

$$\begin{aligned} \log p(\mathbf{Y}^{(v)}|\mathbf{X}^{(v)}, \boldsymbol{\theta}) = &-\frac{1}{2}\mathbf{Y}^{\mathrm{T}(v)}\mathbf{K}_y^{-1}\mathbf{Y}^{\mathrm{T}(v)} \\ &-\frac{1}{2}\log|\mathbf{K}_y| - \frac{n}{2}\log(2\pi), \end{aligned} \tag{10}$$

where $\mathbf{K}_y = \mathbf{K} + \sigma_n^2\mathbf{I}$. The process of learning the hyper-parameters is called training. It requires computing the inverse and the determinant of $\mathbf{K}_y$, both of which have $\mathcal{O}(N_v^3)$ complexity.

B. Personalized Gaussian Processes (PGP)

Assume that we have access to a large collection of labeled *source* data and a smaller set of labeled *target* data. For example, when forecasting the development of a patients disease, the target data would be all the data collected from that patient so far and the source data would consist of the collected data of all other patients. The source data is

denoted with $\mathcal{D}^{(s)} = \left(\mathbf{X}^{(s)}, \mathbf{Y}^{(s)}\right)$, where $\mathbf{X}^{(s)} = \{\mathbf{x}_{n_s}^{(s)}\}_{n_s=1}^{N_s}$ and $\mathbf{Y}^{(s)} = \{\mathbf{y}_{n_s}^{(s)}\}_{n_s=1}^{N_s}$. The target data is denoted with $\mathcal{D}^{(t)} = \left(\mathbf{X}^{(t)}, \mathbf{Y}^{(t)}\right)$, where $\mathbf{X}^{(t)} = \{\mathbf{x}_{n_t}^{(t)}\}_{n_t=1}^{N_t}$ and $\mathbf{Y}^{(t)} = \{\mathbf{y}_{n_t}^{(t)}\}_{n_t=1}^{N_t}$.

This PGP algorithm consists of three steps [9]:

1) Train a GP on the source data by maximizing the marginal likelihood $p(\mathbf{Y}^{(s)}|\mathbf{X}^{(s)}, \boldsymbol{\theta})$ to learn the hyper-parameters $\boldsymbol{\theta}$. The posterior distribution is then obtained by applying equations (7) and (8).
2) Use the posterior obtained on the source data as a prior for the GP of the target data $p(\mathbf{Y}^{(t)}|\mathbf{X}^{(t)}, \mathcal{D}^{(s)}, \boldsymbol{\theta})$.
3) Correct the posterior distribution to account for the for the target data $\mathcal{D}^{(t)}$ as well.

That is, our training data will be the target set and our prior will be the predictive distribution of applying a GP to the source data.

Now, the conditional prior of the target data (given the source data) from step 2) is given by applying equations (7) and (8) on $\mathbf{X}^{(t)}$:

$$\boldsymbol{\mu}^{(t|s)} = \mathbf{K}_{st}^{\mathrm{T}(s)} \left(\mathbf{K}^{(s)} + \sigma_{n_s}^2 \mathbf{I}\right)^{-1} \mathbf{Y}^{(s)}, \tag{11}$$

$$\mathbf{V}^{(t|s)} = \mathbf{K}_{tt}^{(s)} - \mathbf{K}_{st}^{\mathrm{T}(s)} \left[\mathbf{K}^{(s)} + \sigma_{n_s}^2 \mathbf{I}\right]^{-1} \mathbf{K}_{st}^{(s)}, \tag{12}$$

where $\mathbf{K}_{st}^{(s)} = k^{(s)}(\mathbf{X}^{(t)}, \mathbf{X}^{(t)})$ and $\mathbf{K}_{tt}^{(s)} = \mathbf{k}^{(s)}(\mathbf{X}^{(t)}, \mathbf{X}^{(t)})$. Given the above prior, the adapted predictive distribution for a test input $\mathbf{x}_*^{(t)}$ after observing the target data is given by [9]

$$\begin{aligned} \mu_{ad}^{(t|s)}(\mathbf{x}_*^{(t)}) &= \mu^{(s)}(\mathbf{x}_*^{(t)}) \\ &+ \mathbf{V}_*^{\mathrm{T}(t|s)} \left(\mathbf{V}^{(t|s)} + \sigma_{n_s}^2 \mathbf{I}\right)^{-1} \left(\mathbf{Y}^{(t)} - \boldsymbol{\mu}^{(t|s)}\right), \end{aligned} \tag{13}$$

$$\begin{aligned} V_{ad}^{(t|s)}(\mathbf{x}_*^{(t)}) &= V^{(s)}(\mathbf{x}_*^{(t)}) \\ &- \mathbf{V}_*^{\mathrm{T}(t|s)} \left(\mathbf{V}^{(t|s)} + \sigma_{n_s}^2 \mathbf{I}\right)^{-1} \mathbf{V}_*^{(t|s)}, \end{aligned} \tag{14}$$

with

$$\begin{aligned} \mathbf{V}_*^{(t|s)} &= k^{(s)}(\mathbf{X}^{(t)}, \mathbf{x}_*^{(t)}) \\ &- K_{st}^{\mathrm{T}(s)} \left(\mathbf{K}^{(s)} + \sigma_{n_s}^2 \mathbf{I}\right)^{-1} k^{(s)}(\mathbf{X}^{(s)}, X_*^{(t)}) \end{aligned} \tag{15}$$

It is clear from (13) that the final prediction shifts the prior mean obtained on the source data towards the distribution of the target data. Also, from (14) we notice that the models confidence is improved by reducing the prior variance.

C. Gaussian Processes Domain Experts (GPDE)

For our training set we have both the source and target data $\mathcal{D} = \left(\mathcal{D}^{(s)}, \mathcal{D}^{(t)}\right)$. We will assume that the source data is a combination of multiple smaller source datasets $\mathcal{D}^{(s)} = \{\mathcal{D}^{(s_1)}, \mathcal{D}^{(s_2)}, ..., \mathcal{D}^{(s_M)}\}$, where M is a total number of these datasets. A GP expert will be trained on each dataset and their results will be combined into a final prediction. An overall computation will be performed by combining many independent smaller computations performed by experts. This approach enables parallelisation and distributed computing.

Given the above mentioned data split and assuming conditional independence of the labels from each domain given their corresponding input features, the marginal likelihood can be approximated by

$$\begin{aligned} &p(\mathbf{Y}^{(s,t)}|\mathbf{X}^{(s,t)}, \boldsymbol{\theta}^{(s,t)}) \approx \\ &p(\mathbf{Y}^{(t)}|\mathbf{X}^{(t)}, \boldsymbol{\theta}^{(t)}) \prod_{k=1}^{M} p_k(\mathbf{Y}^{(s_k)}|\mathbf{X}^{(s_k)}, \boldsymbol{\theta}^{(s)}). \end{aligned} \tag{16}$$

We assume that a standard GP is sufficient to model the source data, so all source domains share a set of hyper-parameters $\boldsymbol{\theta}^{(s)}$. Each factor from (16) is determined by a GP expert. For training the GPDE, we find the GP hyperparameters $\boldsymbol{\theta}^{(s)}$ and $\boldsymbol{\theta}^{(t)}$ that maximize the corresponding log-marginal likelihood

$$\begin{aligned} &\log p(\mathbf{Y}^{(s,t)}|\mathbf{X}^{(s,t)}, \boldsymbol{\theta}^{(s,t)}) = \\ &\log p(\mathbf{Y}^{(t)}|\mathbf{X}^{(t)}, \boldsymbol{\theta}^{(t)}) + \sum_{k=1}^{M} \log p_k(\mathbf{Y}^{(s_k)}|\mathbf{X}^{(s_k)}, \boldsymbol{\theta}^{(s)}). \end{aligned} \tag{17}$$

Each term in (17) is independently computed and given by (10), for $v = t, s_1, s_2, ..., s_M$. This means that the complexity of calculating (17) is much lower than using (10) on the source and target data combined, or just on the source data as is needed in the pGP technique. This is because inverting one big matrix is considerably more expensive than inverting $M + 1$ much smaller ones. Also, in equation (17) we have a sum of two terms where one depends on $\boldsymbol{\theta}^{(s)}$ and the other depends on $\boldsymbol{\theta}^{(t)}$. This means that we can learn these two sets of hyper-parameters independently from one another. If we have a fixed source set, than for each new target that we need to do predictions on, we only need to retrain $\boldsymbol{\theta}^{(t)}$, which can bring even more computational savings.

When the GPDE is trained, we need to combine the prediction of each expert into an overall prediction. The predictive distribution is given by

$$\begin{aligned} p(f_*|\mathbf{x}_*, \mathcal{D}, \boldsymbol{\theta}^{(s,t)}) &= p(f_*|\mathbf{x}_*, \mathcal{D}^{(t)}, \boldsymbol{\theta}^{(t)}) \\ &\prod_{k=1}^{M} p(f_*|\mathbf{x}_*, \mathcal{D}^{(s_k)}, \boldsymbol{\theta}^{(s)}). \end{aligned} \tag{18}$$

Instead of a regular GP for each source expert, we can adapt it to the target data using the pGP technique. Then, the predictive distribution is given by

$$\begin{aligned} p(f_*|\mathbf{x}_*, \mathcal{D}, \boldsymbol{\theta}^{(s,t)}) &= p(f_*|\mathbf{x}_*, \mathcal{D}^{(t)}, \boldsymbol{\theta}^{(t)}) \\ &\prod_{k=1}^{M} p(f_*|\mathbf{x}_*, \mathcal{D}^{(s_k)}, \mathcal{D}^{(t)}, \boldsymbol{\theta}^{(s)}). \end{aligned} \tag{19}$$

In both of these approaches, when predicting unseen target inputs $\mathbf{x}_*^{(t)}$, each expert predicts the mean $\mu_*^{(v)} = \mu^{(v)}(\mathbf{x}_*^{(t)})$ and variance $V_*^{(v)} = V^{(v)}(\mathbf{x}_*^{(t)})$ independently, where $v = t, s_1, s_2, ..., s_M$. The joint prediction is obtained as the product of all experts predictions, which is proportional to a Gaussian distribution with variance and mean [10]

$$V_*^{(gpde)} = \left[(V_*^{(t)})^{-1} + \sum_{k=1}^{M} (V_*^{(s_k)})^{-1}\right]^{-1}, \tag{20}$$

$$\mu_*^{(gpde)} = (V_*^{(gpde)}) \left[(V_*^{(t)})^{-1} \mu_*^{(t)} + \sum_{k=1}^{M} (V_*^{(s_k)})^{-1} \mu_*^{(s_k)} \right]. \quad (21)$$

The strength of this model is that the overall prediction $p(f_*|\mathbf{x}_*, \mathcal{D}, \boldsymbol{\theta}^{(s,t)})$ is straightforward to compute. A shortcoming is that with an increasing number of experts the predictive variances vanish (the precisions add up), which leads to overconfident predictions, especially in regions without data [10]. Thus this model is inconsistent in the sense that it doesn't fall back to the prior far from the training data.

The importance of experts can be increased as

$$p(f_*|\mathbf{x}_*, \mathcal{D}, \boldsymbol{\theta}^{(s,t)}) = p(f_*|\mathbf{x}_*, \mathcal{D}^{(t)}, \boldsymbol{\theta}^{(t)})^{\beta_t} \prod_{k=1}^{M} p(f_*|\mathbf{x}_*, \mathcal{D}^{(s_k)}, \mathcal{D}^{(t)}, \boldsymbol{\theta}^{(s)})^{\beta_{s_k}}. \quad (22)$$

where β_k is the weight (or the contribution) of the k-th expert. The predictive variance and mean are, therefore,

$$V_*^{(gpde)} = \left[\beta_t (V_*^{(t)})^{-1} + \sum_{k=1}^{M} \beta_{s_k} (V_*^{(s_k)})^{-1} \right]^{-1}, \quad (23)$$

$$\mu_*^{(gpde)} = (V_*^{(gpde)}) \left[\beta_t (V_*^{(t)})^{-1} \mu_*^{(t)} + \sum_{k=1}^{M} \beta_{s_k} (V_*^{(s_k)})^{-1} \mu_*^{(s_k)} \right]. \quad (24)$$

The strength of this model is that if $\beta_t + \sum_{k=1}^{M} \beta_{s_k} = 1$ the predictive distribution falls back to the prior outside the range of the training data [10], so the model doesn't make overconfident predictions in that region anymore. A weakness is that inside the range of the data the model tends to overestimate the variances, especially with an increasing number of GP experts.

In this paper, we will not consider the effect of tuning the parameters β_k. They will be set to $\beta_k = \frac{1}{M+1}$, where $M+1$ is the number of experts. In this setting, the prediction means (21) and (24) are identical, but the variance differs in a sense that the variance in equation (20) starts to resemble the prior variance outside the training data range, as mentioned above.

III. Experiments

A. Data

For this article we collected data from the ADNI database (adni.loni.usc.edu). We used the standard dataset processed for TADPOLE challange [5]. This dataset contains 1737 unique subjects and was created from the ADNIMERGE spreadsheet, to which regional MRI (volumes, cortical thickness, surface area), PET (FDG, AV45, AV1451), DTI (regional means of standard indices) and cerebrospinal fluid (CSF) biomarkers were added. We used all the features from this data, except for the normalized verticle volumens (ICVn) and all cognitive scores except ADAS-Cog13. The task was to predict the Alzheimer's Disease Assessment Scale-Cognition Sub-Scale (ADAS-Cog13) score. The subjects clinical status (CS) was used to divide the source dataset into subsets. With that data, multi-modal feature set was constructed from six modalities: demographics (6 features), genetics (3 features), cognitive tests (9 features), CSF (3 features), MRI (365 features), and DTI (229 features). Due to sparseness, we excluded PET data entirely. We used a cohort of 100 subjects with each having 21 planned visits every 6 months. Each subject has no more than 10 visits missing and no more than 82.5% features missing for the experiments.

B. Models

All the models are first-order autoregressive, meaning that they are using the features of the current visit, along with the ADAS-Cog13 current cognitive score $(\mathbf{x}_t, y_t)$ as an input to the model. The goal is to predict the ADAS-Cog13 cognitive score y_{t+1} for the next visit. When we are predicting y_{t+1} for a specific patient, the source data will consist of all other patients we have in the test set, while the target data will consist of all the visits for that patient up to visit $t-1$, and the input to the model will be $(\mathbf{x}_t, y_t)$. We evaluated five models on this dataset:

- **Source GP (sGP)**: A regular GP, as mentioned in section II-A. The training set will consist of the source data, and the predictive distribution is given with equations (7) and (8).
- **Personalized GP (pGP)**: This is the GP adaptation technique explained in II-B. The predictive distribution is given with equations (13) and (14).
- **Target GP (tGP)**: A regular GP, as mentioned in section II-A. The training set will consist of the target data, and the predictive distribution is given with equations (7) and (8). Because of the small amount of subject visits and common missing data, the hyper-parameters for this model are learned on the source data.
- **GP Domain Experts (GPDE)**: This is the technique explained in II-C. This model uses the expert contribution parameters β_i (all experts have the same contribution, and they all sum to 1) and breaks the source data into three subgroups based on the patients clinical status:
  - Subjects who are cognitively normal (CN).
  - Subjects who are mildly cognitively impaired (MCI) or have converted from CN to MCI.
  - Subjects who have Alzheimer disease (AD), or have converted from CN/MCI to AD.

  The predictive distribution is given by equations (23) and (24). The target expert hyper-parameters are taken to be $\boldsymbol{\theta}^{(s)}$, which are trained only on the second term of equation (17).
- **Personalized GP Domain Experts (pGPDE)**: This is the technique explained in II-C. This model uses the expert contribution parameters β_i (all experts have the same contribution, and they all sum to 1) and breaks the source data into three subgroups based on the patients clinical status. First, the model adapts each source expert using equations (13) and (14). Then, it computes the predictive distribution using equations (23) and (24). The

target expert hyper-parameters are taken to be $\boldsymbol{\theta}^{(s)}$, which are trained only on the second term of equation (17).

The sGP, pGP and tGP models are used in [2] and [8] to predict future cognitive scores. We propose using GPDE and pGPDE for the same task, and compare the results. All of the models use the squared-exponential kernel.

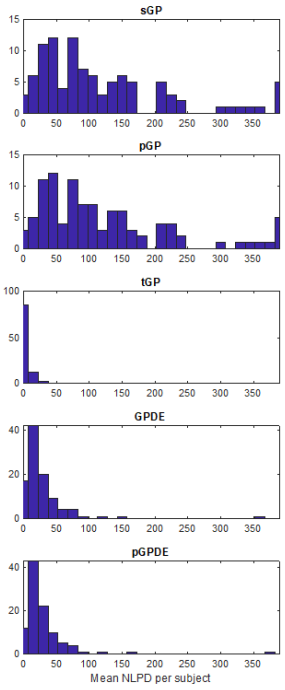

Fig. 1. The histograms of the NLPD metric averaged per subject for all of the considered models during the leave-one-subject-out validation procedure.

C. Evaluation

All models are evaluated using the leave-one-out validation method—each subject is selected for predictions, while the other 99 make up the source dataset and all the results are averaged at the end. Each subject that is selected for prediction has 21 doctor visits planned. When he missed a visit, the last available ADAS-Cog13 score was put in the database. Missing features were imputed as zero values. When computing the final metrics, the predictions which have no true label (due to missed visits) are not used. As the evaluation metric, we use the mean absolute error (MAE) defined as:

$$\frac{1}{N}\sum_i |y^{(i)}_{\text{pred}} - y^{(i)}_{\text{true}}|, \tag{25}$$

which encodes the error in the point estimates by the model. However, it fails to encode the model's uncertainty in its prediction. For this, we compute the mean negative log predictive density (MNLPD), defined as:

$$\begin{aligned}&\frac{1}{N}\sum_i -\log p(y^{(i)}_{\text{true}}|\mathbf{x}^{(i)}, \mathcal{D}, \boldsymbol{\theta}) \\ =&\frac{1}{N}\sum_i \left(\frac{1}{2}\log {\sigma^{2}}^{(i)}_{\text{pred}} + \frac{(y^{(i)}_{true} - \mu^{(i)}_{\text{pred}})^2}{2{\sigma^{2}}^{(i)}_{\text{pred}}} + \frac{1}{2}\log 2\pi\right),\end{aligned} \tag{26}$$

which, in addition to the point estimates, also accounts for the predictive variance. Note that if the prediction is close to the true value, but the model is not confident in its prediction, it receives a lower MNLPD score than a model that has the same good prediction but a lower variance. Similarly, if the prediction is less accurate but the model is overconfident, that is rated worse than when the model is uncertain about its prediction.

D. Results

Experimental results are shown in Table I. By looking into the performance measures for all subjects (all theree subgroups trained together), we note that while pGP and pGPDE models have similar MAE for their point estimates, the MNLPD of the latter is much lower. This can be noticed more clearly by looking at Fig. 1 and it signals that pGPDE provides better estimates of prediction uncertainty (i.e. higher variance when the point estimates are further away from the true label). Also, by looking at Fig. 1 we notice that the GPDE model, which is also based on the idea of combining experts, achieves a relatively low MNLPD per subject. Correctly encoding the model's uncertainty is important for the interpretation of and confidence in the predicted target scores. While looking at the performance measures of the CN subjects, it turns out that the tGP model is best both in terms of MAE and MNLPD. This is because the ADAS-Cog13 score changes very slowly for these subjects, and the tGP model looks only at the previous visits for the observed subject. Thus, a simple smoothing of the subject's previous scores leads to reasonably accurate estimates. When we look at the MCI subjects we notice that the proposed GPDE and pGPDE models achieve the lowest MAE, with a relatively low MNLPD. It is interesting to notice that both GPDE and pGPDE have almost the same MAE. It seems that the effects of the model personalization via the GP posteriors are less pronpunced here. This may be due to the fact that the GPDE model is already performing another type of the model-level personalization by different weighting of the expert models for each test data. Among the expert models, there is an expert that uses the MCI dataset subgroup and that expert could have the largest contribution in the prediction. Finally, when we look at the AD subjects, the pGP model has the best MAE, but its MNLPD is quite poor. The pGPDE achieves a slightly higher MAE, but with a much lower MNLPD, so it can be more useful in real-world applications. All the models evaluated on the AD subjects have considerably larger MNLPD. This tells us that it is an extremely difficult task to predict accurately the scores of the AD subjects, where the changes in their individual scores vary a lot. We plan to investigate alternative strategies for tackling this in our future work.

The tGP model always achieves the lowest MNLPD, but has a relatively high MAE. This is because it makes predictions using a really small target dataset as its training set, so his predictive variance is almost always high. This model makes mistakes often, but it isn't certain in those predictions so the MNLPD doesn't penalize that. Looking only at the MNLPD this model could be declared as the best, but it isn't because

TABLE I

THIS TABLE PRESENTS THE LEAVE-ONE-SUBJECT-OUT VALIDATION RESULTS OF ALL THE MODELS. PERFORMANCE MEASURES WERE FIRST AVERAGED FOR EACH SUBJECT, AND THE MEAN VALUE OF THOSE MEASURES IS PRESENTED IN THIS TABLE ALONG WITH ONE STANDARD DEVIATION. THE METRICS ARE FIRST AVERAGED ON ALL THE SUBJECTS, THEN ON THE SUBJECTS FROM ALL OF THE THREE CLINICAL STATUS GROUPS. DATAPOINTS WITH THE MISSING VISIT y_{t+1} WERE DISCARDED FROM THE EVALUATION.

Models	**All subjects**		**CN subjects**		**MCI subjects**		**AD subjects**	
	MAE	**MNLPD**	**MAE**	**MNLPD**	**MAE**	**MNLPD**	**MAE**	**MNLPD**
sGP	4.01 ± 1.7	142.67 ± 227.54	2.96 ± 1.14	72.9 ± 75.18	3.53 ± 0.99	82.8 ± 55.83	4.82 ± 1.85	212.68 ± 306.13
pGP	$\mathbf{3.77 \pm 1.61}$	145.21 ± 229.42	2.75 ± 1.08	74.60 ± 76.65	3.28 ± 0.84	84.71 ± 56.45	$\mathbf{4.57 \pm 1.76}$	216.02 ± 308.44
tGP	4.32 ± 2.44	5.4 ± 4.81	$\mathbf{2.41 \pm 0.8}$	$\mathbf{2.77 \pm 0.45}$	3.34 ± 0.91	3.34 ± 0.85	5.87 ± 2.61	7.93 ± 5.95
GPDE	3.92 ± 1.94	$\mathbf{29.71 \pm 41.88}$	2.75 ± 1.02	15.44 ± 13.25	$\mathbf{3.08 \pm 0.87}$	$\mathbf{15.45 \pm 10.1}$	5.01 ± 2.15	$\mathbf{45.16 \pm 55.19}$
pGPDE	$\mathbf{3.79 \pm 1.83}$	$\mathbf{30.79 \pm 43.11}$	2.6 ± 1	16.02 ± 13.77	$\mathbf{3.07 \pm 0.86}$	$\mathbf{16.27 \pm 10.46}$	4.82 ± 1.99	$\mathbf{46.65 \pm 56.81}$

TABLE II

AVERAGE TRAINING TIME, ALONG WITH ONE STANDARD DEVIATION, FOR MODELS THAT USE THE WHOLE SOURCE SET VERSUS EXPERT MODELS THAT USE THE SOURCE SUBGROUPS (CN, MCI, AD). THIS IS OBTAINED BY THE LEAVE-ONE-SUBJECT-OUT VALIDATION PROCEDURE.

Models	**Average training time**
Single expert models (sGP, pGP, tGP)	54.78 ± 2.72s
Domain expert models (GPDE, pGPDE)	17.5 ± 0.94s

it is very often uncertain in his predictions, while also having a relatively high error.

The average training time during the leave-one-out validation is shown in II. We can see that the expert models, GPDE and pGPDE, which break the source dataset of size N into three subgroups ($\sim \mathcal{O}\left(3(\frac{N}{3})^3\right)$ complexity), need considerably less time to learn the hyper-parameters than other models that learn hyper-parameters on the whole source dataset ($\mathcal{O}(N^3)$ complexity). In this article we used a relatively small cohort of 100 subjects. In practical application, the cohort could be much larger and the difference in the training times could be much bigger. Also, if the datasets were too big for matrix inversions and storage, using the GP experts could make the problem more computationally tractable.

IV. CONCLUSION

We proposed using the GPDE and pGPDE models for predicting a subject's next visit ADAS-Cog13 cognitive score, with the current score and current genetic, demographic, DTI, MRI and CSF features as inputs to the models. We compared their results with the standard and domain adaptive GP models which were used on the same dataset in previous research [2], [8]. We show that the expert models tend to be more confident in more accurate point estimates and less confident in less accurate point estimates than the previously proposed domain adaptive GPs that employ a single expert (learn using the whole training population data), while achieving a relatively good mean absolute error. Also, we show that the expert models have a clear advantage in terms of the required training time and point out that this would have a much larger impact in practical settings, where the datasets would be much larger.

Estimacija trajektorije i kinematičkih parametara pasivnom monosenzornom kamerom

Marko Antonijević, Filip Ilić, *Vojna Akademija, Univerzitet Odbrane, Beograd*

***Apstrakt*— U ovom radu je analizirana procena daljine i kinematičkih parametara cilja na osnovu površine cilja, koja je izdvojena osnovnim metodama obrade slike. Korišćeni su rezultati eksperimenta u kojima je simulirano kretanje cilja. Model Sistema za pasivnu osmatranje i praćenje činili su VC-C50i kamera i PC računar. Za digitalnu obradu slike korišćen je MATLAB softver. Dobijeni rezultati prikazuju trajektoriju i osnovne kinematičke parametre cilja kao što su pozicija, brzina i ugaona brzina.**

***Ključne reči*—Estimacija trajektorije, praćenje cilja, upravljanje kamerom, estimacija kinematičkih parametara**

I. UVOD

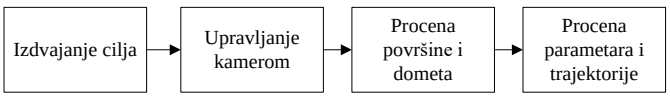
Sistemi sa pasivnim senzorima imaju mnoge primene, najčešće za video nadzor, bezbednost, kontrolu vazdušnog prostora, navođenje raketa, u robotici. Zbog povećane upotrebe bespilotnih letelica ,dronova i drugih letelica male brzine u vojne svrhe,njihova detekcija konvencionalnim radarskim sistemima je otežana. Sistemi sa pasivnim pasivnim senzorima u ovim primenama je pogotovo izražena, a najviše u sistemima za proenu daljine i praćenje. Druga važna prednost primene sistema sa pasivnim senzorom u vojne svrhe je što tokom osmatranja ne emituju zračenje tako da ne odaju položaj i time pružaju bezbednost operaterima.

Rad [1] analizira procenu daljine bespilotne letelice, a radovi [2,3] pokazuju procenu daljine digitalnom obradom slike. Takođe, čest problem koji se rešava pasivnim monosenzornim sistemima je procena daljine u robotici [4].

Cilj ovog rada je da se na temelju znanja iz obrade slike pokaže moderan algoritam za obradu slike i procenu daljine, a da se zatim to znanje potkrepi eksperimentalnim rezultatima dobijenim kontrolisanom kamerom

II. BLOK DIJAGRAM SISTEMA

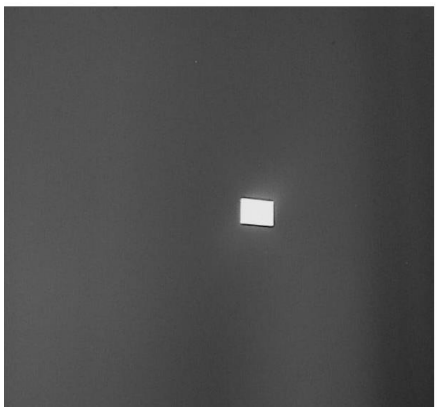
Sistem za praćenje sa video senzorom može se opisati blok šemom sa slike 1. Prvi blok služi za obradu slike koja odvaja cilj od okruženja u svakom frejmu. Drugi blok služi za kontrolu step motora kamere na osnovu pozicije cilja na slici. Tu se računaju pomeraji uglova kamere i komunicira sa kamerom. Sledeći blok procenjuje daljinu na osnovu površine cilja. Poslednji blok iscrtava trajektoriju clja i daje informacju o kinematičkim i drugim značajnim parametrima cilja .



Slika 1. Blok šema sistema

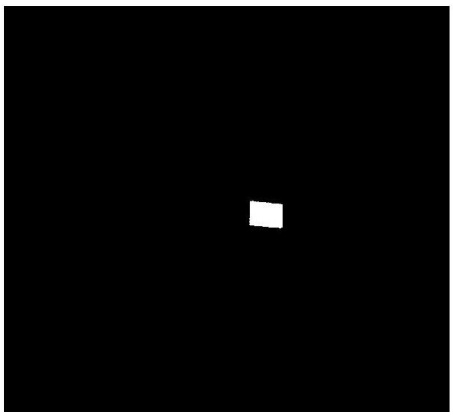
III. BLOK ZA IZDVAJANJE CIJJA

Da bi se izračunala trajektorija cilja prvo je potrebno da se cilj odvoji od okoline. Početna slika sadrži cilj sa okruženjem (Slika 2.).



Slika 2. Cilj sa okruženjem

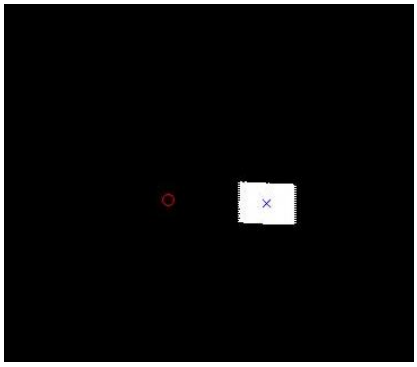
Slika se zatim obrađuje Kapur metodom. Ova metoda izračunava prag . Time se vrši binarizacija slike i svi pikseli koji su prešli izračunati prag dodeljuju se cilju.



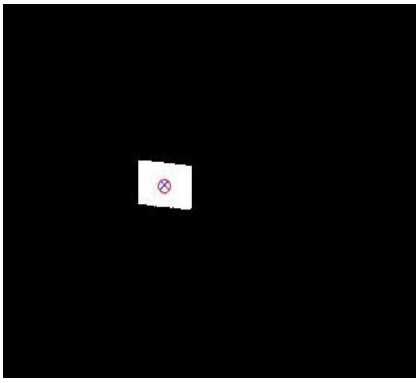
Slika 3. Cilj nakon binarizacije

IV. BLOK ZA KONTROLU KAMERE

Kada se cilj izdvoji računa se njegov centar.U svakom frejmu računa se daljina u pikselima između centra cilja i centra slike. Ta razlika se zatim pretvara u u uglove po azimutu i elevaciji. Izračunati uglovi se pretvaraju u ASCII kod koji predstavlja pomeraje step motora koji kontrolišu kameru. VC-C50i kamera sa računarom komunicira preko serijskog porta. Centar cilja i centar kamere se zatim poravnavaju u svakom frejmu i kamera prati cilj (slika 4, 5)



Slika 4. Cilj je detektovan



Slika 5. Cilj je centriran

Step motori korišćene kamere dozvoljavaju maksimalni pomeraj od +/− 90° po azimutu i +/− 10° po elevaciji. Takođe maksimalna brzina okretanja kamere je 90°/s što može predstavljati problem ako se cilj kreće brže ili izvan zadatih granica.

V. BLOK PROCENU POVRŠINE I DALJINE

Kada je cilj izdvojen i centriran moguće je izračunati površinu cilja a na osnovu površine proceniti daljinu do cilja .Korišćene metode date su u [5-8]. Matematička relacija koja opisuje zavisnost površine i daljine je:

$$D_e(k) = D_0\sqrt{\frac{S_0}{S_e(k)}}. \qquad (1)$$

gde su: $D_e(k)$ procenjena daljina do cilja, $S_e(k)$ procenjena površina cilja na k-toj slici, a D_0 i S_0 daljina do cilja i površina na prvoj slici. Što znači da je za estimaciju potebno poznavati unapred samo daljinu od cilja u početnom trenutku.

VI. BLOK ZA PROCENU TRAJEKTORIJE I KINEMATIČKIH PARAMETARA CILJA

Koriseteći procenjenu daljinu i poznate uglove azimuta i elevacije koje kamera vraća u svakom frejmu moguće je estimirati i iscrtati trajektoriju.Koriste se poznate relacije iz fizike:

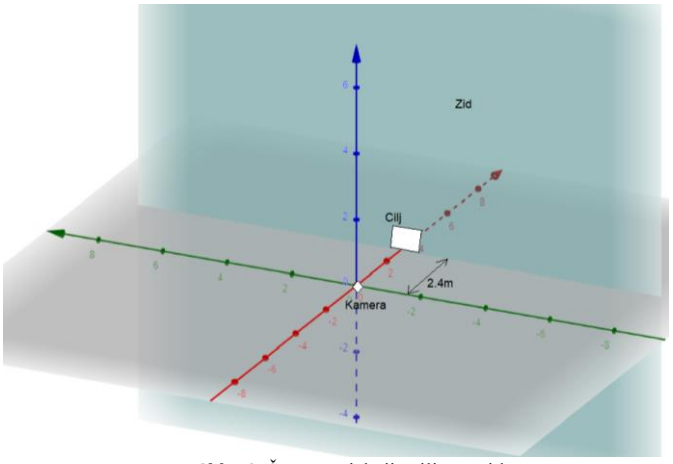
$$v_x = \frac{dx(t)}{dt}, v_y = \frac{dy(t)}{dt}, v_z = \frac{dz(t)}{dt}. \qquad (2)$$

$$\omega_a = \frac{d\varphi(t)}{dt}, \omega_e = \frac{d\phi(t)}{dt}. \qquad (3)$$

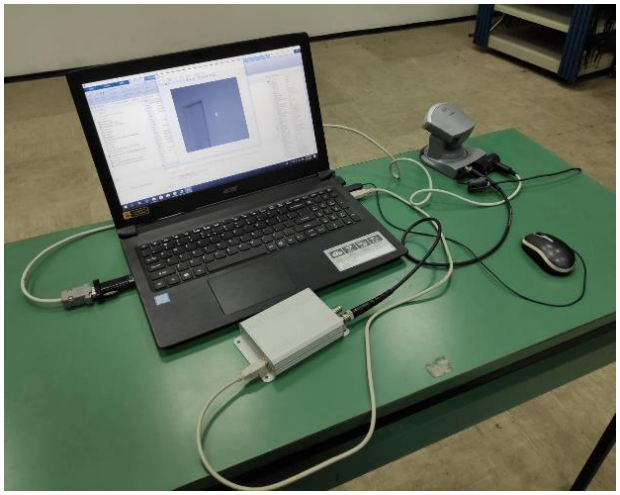
Pri čemu su v_x, v_y i v_z komponente linijske brzine, φ ugao azimuta , ϕ ugao elevacije ,a ω_a i ω_e ugaone brzine azimuta i elevacije respektivno.Na osnovu relacija (2,3) moguće je proceniti osnovne kinematičke parametre cilja kao što su linijska i ugaona brzina.

VII. POSTAVKA EKSPERIMENTA

Cilj je u ovom eksperimentu bio je pravougaonik projektovan na zid (slika 6.) čije je rastojanje od kamera unapred izračunato.Kamera je priključena na računar preko COM porta i komunicirala je RS-232 komunikacijom sa zadatkom da prati cilj (slika 7.), dok se na računaru obrađuje slika. Cilj se kretao po zadatoj trajektoriji.



Slika 6. Šema projekcije cilja na zid

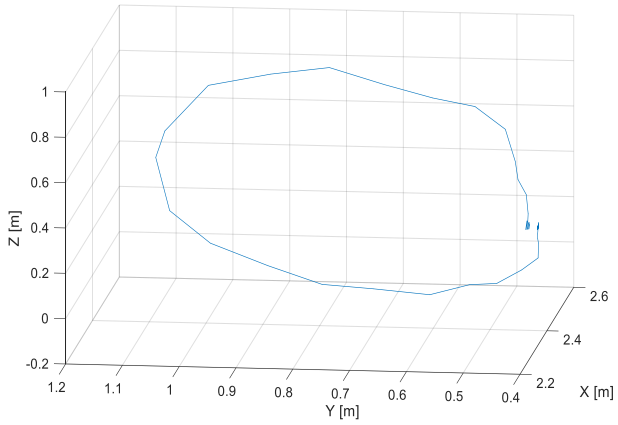


Slika 7. Kamera povezana sa računarom na kome se vrši obrada slike

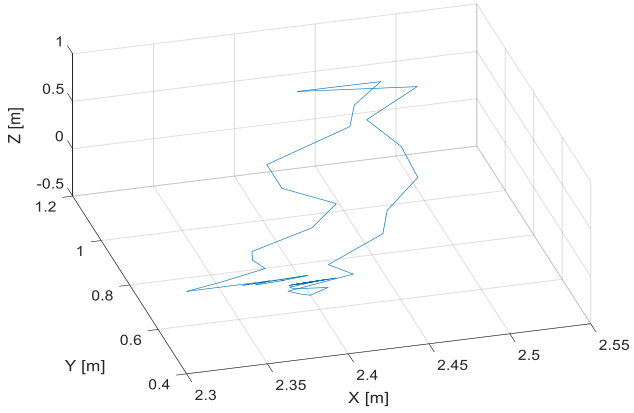
Korišćene su dve vrste trajektorija. Prvu vrstu su činile kružna i trougaona trajektorija sa ciljem da se na osnovnim trajektorijama kao što su gore navedene izračuna greška koju kamera pravi u proceni daljine do cilja. Druga vrsta trajektorija je bila iscrtana slobodnom rukom sa ciljem da se simulira let cilja što verniji realističnoj situaciji.

VIII. REZULTATI PROCENE TRAJEKTORIJE

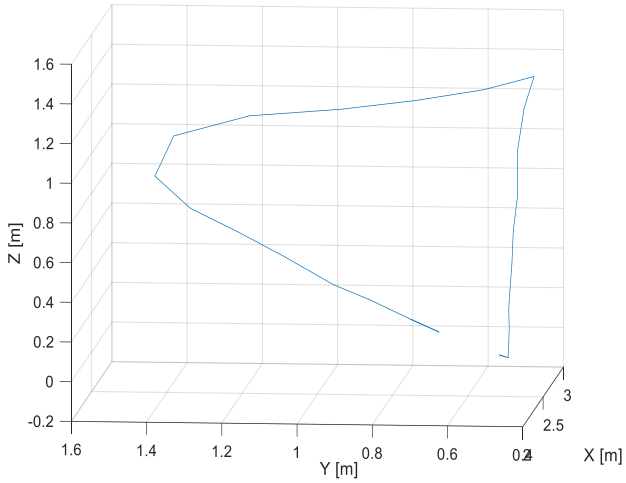
Merenjem kamerom dobijeni su sledeći rezultati za procenu trajektorije:



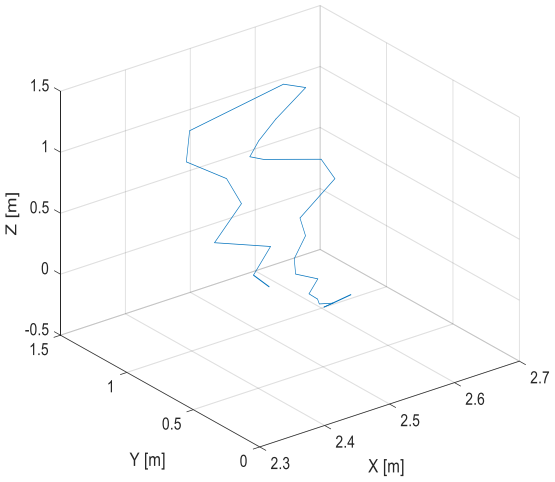
Slika 8. Kružna trajektorija (pogled iz ugla kamere)



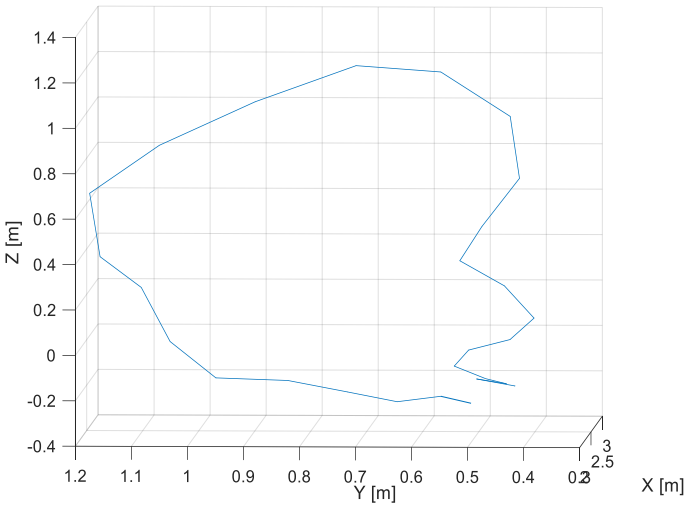
Slika 9. Kružna trajektorija (pogled sa strane)



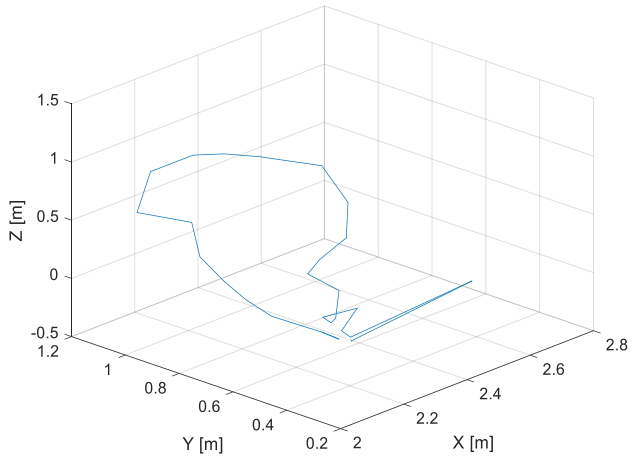
Slika 10. Trougaona trajektorija (pogled iz ugla kamere)



Slika 11. Trougaona trajektorija (pogled sa strane)



Slika 12. Trajektorija nacrtana slobodnom rukom (iz ugla kamere)

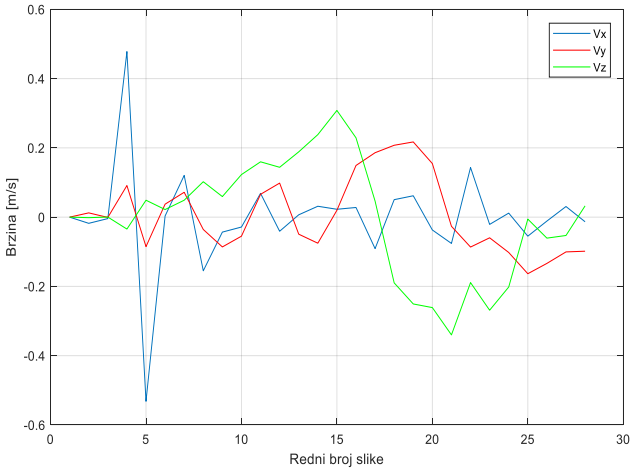


Slika 13. Trajektorija nacrtana slobodnom rukom (pogled sa strane)

Sa slika (8-13) uočava se da postoji greška u proceni trajektroije. Grafik priakzuje kretanje i po x-osi iako ono postoji samo u yOz ravni.Ovo je posledica nemogućnosti kamere da trenutno izoštri sliku. Zato što je cilj zamućen pravi se procena površine cilja, a samim tim i greška procene daljine. Ova greška raste sa porastom brzine cilja ,a manja je ukoliko je cilj dalje od kamere. Greška proocenene ne prelazi 6.4% za trougaonu i kružnu trajektroiju ,a 4.8% za trajektoriju nacrtanu slobodnom rukom što je prihvatljivo.

IX. PROCENJENI KINEMATIČKI PARAMETRI

S obzirom da imamo poznatu poziciju cilja u svakom trenutku, možemo odrediti brzinu i koristeći (2-6). Razmatrana je samo trajektorija crtana slobodnom rukom zato što za tu trajektoriju kretanje cilja najviše odgovara realističnom. Dobijeni su sledeći rezultati:

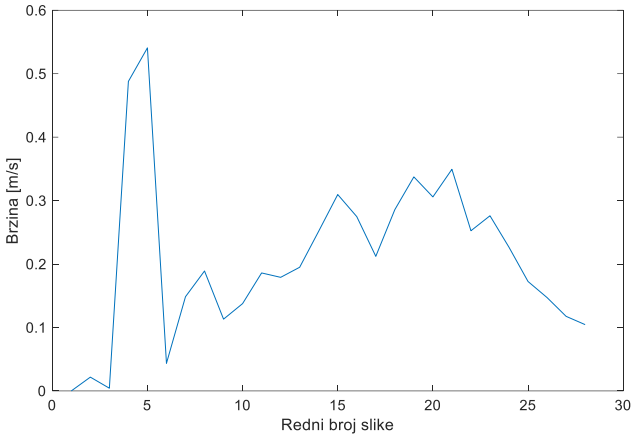


Slika 14. Promena komponenti linijske brzine po svakoj od koordinata

Kada su poznate komponente brzine linijsku brzinu moguće je odrediti prema formuli:

$$v = \sqrt{v_x^{\,2} + v_y^{\,2} + v_z^{\,2}}\,. \tag{7}$$

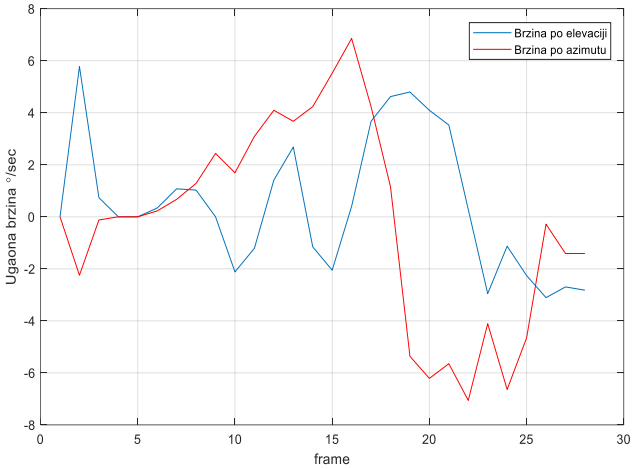
Dobijeni su rezultati:



Slika 15. Promena linijske brzine

Sa slika 14 i 15 može se primetiti da veliki skok brzine po x-osi , uzrokovan lošom procene daljine, izazvao i skok linijske brzine u 4 i 5 frejmu. U narednim frejmovima greška se smanjuje, rad kamere je pravilniji i brzina se kreće oko srednje vrednosti od 2.8 m/s bez značajnijih odstupanja.

Kamera u svakom trenutku vraća i vrednosti uglova na osnovu kojih se procenjuje ugaona brzina:

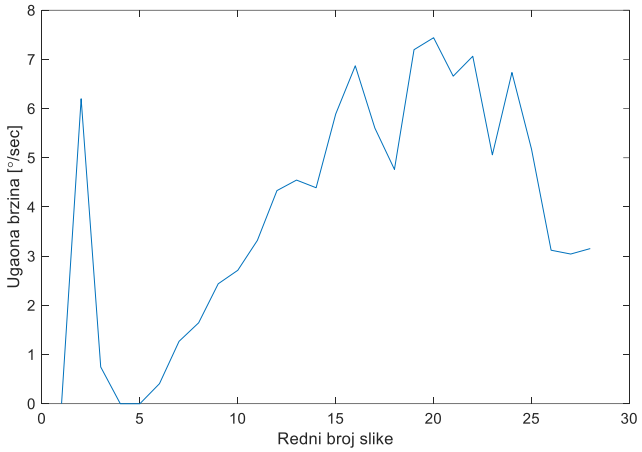


Slika 16. Promena komponenti ugaone brzine

Na osnovu vrednosti komponenti moguće je izračunati vredost ugaone brzine koristeći relaciju:

$$w = \sqrt{w_e^{\,2} + w_a^{\,2}}\,. \tag{8}$$

Dobijene vredosti ugaone brzine su:



Slika 17. Promena ugaone brzine

Ugaona brzina ima veliki skok samo između 2 i 4 frejma kada cilj pravi najbrži manevar. Uglovi na osnovu kojih je izračunata ugaona brzina dobijaju se sa kamere i ne zavise od obrade slike. Poređenjem slike 17. sa slikom 15. dolazi se do zaključka da je veliki skok u 4 i 5 frejmu zaista posledica pogrešne procene daljine.

X. ZAKLJUČAK

Ovim radom eksperimentalno je pokazano da je moguće uspešno detektocati i pratiti cilj koristeći VC-C50i kameru, računar i softverski paket MATLAB. Praćenje kamere je funkcionisalo na osnovu obrade slike i računanju razlike centra slike i centra cilja. Obrada slike omogućavala procenu daljine, samim tim i računanje kinematičkih parametara. Procenjena daljina omogućava proračun trajektorije cilja ,a izračunati parametri omogućavaju klasifikaciju ciljeva prema brzini.

U budućim radovima biće implementiran i Klamanov filtar koji omogućuje predikciju kretanja cilja i povećava tačnost estimacije trajektorije i parametara.

ABSTRACT

In this paper distance and kinematic parameter estimation based on the area of the target which has been extracted using basic image processing methods has been analyzed. The results from the experiment designed to simulate target movement were used. The model for target tracking was made of the controlled camera, VC-C50i and a personal computer. The results show the calculated trajectory and basic kinematic parameters such as speed and angular speed.

Trajectory and kinematic parameter estimation using passive monosensor camera

Marko Antonijević, Filip Ilić

Analiza kvaliteta estimacije u sistemu za praćenje više ciljeva sa video senzorom u zavisnosti od šuma merenja

Filip Ilić, Marko Antonijević, *Vojna Akademija, Univerzitet Odbrane, Beograd*

***Apstrakt*—U ovom radu je izvršena višestruka analiza kvaliteta estimacije u sistemu za praćenje više ciljeva. Sistem za praćenje više ciljeva sadrži senzor slike na osnovu kojeg su formiranja merenja. Gausov šum merenja različitih vrednosti varijansi je dodat generisanim trajektorijama četiri bliska cilja. Upoređeni su rezultati procene pozicije ciljeva na slici u zavisnosti od primene algoritama za pridruživanje podataka: globalno najbliži sused, najboljih *n* rešenja i Munkresov algoritam. Druga analiza je izvršena kroz uticaj proračuna ukupne estimacije stanja, dobijena na osnovu težinskih koeficijenata u interaktivnom višestrukom modelu za estimaciju.**

***Ključne reči*— Pridruživanje podataka; Praćenje više ciljeva; Video senzor; Estimacija.**

I. UVOD

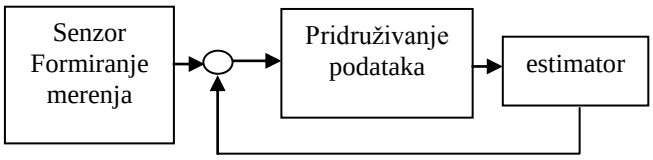
Kada se prikupljaju podaci sa nekog senzora, veoma je bitno imati na umu greške koje taj sensor unosi prilikom merenja. Unešene greške tokom merenja mogu dovesti do toga da obrađeni rezultati budu neupotrebljivi u određene svrhe. Shodno tome treba ispitati do kojih granica i pod kojim uslovima su greške dozvoljene a da rezultati budu merodavni.

Današnji sistemi, čiji su osnovni zadaci praćenje više ciljeva, su veoma rasprostranjeni. Njihova kompleksnost se sastoji u složenim matematičkim algoritmima i operacijama, koje su potrebne u cilju što kvalitetnije procene obeležja ciljeva koji se prate, neki od njih su dati u [1]. Najpre se treba fokusirati na senzor koji formira merenje na osnovu kojeg se može govoriti o sistemima sa pasivnim ili aktivnim senzorima koji su opisani u [2]. Sistemi sa aktivnim senzorima, često imaju male šumove merenja što ima za posledicu nižu grešku procene. S druge strane, sistemi za praćenje sa pasivnim senzorima su u prednosti jer je teško odrediti njihovu lokaciju, ali su metode za procenu često nelinearne i kompleksne. Drugi bitan blok ovakvih sistema je estimator. Kada se govori o linearnim modelima procesa koristi se optimalni estimator, a to je Kalmanov filter, dok se u nelinearnim procesima upotrebljeva prošireni Kalmanov filter, čestični filter ili neki od adaptivnih algoritama estimacije koji su predloženi u [3].
Problem opisanih sistema je dodatno usložen ukoliko se razmatra problem pridruživanja podataka sto je predstavljeno u [4]. Estimator ima osnovnu ulogu da proceni stanja slučajnog procesa, odnosno kada se govori o sistemima za praćenje tada je uloga u proceni položaja cilja koji se prati. Informacije koje su potrebne estimatoru su merenje i prethodna estimacija kako bi formirao novu procenu. Sada se može videti problem koji nastaje u sistemima za praćenje više ciljeva a to je odluka o dodeljivanju merenja prethodno formiranim procenama. Kvalitet odluke o dodeljivanju merenja značajno utiče ne samo na kvalitet procene već i na to da li će se procenjeni ciljevi međusobno zameniti u daljoj obradi.

Kao što je navedeno u [5], kvalitet odluke između ostalog zavisi od šuma procesa merenja. U ovom radu smo pronašli granice do kojih šum procesa merenja može da varira kako bi dao merodavne rezultate. Osnovni kriterijum procene je srednja kvadratna greška.

II. SISTEM ZA PRAĆENJE VIŠE CILJEVA

Sistem za praćenje više ciljeva je složen sistem, koji se sastoji od nekoliko blokova. Opšta blok šema sistema se može predstaviti kao na slici 1.



Sl. 1. Opšta šema sistema za praćenje više ciljeva.

A. Blok za formiranje merenja

Blok za formiranje merenja ima osnovnu ulogu da obradi prikupljene podatke i generiše informacije o cilju koji se prati. Navedeni blok može da sadrži jedan ili više aktivnih ili pasivnih senzora. U ovom radu je fokus na video senzoru, i odabrana je kamera VC-C50i u toj ulozi. Kvalitet sistema za praćenje umnogome zavisi i od kvaliteta senzora kao i od drugih blokova, ali u ovom radu je izvršena jedna od analiza a to je uticaj šuma merenja. Analiza se zasniva na proceni kinematičkih stanja cilja u zavisnosti od dodatog Gausovog šuma generisanim trajektorijama, čime je modelovan šum merenja senzora.

Kamera snima scenario koji je generisan i objašnjen u daljem tekstu. Sa senzora prikupljamo podatke u vidu slike koju konvertujemo u sive slike, a zatim primenjujemo Kittlerovu metodu za određivanje adaptivnog praga inteziteta sive slike kao što je opisano u [6].

B. Blok za estimaciju

U modernim sistemima za praćenje više ciljeva obično se koristi nekoliko Kalmanovih filtera sa različitim modelima kretanja ciljeva koji rade paralelno. Najpoznatiji i danas najviše primenjivan je interaktivni višestruki model (IMM), koji daje dobre rezultate posebno za praćenje ciljeva koji prave složene manevre. IMM algoritam je metoda za kombinovanje stanja hipoteze iz više modela filtera kako bi se poboljšala procena stanja ciljeva sa promenljivom dinamikom kretanja. Osnove IMM algoritma su date u [7], gde je detaljno opisan rad navedenog modela ali i njegove prednosti u odnosu na jednostruke klasične modele.

Blok za estimaciju se sastoji iz algoritma sa interaktivnim višestrukim modelima. IMM algoritam je realizovan pomoću dva Kalmanova filtera u paraleli, prvi je model kretanja sa manjim manevrom a drugi model kretanja sa oštrijim manevrom. Jedan od problema koji se rešava primenom IMM algoritma je proračun estimacije kinematičkih stanja. Međutim kako se za svaki od modela takođe proračunavaju težinski koeficijenti, tako se oni mogu iskoristiti u bloku za pridruživanje podataka. Dakle, formiranje estimacija za svaki model se koristi u bloku za pridruživanje podataka da bi se izračunala statistička distanca, a zatim uz primenu težinskih koeficijenata dobija se konačna statistička distanca. Ovo se može uraditi na dva načina i to je takođe bila analiza u ovom radu. Prvi metod se naziva kumulativni metod i izračunava se prema sledećem izrazu:

$$d^2(k) = \sum_{i=1}^{r} \mu_i d_i^2(k), \tag{1}$$

gde su μ_i verovatnoća i -tog modela i $d_i^2(k)$ distanca u k-tom trenutku i -tog modela.

Drugi metod se zasniva na određivanju konačne statističke distance na osnovu maksimalne vrednosti težinskih koeficijenata IMM algoritma:

$$d^2(k) = d_i^2(k), \text{gde je } i \text{ za koje je } \max_{i=1,\ldots,r}(\mu_i). \tag{2}$$

Za praćenje ciljeva odabran je model konstantnog kretanja (*Constant Velocity* - CV) sa dva stanja po x i y koordinati i njihovim brzinama, tako da je ukupan vektor stanja definisan kao:

$$X = \begin{bmatrix} x & \dot{x} & y & \dot{y} \end{bmatrix}. \tag{3}$$

Polazeći od dinamičkih jednačina stanja, koje se mogu modelovati izrazom:

$$X(k+1) = F(k)X(k) + G(k)v(k), \tag{4}$$

i jednačine merenja koja je data kao:

$$Y_j(k) = H(k)X(k) + w(k),\ j = 1, 2, \ldots, m(k). \tag{5}$$

Pri čemu je:

$X(k)$ – vektor stanja cilja u k-tom skenu,

$Y_j(k)$ – j-ta opservacija koja je primljena u k-tom skenu,

$F(k)$ – Tranziciona matrica (matrica prelaza iz stanja u stanje),

$H(k)$ – matrica merenja (opservacija),

$v(k)$ – šum procesa,

$w(k)$ – šum merenja, tj. nekorelisani beli Gausov šum sa poznatom kovarijacionom matricom R,

$G(k)$ – matrica šuma procesa $v(k)$,

$m(k)$ – broj merenja pristiglih u k-tom skenu.

Matrice prelaza stanja i uticaja šuma procesa na vektor stanja za oba modela su:

$$F_1 = F_2 = \begin{bmatrix} 1 & T & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & T \\ 0 & 0 & 0 & 1 \end{bmatrix}; G_1 = G_2 = \begin{bmatrix} \frac{T^2}{2} & 0 \\ T & 0 \\ 0 & \frac{T^2}{2} \\ 0 & T \end{bmatrix}. \tag{6}$$

Gde je sa T označena perioda skeniranja. Kovarijaciona matrica šuma procesa i merenja su:

$$Q^j = \sigma_j^2 \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}; H = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}, j = 1, 2. \tag{7}$$

Gde σ_j^2 predstavlja varijanse šumova procesa i iznose $\sigma_1^2 = 1^2\ piksel/s^2$ i $\sigma_2^2 = 5^2\ piksel/s^2$.

IMM algoritam je projektovan sa sledećim verovatnoćama za prelazak na novi model:

$p_{11} = 0.95, p_{12} = 0.05, p_{22} = 0.1, p_{21} = 0.9$.

C. Blok za pridruživanje podataka

Sledeći blok je blok za pridruživanje podataka, koji se koristi nakon formiranih merenja, a nakon što su izvršene procene stanja ciljeva u prethodnom diskretnom trenutku. U ovom blok su implementiraju matematički metode za pridruživanje podataka i u ovom radu su odabrane globalno najbliži sused (*Global Nearest Neighbour* - GNN), najboljih *n* rešenja i Munkresov algoritam.

1) GNN

Kada se odrede distance matrice asocijacije, GNN algoritam postupa po sledećim pravilima:

- Dodeliti opservaciju tragu, ako je jedina u prozoru tog traga
- Dodeliti trag opservaciji, ako prozor tog traga obuhvata jednu opservaciju
- Dodeliti *j*-tu opservaciju *i*-tom tragu, čija je distanca najmanja u matrici asocijacije

Neke od primene ovog algoritma su date u [8].

2) Najboljih n rešenja

Algoritam određuje sve moguće dodele na osnovu distanci iz matrice asocijacije. Zatim sortira sve moguće dodele po kritrijumu minimalne distance i uzima u obzir *n* najboljih dodela.

3) Munkresov algoritam

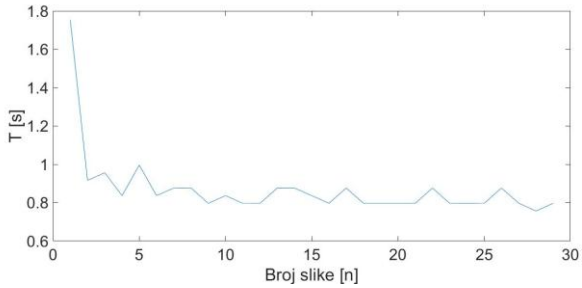
Algoritam se zasniva na obradi matrice asocijacije čiji su elementi distance. Princip rada algoritma je opisan u [9], neke od primena algoritma se mogu naći u [10].

III. REZULTATI

Ovo poglavlje će biti podeljeno u tri celine. Prva celina je opis generisanog scenarija i formiranje merenja video senzorom, dok druga i treća celina sadrže objašnjenja, prikaz i komentare rezultata estimacija na osnovu izvršenih analiza i implementacija.

A. Opis generisanih trajektorija

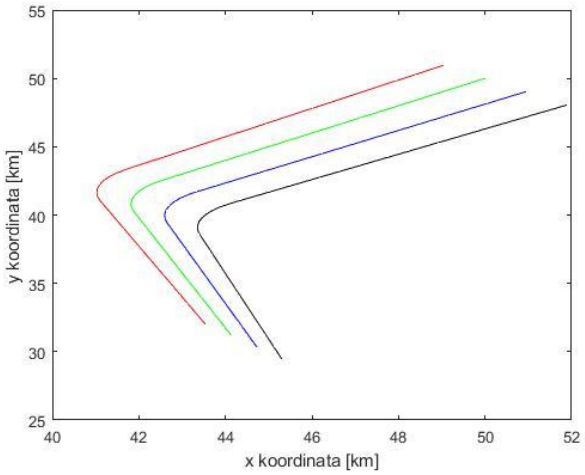
U ovom radu je generisan scenario koji sadrži trajektorije 4 cilja. Vrednost periode diskretizacije je usvojena na osnovu diskretnih vremenskih trenutaka koji su dobijeni pri preuzimanju slike sa video senzora, čije vrednosti su date na Sl. 2.



Sl. 2. Vrednost periode diskretizacije

Na osnovu prikazanih vrednosti prvih 30 slika koje se dobijaju sa kamere, može se usvojiti srednja vrednost i ona iznosi T= 0.9 s. Naravno mora se napomenuti da će se usvajanjem konstantne vrednosti za periodu diskretizacije uticati na kvalitet estimacije, ali obzirom da su merenja zašumljenja, navedeni uticaj neće doći do izražaja.

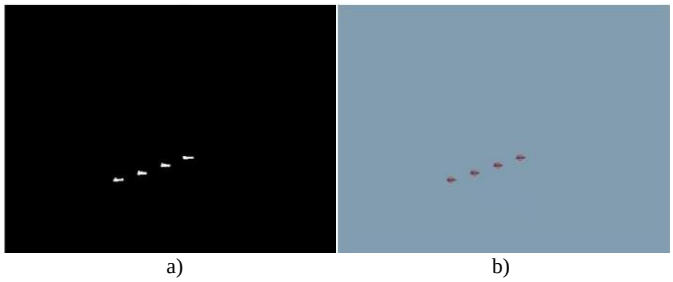
Referentne trajektorije su definisane na osnovu [2], gde su formirana 4 cilja sa brzinom kretanja od V=311 m/s, pri čemu su vršeni manevri inteziteta od 4g u periodu od 38·T do 42·T, pri čemu je ukupno trajanje od 72·T, Sl. 3.



Sl. 3. Trajektorije ciljeva

Ovako definisane trajektorije su prikazane u ravni prostora dimenzija [40 km – 52 km] × [25 km – 55 km] i projektovane na platno, tako da video senzor VC-C50i vidi kompletan prostor i na taj način se konvertuje u sliku dimenzija 704×576 piksela.

Slike koje se dobijaju sa video senzora se konvertuju u sive slike a zatim po Kittlerovoj metodi određen je prag inteziteta sive slike nakon čega se slika binarizuje tako što svaki piksel čiji je intezitet ispod praga dobija vrednost 0, dok pikseli čiji su inteziteti veći od praga dobijaju vrednost 1, kao što je prikazano na slici 4. a). Na taj način se dobija maska pomoću koje se izdvajaju ciljevi i određuju se njihovi centroidi, Sl 4.b, koji predstavljaju koordinate ciljeva koje dalje obrađuje estimator. Obrada slike koja je pomenuta data je u [11].



a) b)

Sl. 4. a) Segmentacija slike primenom adaptivnog praga, b) Detektovani ciljevi i prikaz njihovih centroida.

Na osnovu formirana merenja sledi analiza uticaja varijanse šuma merenja i proračuna ukupne distance na kvalitet estimacije primenom različitih metoda za pridruživanje podataka.

B. Uticaj šuma merenja na kvalitet estimacije

Sistemi za praćenje pokretnih ciljeva koriste estimatore stanja u situacijama kada se prati jedan cilj. Međutim, proces praćenja se komplikuje kada se u gejtu posmatranog traga nađu dva ili više ciljeva kao što je objašnjeno u [12]. Tada je neophodno koristiti algoritme za pridruživanje podataka. Algoritmi za pridruživanje podataka, po pravilu, sadrže neki od filtera za estimaciju stanja. Na taj način moguće je

napraviti poređenje ovih algoritama sa stanovišta srednje kvadratne greške praćenja po poziciji.

Osnovni kriterijum za uporednu analizu bila je srednja kvadratna greška po poziciji (RMSE), koja se izračunava kao:

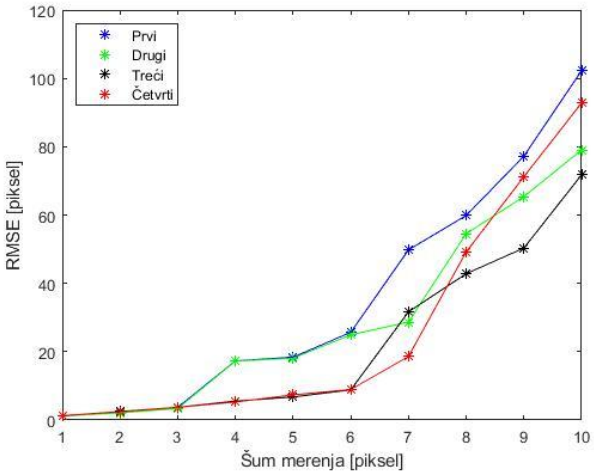
$$RMSE(k) = \sqrt{(x\ (k) - x_e(k))^2 + (y\ (k) - y_e(k))^2}\ , \qquad (8)$$

gde su x i y vrednosti koordinata cilja bez merenog šuma, dok su x_e i y_e estimacije po koordinatama u *k*-tom trenutku.

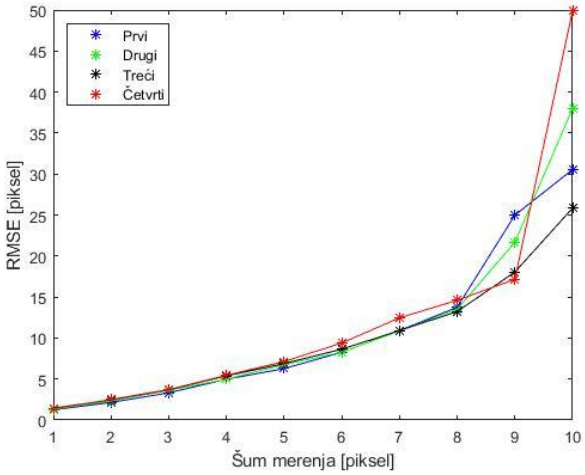
Kako je potrebno odrediti do kojih granica možemo verovati algoritmima za dodelu podataka, trajektorijama ciljeva dodat je šum merenja procesa sa Gausovom raspodelom sa nultom srednjom vrednosti. Standardna devijacija merenja σ_m varira od jednog piksela do 10 piksela × 10 piksela.

Na slici 5. prikazana je RMSE po poziciji sva četiri cilja u odnosu na prave pozicije, odnosno pozicije bez dodatog šuma u zavisnosti od šuma merenja koji varira. RMSE predstavlja srednju vrednost trenutnih grešaka tokom scenarija i izračunava se na sledeći način:

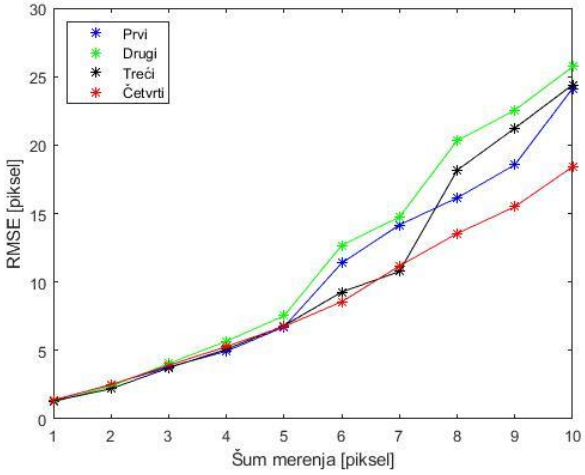
$$RMSE = n^{-1} \cdot \sum_{k=1}^{n} RMSE(k) \qquad (9)$$



a)



b)

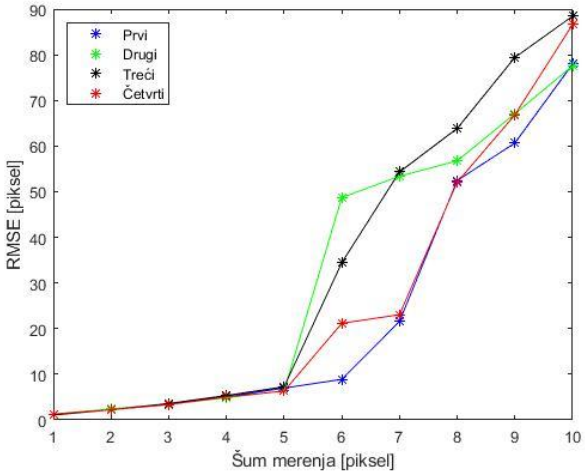


c)

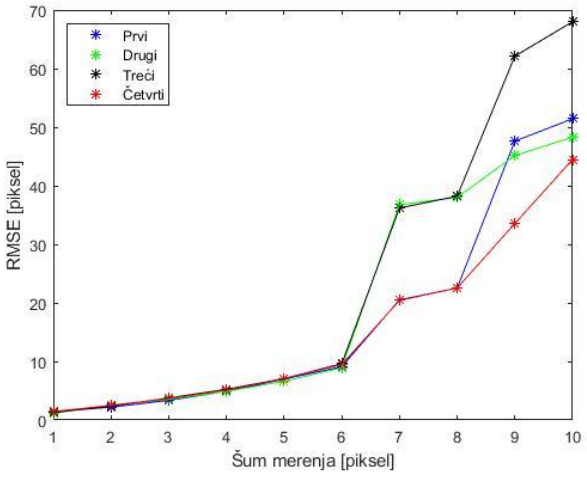
Sl. 5. RMSE a) primenom GNN, b) primenom najboljih *n* rešenja, c) primenom Munkres algoritma.

C. Uticaj proračuna ukupne statističke distance na kvalitet estimacije

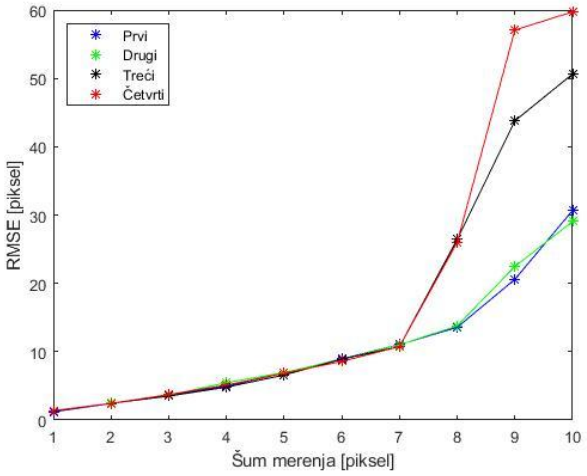
U ovom delu će biti razmatran i uticaj šuma na kvalitet estimacije ukoliko se primeni kumulativna metoda proračuna ukupne statističke distance, što je prikazano na slici 6.



a)



b)



c)

Sl. 5. RMSE kumulativnom metodom a) primenom GNN, b) primenom najboljih *n* rešenja, c) primenom Munkres algoritma.

IV. ZAKLJUČAK

Rezultati sa Sl. 5. i 6. prikazuju da sa povećanjem šuma merenja, povećava se i RMSE. Kada uporedimo rezultate jednostruke metode, vidimo da za GNN algoritam RMSE prvog i drugog cilja drastično raste sa 3 piksela na 20 za šum merenja od 4^2 piksela^2. Algoritam sa Najboljih *n* rešenja daje malo bolje rezultate. Kod njega RMSE raste linearno do šuma merenja od 8^2 piksela^2 nakon čega RMSE naglo raste. Najbolje rezultate daje Munkresov algoritam, gde RMSE raste linearno gde za vrednost varijanse šuma merenja od 10^2 piksela^2 i iznosi svega 30 piksela.

Što se tiče uporedne analize kumulativne metode vidimo da se nagli skokovi za algoritme GNN, Najboljih *n* rešenja i Munkres algoritma javljaju na varijanse šuma merenja od 5^2, 6^2 i 7^2 piksela^2, respektivno.

Na osnovu ove analize može se zaključiti da jednostruki metod daje nešto bolje rezultate od kumulativne metode kada su u pitanju veliki šumovi merenja. Za male šumove merenja, kumulativna metoda daje bolje rezultate jer je rast RMSE u odnosu na šum merenja linearan.

Ono što se još može zaključiti na osnovu komparativne analize, jeste da Munkresov algoritam daje najbolja rešenja i po jednoj i po drugoj metodi, stoga se preporučuje njegovo implementiranje u aplikacijama koje se bave praćenjem više ciljeva.

ABSTRACT

In this paper, the quality estimation in multiple target tracking system was analysed. Multiple target tracking system has a video sensor which is used for recording. Gauss noise of different variances was added to the generated trajectories of four imminent targets. The position estimation results were compared based on the algorithm that was used: Global nearest neighbor, N best solution and Munkres algorithm. The second analysis was made trough the influence of the calculation of the total estimation, that was calculated based on weight coefficients in interactive multiple model.

Analysis of the quality of the estimation in the multi target tracking system using one video sensor depending on the measurment noise

A 5 GHz Low-Noise Amplifier with Sliding Mode Based Phase Control Loop

Darko Mitić, *IEEE*, Goran Jovanović, Tatjana Nikolić and Dragan Antić, *Member, IEEE*

***Abstract*— The paper considers a tunable Low-Noise Amplifier (LNA) incorporating a phase loop with sliding mode control (SMC). Phase control loop forces a resonant frequency to be equal to an input signal frequency by tuning the amplifier resonant constituents. Thanks to the sliding mode control, LNA is robust to parameter perturbations in the full operating range, possesses maximum gain at the resonant frequency and attain input signal frequency faster. The 0.13 μm SiGe BiCMOS technology was used for LNA design and validation. LNA has ~30 dB gain, quality factor *Q* ~ 41 and resonant frequency from 5133 up to 5783 MHz.**

***Index Terms*— Low-Noise Amplifier, Self-tuning, Phase Control Loop, Resonant circuit, Sliding Mode Control.**

I. Introduction

Low-Noise Amplifier (LNA) is basically used in the receiving end of wireless communication system to amplify very weak received signal to the acceptable level with adding as little additional noise as possible and providing high linearity, sufficient gain, low power consumption and well defined resistive input impedance [1, 2]. With the aforementioned characteristics, LNA can be considered as band-pass filter as well.

The values of manufactured analog circuit components often differ from the design specifications because of process parameters, supply voltage, and temperature (PVT) variations, so that the practically obtained results are not optimal. In order to compensate frequency characteristic variations caused by these PVT perturbations, tunable filters, master-slave filter tuning schemes and self-tuning filters [3-6] are proposed in the literature. The latter approach, based on using of the phase loop with sliding mode control (SMC), is suggested in this paper.

Tunable selective amplifiers can be realized by using digitally controlled binary-weighted capacitor array, or current mirror array [4]. The frequency accuracy depends on the number of tuning bits used. Analog filters and selective amplifier are also adjusted by master–slave tuning schemes [5, 6] with a master-circuit designed as the voltage-controlled oscillator (VCO), and a slave filter built with identical integrators. By comparing the phases of input and output signals, it is possible to detect the mismatch of LNA characteristics [7]. To obtain the desired phase transfer function, self-tuning filters use the estimated phase error as correction factor and a phase control loop similar to one used in tuning oscillators with phase locked loop (PLL), or delay lines with delay locked loop (DLL) [8, 9].

In this paper, we propose cascade common source LNA with a sliding mode based phase control loop forming a self-tuning LNA (STLNA) with SMC. STLNA with SMC has a defined phase shift at resonant frequency, so the phase comparison of input and output signals detects amplifier characteristics mismatch. The phase loop with SMC utilizes a phase shift value to adjust LNA to maximal gain by using MOS varicap for frequency tuning. STLNA with SMC will be always tuned to the input signal frequency even in the presence of parameter variations, and will have the maximal gain at input signal frequency, acting as a selective amplifier in a wide frequency range. The similar sliding mode based phase control loop is considered for design of phase-synchronizer in [10].

The paper is organized as follows. Section II concentrates on realization of the tunable LNA. The structure of STLNA with sliding mode based phase control loop is defined and described in the Section III. Simulation results are shown in Section IV and the example of STLNA application is presented in Section V. Section VI contains some concluding remarks.

II. A Tunable Narrowband Low-Noise Amplifier

The LNA schematic is based on the inductively degenerated common source LNA topology [11] and it is shown in Fig. 1. It consists of two MOS transistors, M_1 and M_2, where M_1 operate as common-source. The inductor L_{pr} is connected to a DC biasing node. To decrease the Miller effect for LNA that strongly limits its frequency characteristics and provides poor reverse isolation, the transistor M_2 operates in common-gate mode. Thanks to two active elements, M_1 and M_2, a high LNA gain is obtained.

The output load is implemented as resonant circuit consisting of L_1, C_1 and MVaricap. The voltage drop over the load is lower than the drop over a resistive load of the same impedance. This solution provides correct circuit operation at lower power supply voltage level (V_{dd} = 1.8 V), and has lower power dissipation.

MVaricap element corresponds to the voltage controlled capacitor. In IHP BiCMOS technology, it is implemented as a modified PMOS transistor [12]. By controlling polarization voltage of a N-well, the capacitance between gate and channel of PMOS transistor varies. The value of a control voltage, V_{ctrl}, determines a capacitance of MVaricap element [12]

$$C_{MVar} = \frac{C^*_{MVar}}{\sqrt{1+V_{ctrl}/V_\rho}}, \quad (1)$$

All authors are with the Faculty of Electronic Engineering, University of Niš, 14 Aleksandra Medvedeva, 18000 Niš, Serbia (e-mail: {darko.mitic, goran.jovanovic, tatjana.nikolic, dragan.antic}@elfak.ni.ac.rs).

and the resonant frequency f_r is given by

$$f_r = \frac{1}{2\pi\sqrt{L_1(C_1 + C_{MVar})}}. \quad (2)$$

The dynamic impedance of a resonant circuits, at f_r, is very high so that the LNA has very high gain, as well. The phase shift of LNA is

$$\theta = -180^o - \text{atan}\left(2Q\frac{f_s - f_r}{f_r}\right), \quad (3)$$

where f_s is a frequency of input signal V_{in} and Q is a quality factor.

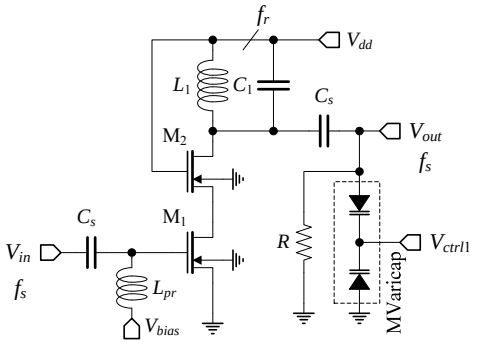

Fig. 1. Low-noise amplifier scheme

Elements of resonant circuit are also chosen in order to provide high quality factor Q and, consequently, narrow LNA bandwidth $BW = f_r/Q$. When BW is narrow then LNA gain is high, the receiver selectivity is good, the attenuation of symmetrical signals in heterodyne receiver is high, and noise level is low. The amplitude and phase characteristics of proposed LNA are given in Fig. 2. As one can see, the maximal gain is obtained at the resonant frequency for the phase shift of –180°.

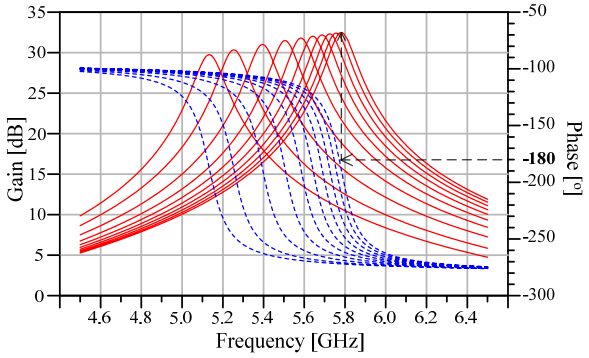

Fig. 2. Gain magnitude and phase characteristics

III. Architecture of Self-Tuning LNA with Sliding Mode Control

The design concept of STLNA employs phase control strategy where the phase shift between input and output signals is used to generate control voltage, V_{ctrl}. The control voltage defines the resonant frequency f_r, which determines the LNA phase characteristic (3). When the filter phase shift is –180°, then f_r is tuned to the frequency of the input signal f_s. In that manner, we control the phase shift of the output signal similar to the pulse delay control that can be found in DLL circuits [8, 9]. The block diagram of the STLNA with SMC is depicted in Fig. 3. The LNA, introduced in Sec. II, represents a building block of the proposed architecture (see Fig. 3).

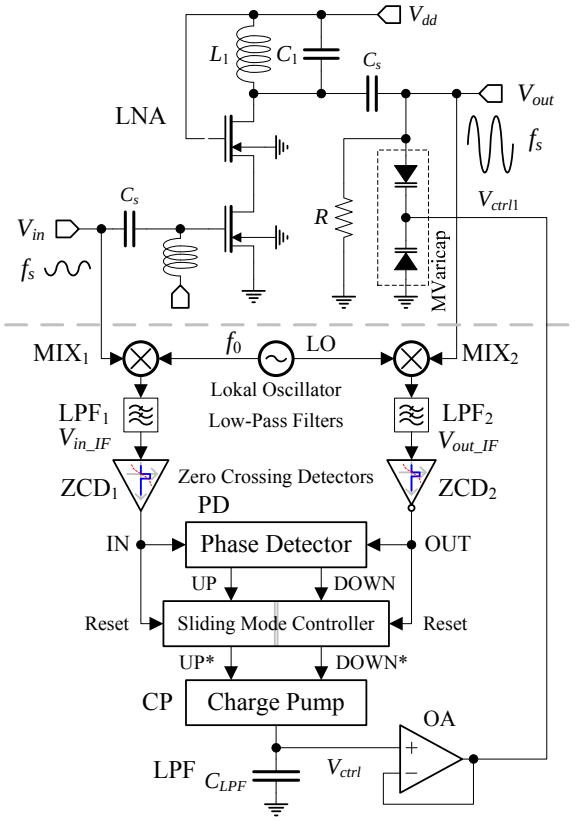

Fig. 3. Block diagram of STLNA with SMC.

Correct operation of a phase detector is difficult to realize at high RF/MW frequency so the frequency down conversion of signals V_{in} and V_{out} is performed by using two mixers, MIX_1 and MIX_2, local oscillator (LO), as generator of frequency f_0, and two low-pass filters, LPF_1 and LPF_2 (see Fig. 3.). The outputs of frequency down converter are two signals, V_{in_IF} and V_{out_IF}, at lower frequency, $f_0 - f_s$. Then signals V_{in_IF} and V_{out_IF}, is amplified first and shaped to rectangular forms by using two zero crossing detectors, ZCD1 and ZCD2 presented in Fig 4. ZCD_2 has one inverter stage more than ZCD_1, introducing an additional -180° phase shift to the output signal. In that way, the phase error, estimated by phase detector, PD, is

$$\theta_{PD} = -\text{atan}\left(2Q\frac{f_s - f_r}{f_r}\right). \quad (4)$$

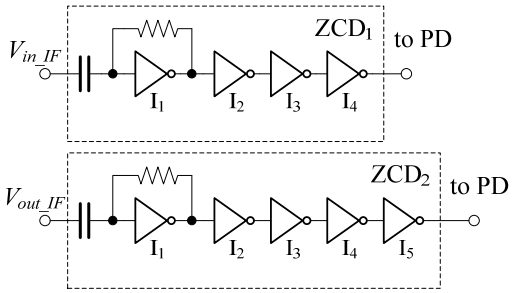

Fig. 4. Zero crossing detector

Phase comparison of input IN and output OUT signals is performed by a PD, which generates UP and DOWN signals. DOWN signal is on when the OUT signal phase leads in respect to the IN signal phase, while in the opposite, UP signal is active. Time durations of UP and DOWN signals are proportional to the phase shift. UP and DOWN signals represent error signal used in the sliding mode controller to generate the UP* and DOWN* control signal that drive a charge pump (CP). CP charges and discharges the load capacitor C_{LPF} providing V_{ctrl} that is used as control voltage for LNA. CP acts as an integrator and, therefore, V_{ctrl} can be written as

$$V_{ctrl} = -k_{cp}\int_{-\infty}^{t} V_{smc}(\theta_{PD})\mathrm{d}\tau\,, \quad (5)$$

where k_{cp} is a CP positive gain depending on a constant current of charge pump I_{CP} and the capacitor C_{LPF}. $V_{smc}(\theta_{PD})$ is a SMC law. In stable-state the phase shift between V_{out} and V_{in} signals is 0°. The detailed descriptions of all these elements from Fig. 3 are presented in [7]. This paper would focus only on design of the sliding mode controller.

SMC belongs to the class of nonlinear control techniques known as variable structure control [13], which has been studied and implemented worldwide since 1950's. A sliding mode exists in control system when a system state is forced to move along a predefined sliding manifold by discontinuous control with infinite switching, providing system robustness to parameter perturbations and external disturbances. Such control action has to satisfy the reaching and existence conditions of sliding mode for all time, i.e. to ensure that the velocity vector of the system state trajectories always points toward the sliding manifold. The motion of a system with SMC consists of a reaching phase, where the system state is driven to the sliding manifold from any initial state, and a sliding mode phase, where the system state slides along predefined switching manifold having predetermined stable dynamics. Therefore, SMC design procedure has two steps. The first step is to select the sliding manifold so that the system has desirable dynamical behavior in the sliding mode. Secondly, a discontinuous control algorithm should be found to ensure that the system state reaches the sliding manifold in finite time. In order to describe the SMC design procedure briefly, let us consider the system

$$\dot{\mathbf{x}} = \varphi(\mathbf{x},t) + \gamma(\mathbf{x},t)u\,, \quad (6)$$

where $\mathbf{x} \in R^n$ is a system state vector, u is a scalar control input, $\varphi(\mathbf{x},t)$ and $\gamma(\mathbf{x},t)$ are nonlinear functions, and n is a system order. Following SMC design steps, the sliding manifolds with desirable dynamics is defined as

$$s(\mathbf{x}) = 0\,, \quad (7)$$

where $s(\mathbf{x})$ also represents the switching function. Then SMC u is selected as

$$u = \begin{cases} u^+(\mathbf{x}) & \text{for } s(\mathbf{x}) > 0 \\ u^-(\mathbf{x}) & \text{for } s(\mathbf{x}) < 0 \end{cases}, \quad (8)$$

to meet the reaching and existence conditions of sliding mode

$$s(\mathbf{x})\dot{s}(\mathbf{x}) < 0\,. \quad (9)$$

Taking into account (1), (2) and (5), the LNA phase loop dynamics can be obtained by time-differencing (4)

$$\frac{d\theta_{PD}}{dt} = -\frac{2k_{cp}\pi^2 QL_1 C_{MVar}^3 f_s f_r^3}{V_\rho\left(C_{MVar}^*\right)^2\left(f_r^2 + 4Q^2\left(f_s - f_r\right)^2\right)}V_{SMC}\left(\theta_{PD}\right). \quad (10)$$

Since the LNA phase loop dynamics (10) is of the first order, the switching function is chosen according to

$$s(\theta_{PD}) = \theta_{PD}\,, \quad (11)$$

and SMC law is selected as

$$V_{smc}(\theta_{PD}) = \text{sgn}(\theta_{PD})\,. \quad (12)$$

One can see that by substituting (12) in (10), the reaching and existence condition of sliding mode (9)

$$s(\theta_{PD})\dot{s}(\theta_{PD}) = \theta_{PD}\dot{\theta}_{PD} = -\zeta\left|\theta_{PD}\right| < 0 \quad (13)$$

is always satisfied since

$$\zeta = \frac{2k_{cp}\pi^2 QL_1 C_{MVar}^3 f_s f_r^3}{V_\rho\left(C_{MVar}^*\right)^2\left(f_r^2 + 4Q^2\left(f_s - f_r\right)^2\right)} > 0\,. \quad (14)$$

The relay type SMC law (12) produces the chattering, the undesirable phenomenon [14] involving high control activities that may excite non-modeled high frequency dynamics and oscillations of phase in vicinity of $\theta_{PD} = 0$. To alleviate the chattering, the boundary-layer approach [15] is suggested with the control

$$V_{smc}(\theta_{PD}) = \begin{cases} +1 & \theta_{PD} > \delta \\ \theta_{PD} & \left|\theta_{PD}\right| \le \delta \\ -1 & \theta_{PD} < -\delta \end{cases}, \quad (15)$$

where δ is a positive real constant defining the boundary-layer width around $\theta_{PD} = 0$. Note that the control law $V_{smc}(\theta_{PD})$ is linear in δ - neighborhood of $\theta_{PD} = 0$, so by the appropriate choice of δ, the chattering could be eliminated. The scheme of sliding mode controller with control law (15) is shown in Fig. 5.

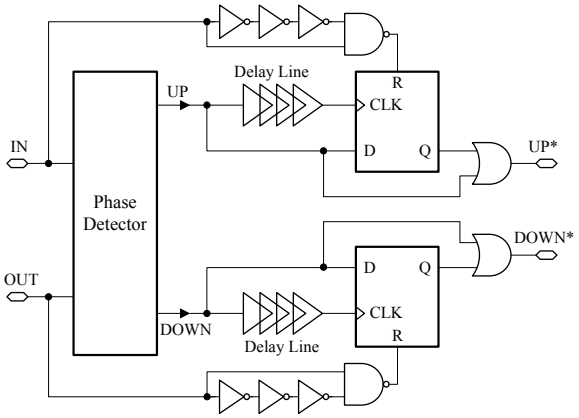

Fig. 5. Scheme of sliding mode controller.

IV. Simulation Results

The proposed solution, which relates to design of STLNA with sliding mode based phase control loop, is verified by Spice simulation. The IHP design kit for 0.13 µm SiGe BiCMOS technology was used [12]. The supply voltage V_{dd} was chosen to be 1.8 V. The characteristics of LNA are shown in Table I.

TABLE I
LNA CHARACTERISTICS

Gain	29.7 – 32.5 dB
Resonant frequency range	5133 –5783 MHz
Bandwidth	126 – 136 MHz
Quality factor	37 – 45
P_{total} (LNA core)	2.1 mW

First we have realized the selective LNA whose resonant frequency is tunable. The tuning process, in our design, was performed by varying the capacitance MVaricap, what was achieved by adjusting a DC biasing point. Consequently, the resonant f_r frequency was subject to change.

Fig. 6 presents time responses of STLNA with SMC. The waveforms of the down-converted input V_{in_IF} and output V_{out_IF} signals are given in Fig. 6(a). IN and OUT signals at the outputs of ZCD1 and ZCD2 respectively, UP and DOWN control signals, obtained at the outputs of PD, UP* and DOWN* control signals, derived from sliding mode controller, as well as V_{ctrl}, are presented in Fig. 6(b). The steady-state state is reached, i.e. the phase loop is locked, at the moment when: i) the signals V_{in} and V_{out} , i.e V_{in_IF} and V_{out_IF} are of opposite phases, ii) UP, DOWN, UP*, and DOWN* signals disappear, and iii) the control voltage V_{ctrl} has a constant value. The settling time of a system is approximately 50 ns - 5 times faster than in the case without sliding mode controller in the phase control loop. Settling time of the LNA input V_{in} and output V_{out} signal is presented in Fig. 6(c). The sliding mode based phase control loop changes the referent resonant frequency of resonant circuits until a condition $f_r = f_s$ is reached. At the resonant frequency STLNA has its maximal gain.

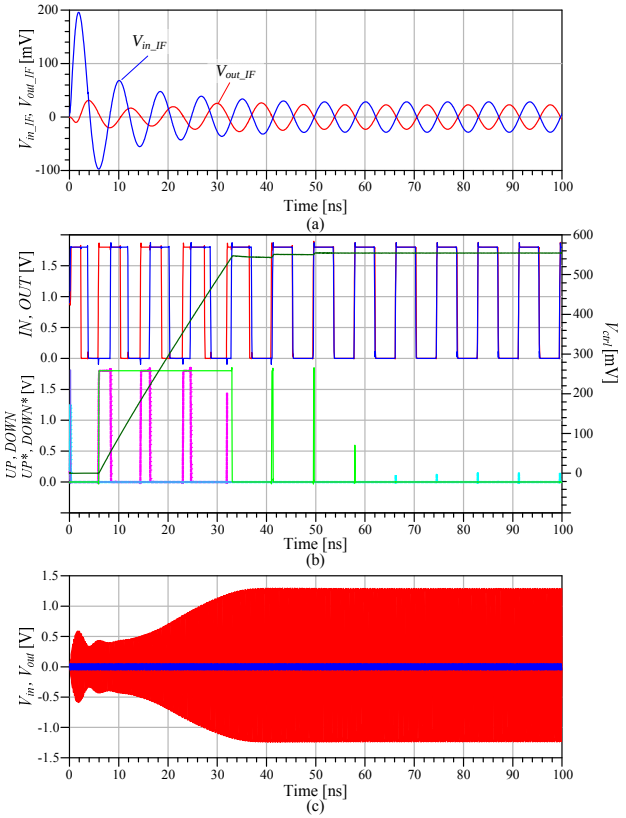

Fig. 6. Time response of STLNA with SMC: (a) V_{in_IF} and V_{out_IF} and (b) IN, OUT, UP, DOWN, UP*, DOWN* and V_{ctrl}, (c) V_{in}, V_{out}

V. Application of STLNA with SMC

The application of STLNA with SMC is shown in Fig. 7. The structure consists of two STLNAs, master and slave. The master STLNA is excited by the referent frequency source f_s and it generates control voltage, V_{ctrl}. The slave STLNA is of identical structure as the master. It is driven with the same control voltage V_{ctrl}, generated by the master STLNA. The slave is used for filtering and amplification of the input signal.

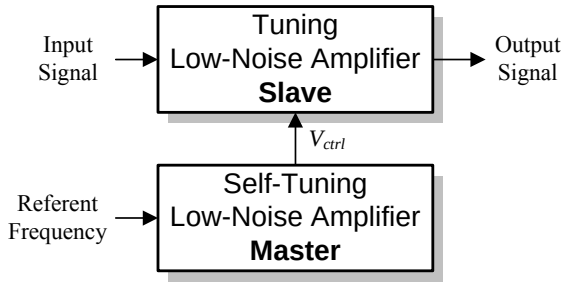

Fig. 7. Typical application for self-tuning band-pass filter

VI. Conclusion

Selective self-tuning low-noise amplifier (STLNA) with sliding mode based phase control loop is considered in this paper. The proposed solution is suitable for VLSI implementation. Unlike self-tuning solutions based on sensing of power [16] or voltage [17] level, the phase loop with sliding mode control (SMC) is introduced to tune the circuit resonant frequency to the frequency of input signal in the presence of PVT variations. This is performed by changing MOS varicap capacitance with control voltage, which is designed according to SMC theory. STLNA is working within a frequency range from 5133 up to 5783 MHz, and has high quality factor Q (37-45), and high gain (29.7 – 32.5 dB). The duration of the entire self-tuning process is less than 50 ns in full frequency range of STLNA operation. The proposed circuit is useful for realization of narrow-band amplifiers implemented in heterodyne receivers. Simulation results are promising for practical implementation of the described solution.

FPGA-based quadrotor attitude estimation using experimental results from 9DOF IMU sensor

Taki Eddine Lechekhab, Stojadin Manojlović, Slobodan Simić, Davorin Mikluc

Abstract— **In order to build quadrotor prototype and apply different control algorithms, in this paper, experimental results from Inertial Measurement Unit (IMU) sensor fixed on a quadrotor test bench, mounted on the 3-axis platform, are analyzed and discussed. A Field Programmable Gate Array (FPGA) platform is used to control the 3-axis platform and process the measurements. The raw data are analyzed and processed by two algorithms: Kalman filter (KF) and Complimentary Filter (CF) to estimate the attitude angles of quadrotor, combining the measurements from the gyroscopes and the accelerometers.**

***Index Terms*— Quadrotor, FPGA, Attitude estimation, Kalman Filter , Complimentary Filter, MPU9250 IMU sensor.**

I. INTRODUCTION

Recently the interest in the unmanned aerial vehicles (UAVs) is increasing, and they have been used for many applications as: military operations, aerial photography for mapping, news coverage, inspection of power lines, atmospheric analysis for weather forecasts, traffic monitoring in urban areas, crop monitoring and spraying, border patrol, surveillance for illegal imports and exports, fire detection and control, agriculture, search and rescue operations for missing persons, natural disasters, etc [1] [2].

The quadrotors make up an easy-to-use and challenging platform for students and researchers from control systems area, because of its low-cost, the nonlinear nature and under-actuated configuration, and make it ideal to synthesize and analyze different control algorithms [1].

The quadrotor has a cross design with two pairs of opposite rotors rotating clockwise, while the other rotor pair rotating counter-clockwise to balance the torque. The attitude of the quadrotor and up-thrust actions are controlled by changing the angular velocities of the actuator rotors using pulse width modulation (PWM) to give the desired output. The current control and PWM control can be generated using different types of platforms as Arduino, FPGA, Raspberry pi etc. In this work a FPGA BASYS 2 platform is used. Nowadays the FPGAs are increasingly used as embedded systems in this field, which gives a motivation for research and using them to integrate different control algorithms on quadrotors.

The advances in electronics' field allowed producing cheap lightweight flight controllers, IMUs, actuators, positioning system (GPS) and other sensors [3]. This resulted in the quadrotor configuration becoming popular for small UAVs. With their small size and maneuverability, these quadrotors can be flown indoors and outdoors as well for different missions.

The aim of this work is to study the reliability of a low cost 9DOF MPU9250 IMU sensor for the stability and orientation feedback, in order to build a quadrotor test bench for application of different controllers using FPGA platform. It receives the raw measurements from the gyroscopes and the accelerometers, and compare them to the reference angles translated from the potentiometers placed on each axis (X, Y, Z) of the 3-axis platform equipped with the DC motors that control the pan, tilt and roll motions.

Among the plenty approaches to solve the attitude estimation problem, the Kalman filter took the main interest [4]. In our work the measurement results from the gyroscopes and the accelerometers are used to estimate the quadrotor attitude angles. Therefore two filters are used and compared: Kalman filter and complimentary filter, which combine the accelerometers and the gyroscopes measurements for estimating the roll and pitch angles. These methods are taking on consideration the measurement noise from each, and the biases from the gyroscopes that causes the drifting .

This paper is organized in six sections. The hardware used in the experiments is described in the second section, while the measurement models and proposed filters are explained in the third and fourth sections, respectively. After the experimental results presented in the fifth section, the paper ends with conclusions and future perspectives.

II. HARDWARE DESCRIPTION

A. Three-axis platform

The 3-axis platform (pan, tilt and roll) used in this work is presented in Fig. 1. It consists of an outer gimbal, inner gimbal, test table, three DC motors as axis actuators and three axis positional sensors, all mounted on the fixed platform base. The quadrotor prototype is mounted on the test table. The outer gimbal rotates around a pan axis and it is driven by a motor located inside the base. The inner gimbal is driven by a DC motor, which is fixed on the outer gimbal and it moves around the polarization axis. The third motor drives the

Slobodan Simic is with the Military academy, University of Defense, Pavla Jurisica Sturma 33, 11000 Belgrade, Serbia (e-mail: simasimic01@gmail.com).

Dovorin Mikluc is with the Military academy, University of Defense, Pavla Jurisica Sturma 33, 11000 Belgrade, Serbia (e-mail: miklucd@yahoo.com)

platform around the tilt axis (yaw angle of the quadrotor), and it is fixed inside the inner gimbal [5] .

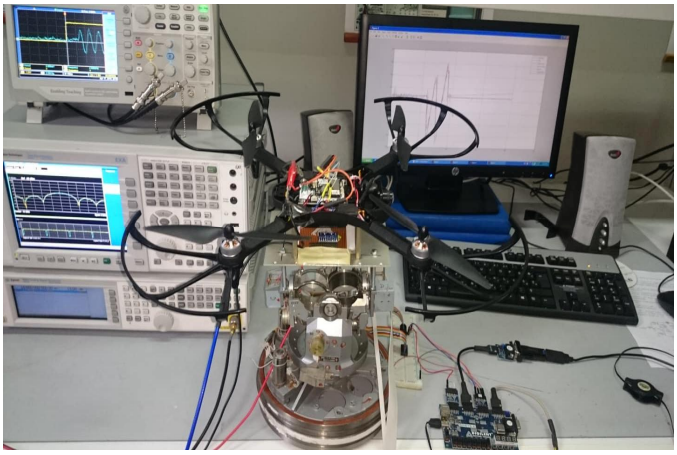

Fig. 1. Quadrotor prototype mounted on the three-axis platform.

B. *Field Programmable Gate Array platform*

In this work a Digilent's BASYS 2 FPGA board, shown in Fig. 2 (d), is used, which is an circuit design and implementation platform. The specifications of this platform provides us a complete and easy to use hardware for hosting circuits ranging from basic logic devices to complex controllers. The considerable number of I/O, make it ideal to design the suitable filters and control algorithms, and reading the measurements from different sensors and modules, simultaneously.

The figure. 2.(a) shows PmodRS232X a serial converter and interface that connects the FPGA platform with the computer for data processing and analyzing using different software like MATLAB. The Digilent's Pmod AD1, represented in Fig. 2.(c), is a two channel, 12-bit analog-to-digital converter that features Analog Devices AD7476A. With a sampling rate of up to 1 million samples per second, it is used to link and calibrate the potentiometers, from which the raw measurements are used as referent angles, because they give the platform attitude angles in the inertial coordinate system.

C. *MPU9250/6500 IMU module*

The MPU-9250 is a 9-axis (gyro+accelerometer+ compass) MEMS motion tracking device. This multi-chip module (MCM), shown in Fig. 2.(b), consists of two dies integrated into a single QFN package. One die houses the 3-axis gyroscope and the 3-axis accelerometer. The other die contains the AK8963 3-axis magnetometer. These integrated dies are controlled by a Digital Motion Processor (DMP) , all combined and boxed in a small 3x3x1mm package. This module has an embedded temperature sensor and an on-chip oscillator with ±1% variation over the operating temperature range. This tracking module can be fined in many devices as mobile phones, virtual reality devices and UAVs. The characteristics of this module are given in Table. I, that can be found in [6].

TABLE I
MPU9250 IMU SENSOR MODULE SPECIFICATIONS

Specifications	MPU9250/6500
Size	25.5 × 15.4 × 3 mm
Weight	2.72 g
Gyro range	±250, ±500, ±1000, ±2000 °/s
Gyro bias	2 °/s
Gyro nonlinearity	±0.1 %
Gyro noise performance	0.1 (rms)
Accel. range	±2g, ±4g, ±8g, ±16 g
Accel. bias	±60 mg
Accel. nonlinearity	±0.5 %
Accel. noise performance	8 mg(rms)
Magnetometer range	± 4800 µT

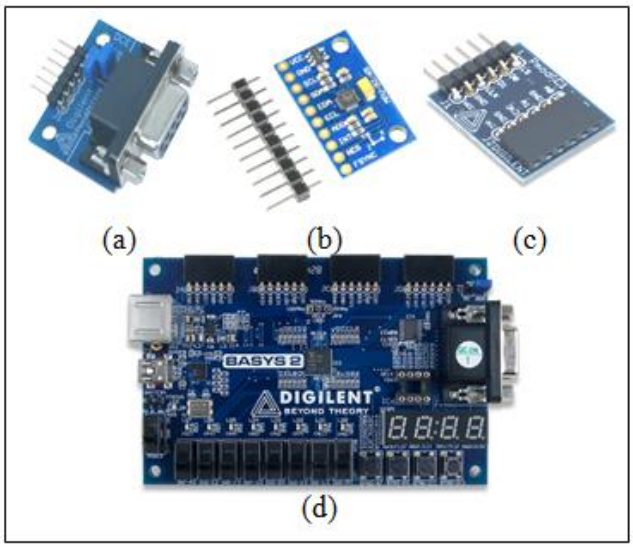

Fig. 2. The hardware used for the measurements .

III. MEASUREMENT MODELS

The mathematical model of the quadrotor is based on the Newton-Euler equations which describe its translational and angular dynamics. The translational dynamics is defined in the Earth-centred-Earth-fixed (ECEF) reference frame and the angular dynamics is represented in the body-fixed reference frame [7]. The rotation matrix $\mathbf{T}_{B/E}$ that define the orientation of the body frame (B) with respect to the Earth reference frame (E), using the sequence of yaw-pitch-roll elementary transformations, is expressed as:

$$\mathbf{T}_{B/E} = \begin{bmatrix} c\theta c\psi & c\theta s\psi & -s\theta \\ s\phi s\theta c\psi - c\phi s\psi & s\phi s\theta s\psi + c\phi c\psi & s\phi c\theta \\ c\phi s\theta c\psi + s\phi s\psi & c\phi s\theta s\psi - c\phi c\psi & c\phi s\theta \end{bmatrix} \quad (1)$$

with 'c' and 's' denoting cos and sin, respectively. The components of the quadrotor body absolute angular velocity,

expressed in the body frame $\omega_B = \begin{bmatrix} p & q & r \end{bmatrix}^T$, are related with Euler angles $\xi = \begin{bmatrix} \phi & \theta & \psi \end{bmatrix}^T$ as following:

$$\dot{\xi} = \begin{bmatrix} 1 & \sin\phi\tan\theta & \cos\phi\tan\theta \\ 0 & \cos\phi & -\sin\phi \\ 0 & \dfrac{\sin\phi}{\cos\theta} & \dfrac{\cos\phi}{\cos\theta} \end{bmatrix} \omega_B \qquad (2)$$

The stabilization of the quadrotor at hover mostly depends on the control of the roll and pitch angles, so in this work the magnetometer measurements are not used, and the yaw angle is not considered in the experimental results.

The accelerometers measure the quadrotor body translational accelerations $\mathbf{a}_B$ in the body-fixed frame. According to [8] and [9] the approximated relation of the components of the normalized acceleration vector in the body frame and the pitch and roll angles is:

$$\mathbf{a} = \frac{\mathbf{a}_B}{|\mathbf{a}_B|} \approx \begin{bmatrix} \sin\theta \\ -\sin\phi\cos\theta \\ \cos\phi\cos\theta \end{bmatrix} \qquad (3)$$

The measurement models of the IMU sensors include accelerometer noise n_a, gyroscope noise n_g and gyroscope bias β_ω:

$$\begin{aligned} \bar{\omega} &= \omega + \beta_\omega + n_g \\ \bar{a} &= a + n_a \end{aligned} \qquad (4)$$

where ω and $\bar{\omega}$ are true and measured gyroscopes data, and a and $\bar{a}$ are true and measured accelerometers data.

IV. Attitude Estimation Algorithms

A. *Kalman filter*

In order to estimate the attitude angles and the gyroscopes biases the state vector is chosen as $x = \begin{bmatrix} \phi & \beta_x & \theta & \beta_y \end{bmatrix}$,where β_x and β_y are the biases along X and Y axis. For the implementation of the Kalman algorithm, based on the equations (2), (3) and (4), the state space model can be expressed as following [8]:

$$\begin{aligned} \dot{x} &= \begin{bmatrix} (\bar{\omega}_x - \beta_x) + (\bar{\omega}_y - \beta_y)\sin\phi\tan\theta \\ 0 \\ (\bar{\omega}_y - \beta_y)\cos\phi \\ 0 \end{bmatrix} + \mathbf{w} \\ y &= \begin{bmatrix} \sin\theta \\ -\sin\phi\cos\theta \\ -\cos\phi\cos\theta \end{bmatrix} + \mathbf{v} \end{aligned} \qquad (5)$$

In the nonlinear model (5) with $\bar{\omega}_x$ and $\bar{\omega}_y$ are denoted gyroscope measurements along X and Y axis respectively. The process noise **w** and measurement noise **v** are both assumed to be Gaussian with covariance matrices **Q** and **R**:

$$\begin{aligned} \mathrm{E}\left[\mathbf{w}\mathbf{w}^T\right] &= \mathbf{Q} \\ \mathrm{E}\left[\mathbf{v}\mathbf{v}^T\right] &= \mathbf{R} \end{aligned} \qquad (6)$$

Using small angles approximations: $\sin\alpha \approx \alpha, \cos\alpha \approx 1$, where $\alpha = \{\phi, \theta\}$ the equations (2) and (3) can be linearized, and the model (5) can be represented in the following linear form :

$$\begin{aligned} \dot{x} &= \begin{bmatrix} 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & 0 & 0 \end{bmatrix} x + \begin{bmatrix} 1 & 0 \\ 0 & 0 \\ 0 & 1 \\ 0 & 0 \end{bmatrix} u + \mathbf{w} \\ y &= \begin{bmatrix} 0 & 0 & 1 & 0 \\ -1 & 0 & 0 & 0 \end{bmatrix} x + \mathbf{v} \end{aligned} \qquad (7)$$

The input vector of this system represents the angular velocity measurements $u = \begin{bmatrix} \bar{\omega}_x, \bar{\omega}_y \end{bmatrix}$ and $y = \begin{bmatrix} \bar{a}_x, \bar{a}_y \end{bmatrix}$ represents the acceleration measurements.

The discretization of the linear system (7) can be made with the sampling time *T*, assuming zero-order hold of the inputs:

$$\begin{aligned} x_{k+1} &= \mathbf{A}_k x_k + \mathbf{B}_k u_k & \mathbf{E}\left[\mathbf{w}_k \mathbf{w}_k^T\right] &= \mathbf{Q}_k \\ y_k &= \mathbf{H}_k x_k + v_k & \mathbf{E}\left[\mathbf{v}_k \mathbf{v}_k^T\right] &= \mathbf{R}_k \end{aligned} \qquad (8)$$

where the matrices $\mathbf{A}_k$, $\mathbf{B}_k$ and $\mathbf{H}_k$ are defined as :

$$\mathbf{A}_k = e^{\mathbf{A}T} = \begin{bmatrix} 1 & -T & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & -T \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad \mathbf{B}_k = \int_0^T e^{\mathbf{A}\tau} d\tau = \begin{bmatrix} T & 0 \\ 0 & 0 \\ 0 & T \\ 0 & 0 \end{bmatrix}$$

$$\mathbf{H}_k = \begin{bmatrix} 0 & 0 & 1 & 0 \\ -1 & 0 & 0 & 0 \end{bmatrix}$$

The discrete model (8) is used for Kalman filter implementation. As denoted in [8], the model is decoupled, and it is possible to implement two Kalman filters for each angle estimation.

The equations of KF are summarized in two equation systems defined in the state space form, the time update system (prediction) in (9), and measurement update system in (10):

$$\begin{aligned} \bar{x}_k &= \mathbf{A}_{k-1}x_{k-1} + \mathbf{B}_{k-1}u_{k-1} \\ \bar{\mathbf{P}}_k &= \mathbf{A}_{k-1}\mathbf{P}_{k-1}\mathbf{A}_{k-1}^T + \mathbf{Q}_k \end{aligned} \tag{9}$$

$$\begin{aligned} \mathbf{S}_k &= \mathbf{H}_k\mathbf{P}_k^-\mathbf{H}_k^T + \mathbf{R}_k \\ \mathbf{K}_k &= \mathbf{P}_k^-\mathbf{H}_k^T\mathbf{S}_k^{-1} \\ x_k^+ &= x_k^- + \mathbf{K}_k\left(y_k - \mathbf{H}_k x_k^-\right) \\ \mathbf{P}_k^+ &= \left(\mathbf{I} - \mathbf{K}_k\mathbf{H}_k\right)\mathbf{P}_k^- \end{aligned} \tag{10}$$

B. Complimentary filter

Considering that the raw acceleration measurements along each axis are denoted as $\bar{a}_x$, $\bar{a}_y$ and $\bar{a}_z$, the estimations of the roll and pitch angles can be formed by resolving forces using basic trigonometry:

$$\hat{\phi}_{Acc} = \arctan\left(\frac{\bar{a}_y}{\sqrt{\bar{a}_x^2 + \bar{a}_z^2}}\right) \tag{11}$$

$$\hat{\theta}_{Acc} = \arctan\left(\frac{\bar{a}_x}{\sqrt{\bar{a}_y^2 + \bar{a}_z^2}}\right) \tag{12}$$

Using the equation (2), the roll and pitch angular velocities $\dot{\phi}_{gyro}$ and $\dot{\theta}_{gyro}$ can be calculated based on the gyroscope measurements.

The high frequency noise overlaying the signal disturbs the accelerometer measurement, and effecting on the estimation of the attitude angles. Therefore, some type of the law-pass filter should be added. Complimentary filter reduces the gyroscope drift and the impact of accelerometer noise during the measurements [10]. This filter is based on the sensor data fusion by choosing a constant α where: $0 < \alpha < 1$ and it raises when the accelerometer measurements are showing more reliability. The complimentary filter estimations of the roll and the pitch angle are given with:

$$\begin{aligned} \hat{\phi}(k+1) &= (1-\alpha)(\hat{\phi}(k) + \dot{\phi}_{gyro}(k)T) + \alpha\hat{\phi}_{Acc}(k) \\ \hat{\theta}(k+1) &= (1-\alpha)(\hat{\theta}(k) + \dot{\theta}_{gyro}(k)T) + \alpha\hat{\theta}_{Acc}(k) \end{aligned} \tag{13}$$

V. Experimental Results

Using the hardware explained in Section II, and XILINX System Generator in MATLAB, a number of scenarios are made in order to extract and process the data from the IMU sensor and potentiometer. The SIMULINK/System generator blocks are used to read the data from the gyroscope, accelerometer and potentiometer and are shown in Fig. 3.

The first scenario is rotation along X axis (roll angle only), the second scenario is testing the rotation along Y axis (pitch angle only), while the third scenario is combination of rolling and pitching .

The FPGA platform generates PWM signal to control the 3-axis platform's motors to follow a desired trajectory. The first scenario aims to save the data from the IMU module while the quadrotor test bench changes only the roll angle. Considering that angle measured from potentiometers as a referent angle, the results without filters are shown in Fig. 4.

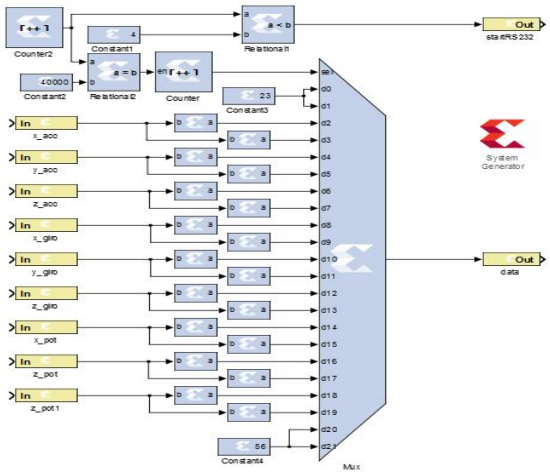

Fig. 3. System Generator blocks to read the measurements from IMU sensor.

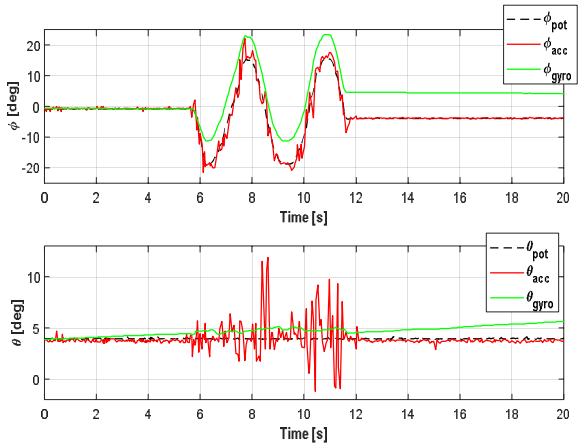

Fig. 4. Attitude angles based on the raw measurements from the first scenario

The accelerometer estimation of the roll angle in Fig. 4 shows a high sensitivity compared to the gyroscope data , and we can notice as well the drift caused by integrating gyroscope noise during the experiment time even along the Y axis. This gives an idea which sensor is more reliable for the complimentary filter method.

The second experiment is made by fixing the role angle while changing the pitch angle and the results are presented in Fig. 5, without any filter, as in the previous experiment.

Unlike the first measurement, the acceleration along the fixed axis shows less sensibility, while the gyroscopic drift still existing caused by integration the bias. The estimated measurements from accelerometer and gyroscope appear to be identical with the reference angle from the potentiometer except the drift of gyroscope angle and accelerometer's noise.

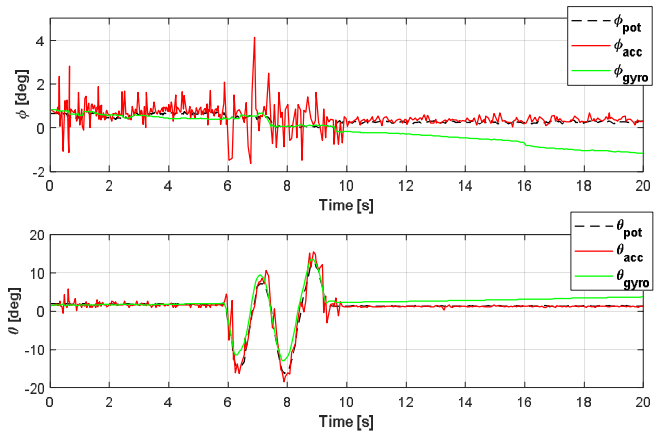

Fig. 5. Attitude angles based on the raw measurements from the second scenario

The third measurement scenario is considered the combined roll-pitch movement and results are presented in Fig. 6.

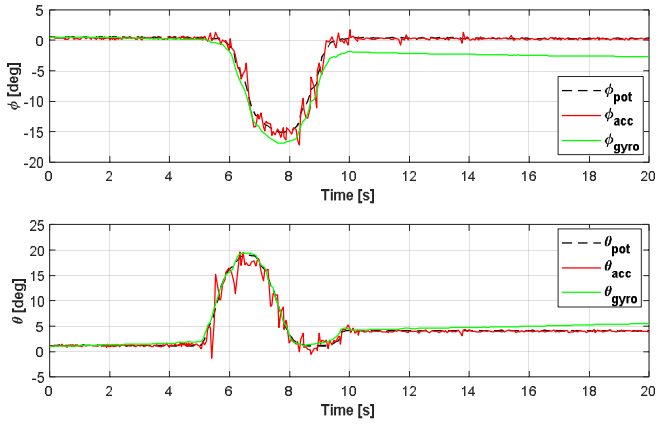

Fig. 6. Attitude angles based on the raw measurements from the third scenario.

By using the equations explained in the fourth section, the Kalman filter has been applied to estimate the attitude and reduce the noise that have been generated by the accelerometer and to eliminate the bias from the gyroscope.

The results are compared with the angles measured by the potentiometer. The values of the covariance matrices elements are chosen based on a number of simulations. For each angle (roll and pitch), two Kalman filters are separately applied. The estimated angles are compared to the referent angles from the potentiometers and illustrated in Figs. 7. – 9.

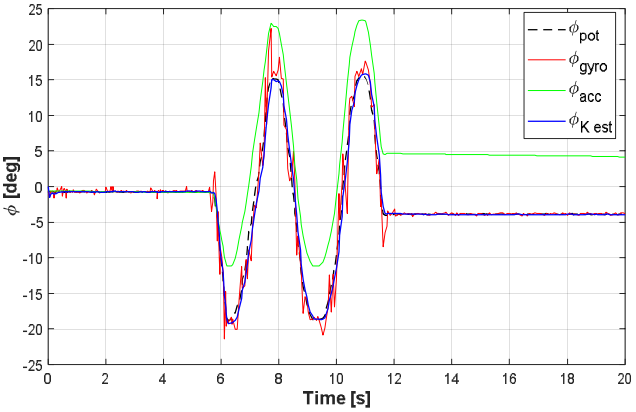

Fig. 7. KF estimation of roll angle (the first scenario).

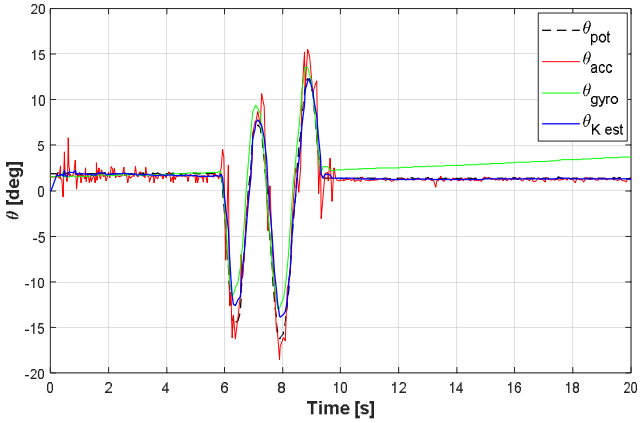

Fig. 8. KF estimation of pitch angle (the second scenario) .

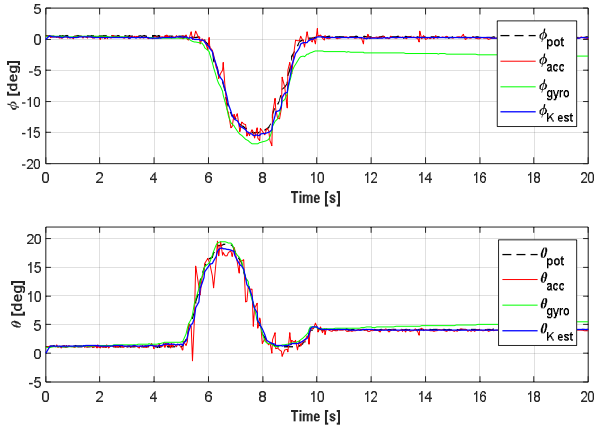

Fig. 9. KF estimation for both angles (the third scenario).

The following Fig. 10. and Fig. 11. show the estimated bias along X and Y axis from the third scenario, where we can notice that when the 3-axis platform is stabilized after 10 sec, the gyroscope biases converge to the constant values approximately $\beta_x = -0.11[\text{deg}/s]$ and $\beta_y = 0.15[\text{deg}/s]$.

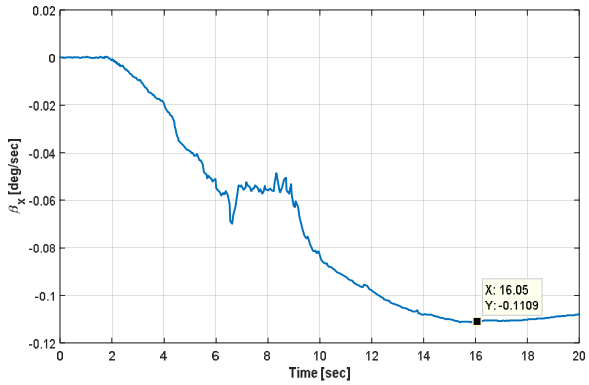

Fig. 10. Bias estimation along X axis

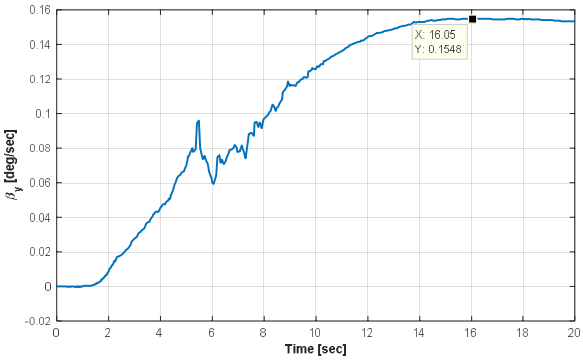

Fig. 11. Bias estimation along Y axis

The complimentary filter needs only one tuning parameter and a simple code, so it is optimal for energy saving, which is the actual UAVs' problem. In all scenarios, the parameter $\alpha = 0.4$ have been chosen after a number of tests that gives the appropriate results. By raising this parameter we more rely on the accelerometer measurements and a higher frequency noise is added. The following figure shows the results by applying this filter during the third scenario, compared with the Kalman filter estimations. As can be seen, the noise from the accelerometer influences the estimated angles, while the gyroscope drift is reduced.

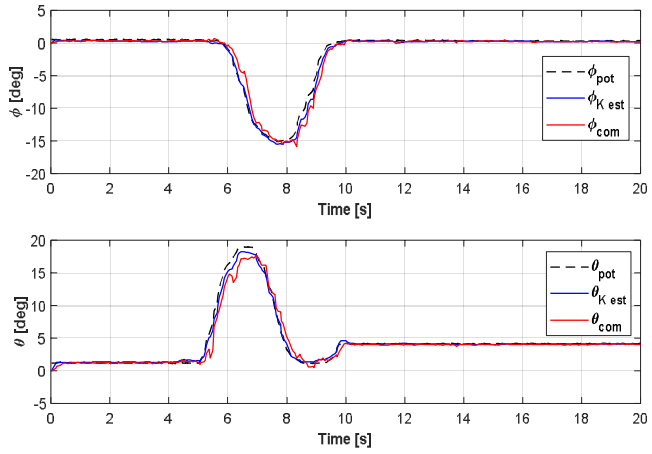

Fig. 12. Comparison of the different estimations results.

VI. Conclusion and Future Works

In this paper the hardware configuration, including 3-axis motion platform and FPGA processing board, for testing the main characteristics of the low-cost MPU9250 IMU module, is evaluated.

The analysis of the raw measurements from the MPU9250 module, allowed us to determinate the main characteristics of this sensor, as the biases and measurement noises, and lead us to apply the suitable filter. The Kalman filter gave better estimation compared to the complimentary filter results. The results show that appropriately filtered measurements from this low-cost module can be used in the next step of building the quadrotor prototype.

The future work will be the FPGA-based implementation of the robust controller for the quadrotor attitude stabilization and trajectory tracking, including the filtering of the vibrations caused by the propellers and testing the energy efficiency of different algorithms.

Primena nelinearnog ADRC algoritma za upravljanje planarnim manipulatorom

Milan Svetozarević, Momir Stanković

***Apstrakt*— U radu je predložena primena nelinearnog regulatora sa aktivnim potiskivanjem poremećaja (*Nonlinear Active Disturbance Rejection Control*-NADRC) za upravljanje planarnim robotskim manipulatorom, koji predstavlja složeni nelinearni sistem sa dva ulaza i dva izlaza. Pri realizaciji upravljanja unakrsna dinamika sistema je uključena u totalne poremećaje po kanalima upravljanja, tako da su projektovani nezavisni regulatori za oba kraka manipulatora. Razmatrani problem praćenja zadate reference je preformulisan u problem regulacije (*error-based structure*), čime je pojednostavljena standardna struktura ADRC regulatora. Detaljna simulaciona analiza je pokazala uticaj izbora parametara nelinearnog regulatora na performanse upravljanja.**

***Ključne reči*— Nelinearno upravljanje sa aktivnim potiskivanjem poremećaja (ADRC); Planarni robotski manipulator; Prošireni opserver stanja (ESO).**

I. UVOD

Opis kinematike kretanja robotskih manipulatora najčešće zahteva kompleksne matematičke modele sa velikim brojem parametara i više ulaznih i izlaznih veličina, koje su međusobno spregnute, i to najčešće nelineranim vezama. Shodno tome, precizna identifikacija parametara ovakvih sistema je prilično otežana i ograničena. U ovom radu je razmatran problem upravljanja planarnog manipulatora sa dva kraka [1], odnosno dva stepena slobode (sistem sa dva ulaza i dva izlaza), koji nalazi široku primenu u različitim industrijskim postrojenjima [2], humanoidnim robotima [3], kao i fizioterapeutskim rehabilitacionim uređajima [4]. Imajući u vidu navedeni problem neodređenosti parametara (*parametar uncertanties*) manipulatora, konvencionalni upravljački algoritmi poput PI/PID regulatora [5], kao i algoritmi koji se baziraju na poznavanju preciznog modela objekta upravljanja [5], uglavnom ne daju zadovoljavajuće performanse. Shodno tome, u radu je analizirana primena regulatora na bazi upravljanja sa aktivnim potiskivanjem poremećaja (*Active Disturbance Rejection Control*-ADRC), koji omogućuje visoke performanse sistema uz minimalnu zavisnost od poznavanja modela objekta upravljanja [6].

Osnovna ideja ADRC-a je primena proširenog opservera stanja (*Extended State Observer*-ESO) pomoću koga se vrši estimacija i nakon toga potiskivanje generalizovanog (totalnog) poremećaja, koji obuhvata sve unutrašnje i spoljašnje poremećaje sistema. Na ovaj način, teoretski je pokazano da se bilo koji složeni sistem *n*-tog reda svodi na model redne veze *n* integratora bez poremećaja (*disturbance free model*), kojom se relativno lako može upravljati.

Primenom ADRC tehnike omogućeno je razdvajanje kanala upravljanja jednog i drugog kraka manipulatora. Naime, sistem sa dva ulaza i dva izlaza je raspregnut na dva sistema sa jednim ulazom i jednim izlazom, gde je celokupna unakrsna dinamika uključena u totalne poremećaje po jednom i drugom kraku.

Imajući u vidu da se upravljanje robotkskih manipulatora uglavnom svodi na problem praćenja zadate referentne pozicije krakova, standradni ADRC algoritam se najčešće analizira kao algoritam sa dva stepena slobode (*two-degree-of-freedom*-2DOF) [7] koji kao ulaze koristi referentni signal i izlazni signal objekta upravljanja. Međutim, kako je većina industrijskih sistema projektovana za upravljačke algoritme sa jednim stepenom slobode (*one-degree-of-freedom*-1DOF), kao što su PI/PID regulatori, jasno je da 2DOF topologija ADRC može predstavljati ograničenje u njegovoj praktičnoj primeni.

Imajući u vidu navedeno, u ovom radu je predložena reformulisana ADRC struktura koja ima za cilj predstavljanje algoritma kao 1DOF strukture, koja kao ulaz koristi grešku praćenja referentnog signala (*error-based structure*). Pored toga, za razliku od [7] razmotrena je primena nelinearnog ADRC (NADRC) algoritma sa različitim parametrima nelinearnih funkcija. Detaljna simulaciona analiza, sprovedena kroz više upravljačkih scenarija, je pokazala prednosti i nedostatke predloženih upravljačkih tehnika.

II. MODEL PLANARNOG MANIPULATORA

Planarni manipulator je sistem koji se sastoji iz dva kraka koja se kreću u istoj ravni i njegova struktura je prikazana na Sl. 1.

Ulazni signali sistema su naponi aktuatora u_{m1} i u_{m2}, koji omogućuju ugaono pokretanje kraka. Izlazni signali sistema su ugaone pozicije θ_1 i θ_2, prvog i drugog kraka planarnog manipulatora, respektivno. Kinematičko kretanje kraka planarnog manipulatora može se opisati kao ,

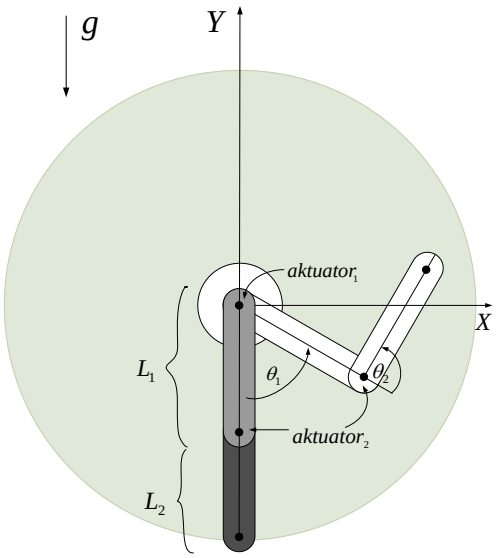
$$I_i\ddot{\theta}_i + F_i\dot{\theta}_i = \tau_{mi} + \tau_{zi} - \tau_{ci}\,, \tag{1}$$

gde se indeks *i*=1, 2 odnose na prvi, odnosno drugi krak, I_i [kgm^2] je ukupni moment inercije na osovini *i* -tog aktuatora, F_i [Nms/rad] predstavlja koeficijent viskoznog trenja, τ_{mi} [Nm], τ_{zi} [Nm], τ_{ci} [Nm], su obrtni moment aktuatora, poremećajni moment i moment unakrsnih veza, respektivno.

Milan Svetozarević – Vojna akademija, Univerzitet odbrane u Beogradu, Pavla Jurišića 31, 11000 Beograd, (e-mail: svetozarevicrks@ gmail.com).

Momir Stanković – Vojna akademija, Univerzitet odbrane u Beogradu, Pavla Jurišića 31, 11000 Beograd, (e-mail: momir_stankovic@ yahoo.com).

Da bismo detaljnije opisali model razmatranog sistema uvedeni su dinamički parametri p_1- p_5 dati u Tabeli I, gde su m_i, L_i, J_i masa, dužina i moment inercije i-tog kraka respektivno, a g je gravitaciono ubrzanje.



Sl. 1. Skica planarnog manipulatora [7]

TABELA I
DINAMIČKI PARAMETRI PLANARNOG MANIPULATORA

p_1 [kg m^2]	$m_2L_2^2 + J_2$
p_2 [kg m^2]	$2m_2L_1L_2$
p_3 [kg m^2]	$J_1 + m_2L_1^2 + 4m_2L_1^2$
p_4 [Nm]	m_2L_2g
p_5 [Nm]	$(m_1L_1 + 2m_2L_1)g$

Na osnovu uvedenih parametara možemo zapisati da je:

$$\begin{aligned} I_1 &= J_{m1} + \eta_1^2(p_1 + p_5), \\ I_2 &= J_{m2} + \eta_2^2 p_4, \end{aligned} \tag{2}$$

gde J_{mi} predstavljaju momente inercije i-tog aktuatora, dok je η_i odnos redukcije preko koje su povezani *i*-ti aktuator i *i*-ti krak . Uticaj unakrsnih veza može se opisati kao:

$$\begin{aligned} \tau_{c1} &= \eta_1\ddot{\theta}_1 p_2 c_{m1} + \eta_2\ddot{\theta}_2 p_2 c_{m2} - \eta_1\dot{\theta}_1\eta_2\dot{\theta}_2 p_2 s_{m2} \\ &- \eta_2\ddot{\theta}_2 p_2(\eta_1\dot{\theta}_1 + \eta_2\dot{\theta}_2)s_{m2} + p_5 c_{m1} + p_4 c_{m12}, \end{aligned} \tag{3}$$

$$\tau_{c2} = (p_2 + p_2 c_{m2})\eta_2\ddot{\theta}_2 + \eta_2^2\dot{\theta}_1^2 p_2 s_{m2} + p_4 c_{m12},$$

gde je $s_{mi} \equiv \sin(\theta_i)$, $c_{mi} \equiv \cos(\theta_i)$, $c_{m12} \equiv \cos(\theta_1 + \theta_2)$.
U ovom slučaju pretpostavljeno je da su aktuatori motori jednosmerne struje pa je obrtni moment definisan kao

$$\tau_{mi} = \frac{k_{Ii}}{R_i}(U_{mi} - k_{ei}\dot{\theta}_i) \tag{4}$$

gde je k_{Ii} [Nm/A] eletktromehanička konstanta, k_{ei} [Vs/rad] mehaničko-električna konstanta i R_i [Ω] otpornost namotaja motora. Treba napomenuti da je u (6) induktivnost rotorskog namotaja motora zanemarena zbog njenog malog uticaja u realnim sistemima.

III. PROJEKTOVANJE NELINEARNOG ADRC ALGORITMA

Opisani model planarnog manipulatora sa dva ulaza i dva izlaza možemo predstaviti kao dva raspregnuta sistema sa jednim ulazom i jednim izlazom

$$\begin{aligned} \ddot{\theta}_1 &= f_1 + b_{01}u_{m1}, \\ \ddot{\theta}_2 &= f_2 + b_{02}u_{m2}, \end{aligned} \tag{5}$$

gde su b_{01} i b_{02} najbolje aproksimacije parametara sistema $b_1 = k_{I1}/(R_1I_1)$ i $b_2 = k_{I2}/(R_2I_2)$, respektivno, dok f_1 i f_2 predstavljaju totalne poremećaje po prvom i drugom kraku:

$$\begin{aligned} f_1 &= -\frac{F_1}{I_1}\dot{\theta}_1 - \frac{k_{I1}k_{e1}}{R_1I_1}\theta_i + \frac{\tau_{z1}}{I_1} - \frac{\tau_{c1}}{I_1} + (\frac{k_{I1}}{R_1I_1} - b_{01})u_{m1}, \\ f_2 &= -\frac{F_2}{I_2}\dot{\theta}_2 - \frac{k_{I2}k_{e2}}{R_2I_2}\theta_2 + \frac{\tau_{z2}}{I_2} - \frac{\tau_{c2}}{I_2} + (\frac{k_{I2}}{R_2I_2} - b_{02})u_{m2}. \end{aligned} \tag{6}$$

Imajući vidu da je predložena identična struktura ADRC regulatora za upravljanje prvim i drugim krakom, u nastavku će njegovo projektovanje biti opisano za i-ti krak (i=1, 2).

Sistem (5) se može predstaviti u formi modela u prostoru stanja

$$\begin{aligned} \dot{x}_{1i} &= x_{2i}, \\ \dot{x}_{2i} &= f_i + b_{0i}u_{mi}, \\ x_{1i} &= \theta_i \end{aligned} \tag{7}$$

Kako razmatramo problem praćenja zadate referentne pozicije *i*-tog kraka θ_{ri}, (7) možemo zapisati u formi greške praćenja $e_{1i} = \theta_{ri} - \theta_i$ [8]:

$$\begin{aligned} \dot{e}_{1i} &= e_{2i}, \\ \dot{e}_{2i} &= f_{ei} - b_{0i}u_{mi}, \end{aligned} \qquad \text{za } i=\{1, 2\}, \tag{8}$$

gde je f_{ei} novi totalni poremećaj koji ima oblik:

$$f_{ei} = \ddot{\theta}_{ri} + (\frac{F_i}{I_i} + \frac{k_{Ii}k_{ei}}{R_iI_i})(\dot{\theta}_{ri} - \dot{e}_i) - \frac{\tau_{zi}}{I_i} + \frac{\tau_{ci}}{I_i} - (\frac{k_{Ii}}{R_iI_i} - b_{0i})u_{mi}, \tag{9}$$

Na ovaj način problem praćenja je preveden u problem regulacije, gde referentni signal možemo okarakterisati kao dodatni poremećaj odnosno kao deo totalnog poremećaja (9), a grešku praćenja kao izlazni signal koji treba minimizovati. Primenom ADRC tehnike upravljanja model (8) se može zapisati u formi sa proširenim stanjem koje predstavlja totalni poremećaj $x_{3ei} = f_{ei}$.

$$\begin{aligned} \dot{x}_{1ei} &= x_{2ei}, \\ \dot{x}_{2ei} &= x_{3ei} - b_{0i}u_{mi}, \\ \dot{x}_{3ei} &= \dot{f}_{ei} \end{aligned} \tag{10}$$

gde je $x_{1ei} = e_{1ei}$ i $x_{2ei} = e_{2ei}$. Pretpostavljajući da u razmatranim sistemima totalni poremećaj najčešće ima sporopromenljivu dinamiku ($\dot{f}_{ei} \approx 0$) za prošireni sistem (10) možemo projektovati klasičan *Luenberger*-ov opserver.

$$\begin{aligned} \dot{\hat{e}}_{1i} &= \hat{e}_{2i} + \beta_{1i}(e - \hat{e}_{1i}), \\ \dot{\hat{e}}_{2i} &= \hat{e}_{3i} + \beta_{2i}(e - \hat{e}_{1i}) - b_{0i}u_{mi}, \\ \dot{\hat{e}}_{3i} &= \beta_{3i}(e - \hat{e}_{1i}), \end{aligned} \tag{11}$$

gde su $\hat{e}_{1i}$ i $\hat{e}_{2i}$ estimacije stanja e_1 i e_2, a $\hat{e}_{3i}$ predstavlja estimaciju dodatnog stanja sistema (8), odnosno totalnog poremećaja f_{ei}, dok su sa β_{1i}, β_{2i} i β_{3i} označena pojačanja opservera.

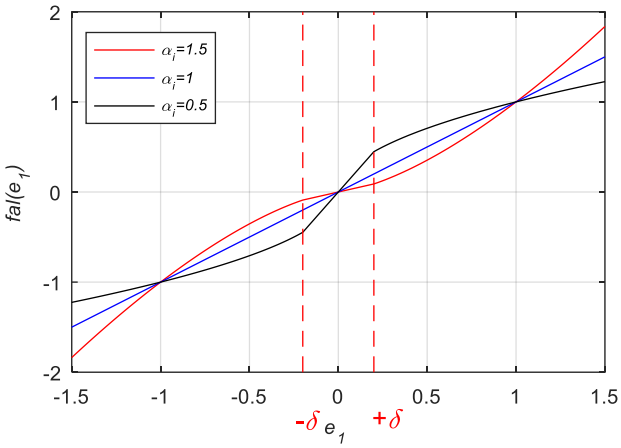
Na osnovu dobijenih estimiranih stanja sistema možemo realizovati nelinearni upravljački zakon sa aktivnim potiskivanjem totalnog poremećaja:

$$u_i = \frac{\hat{e}_{3i}}{b_{0i}} + \frac{k_{1i}\, fal_1(e_{1i}, \alpha_{1i}, \delta) + k_{2i}\, fal_2(e_{2i}, \alpha_{2i}, \delta)}{b_{0i}}, \tag{12}$$

gde su k_{1i} i k_{2i} i-ti koeficijenti upravljanja kojim podešavamo željenu dinamiku sistema u zatvorenoj povratnoj sprezi, Dok je $fal(e_{1i}, \alpha_{1i}, \delta)$ nelinearna funkcija definisana izrazom [1]:

$$fal(e_1, \alpha_i, \delta) = \begin{cases} \dfrac{e_1}{\delta^{1-\alpha_i}}, & |e_1| \le \delta \\ |e_1|^{\alpha} sign(e_1), & |e_1| > \delta \end{cases}, \tag{13}$$

Da bismo pojasnili razlog uvođenja nelinearne funkcije (13) njen grafički prikaz za δ=0.2 i različite vrednosti α_i dat je na Sl. 2.



Sl. 2. Grafički prikaz *fal* funkcije

Kao što možemo uočiti, izborom parametra δ menja se širina linearnog regiona oko nulte vrednosti e_1 i najčešće se δ usvaja tako da bude manje od greške praćenja u stacionarnom stanju [9]. Takođe vidimo da se izborom α <1 vrši smanjenje uticaja pojačanja regulatora kada je greška praćenja velika, čime se smanjuju oscilacije sistema u toku prelaznog perioda, pa se α <1 najčešće usvaja za funkciju fal_1. U drugu ruku, za α >1 imamo suprotan efekat (veće pojačanje pri velikim greškama praćenja), pa je iz tog razloga preporučen izbor α >1 za funkciju fal_2, imajući u vidu da ona utiče na diferencijalno dejstvo regulatora i tako smanjuje preskok u odzivu sistema sa zatvorenom povratnom spregom. Treba primetiti da se izborom α =1 (12) praktično svodi na linearnu funkciju.

IV. Simulaciona analiza

Na osnovu matematičkog modela (1) u programskom paketu Matlab/Simulink je formiran simulacioni model razmatranog planarnog manipulatora, dok je projektovanje ADRC regulatora realizovano na osnovu uprošćenog modela sistema (5). Usvojene vrednosti parametara manipulatora i aktuatora su date u Dodatku rada [7].

Uporedna simulaciona analiza performansi upravljanja je izvršena za sisteme sa različitim vrednostima parametara nelinearne *fal* funkcije. U prvom slučaju usvojeno je $\alpha_1 = 1$ i $\alpha_2 = 1$ što praktično predstavlja linearni ADRC regulator (u nastavku nazvan "LADRC"). Drugi regulator je projektovan sa usvojenim vrednostima $\alpha_1 = 0.5$ i $\alpha_2 = 1$ (uvođene nelinearnosti samo u proporcionalno pojačanje, u nastavku nazvan "NADRC$_1$"), dok je za treći regulator uzeto $\alpha_1 = 0.5$ i $\alpha_2 = 1.5$ (u nastavku nazvan "NADRC$_2$").

Ostali parametri regulatora su bili identični, odnosno usvojeno je δ=0.1. Dok su pojačanja observera definisana izrazima:

$$\beta_1 = 3\omega_o,\ \beta_2 = 3\omega_o^2,\ \beta_2 = \omega_o^3, \tag{14}$$

gde ω_o=80 *rad/s* predstavlja usvojeni propusni opseg

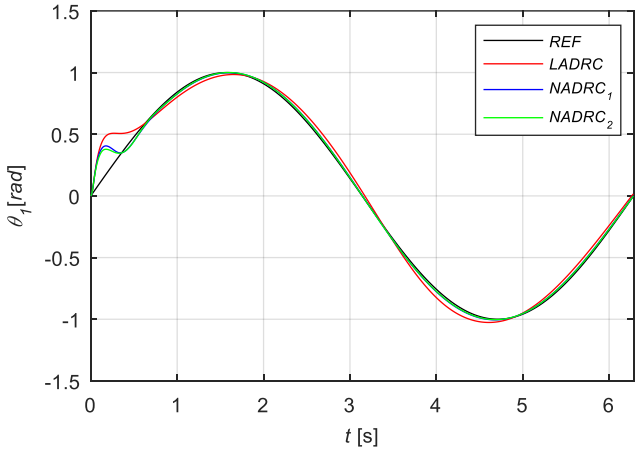
opservera, a pojačanja regulatora izrazima

$$k_1 = \omega_c,\ k_2 = 2\omega_c, \tag{15}$$

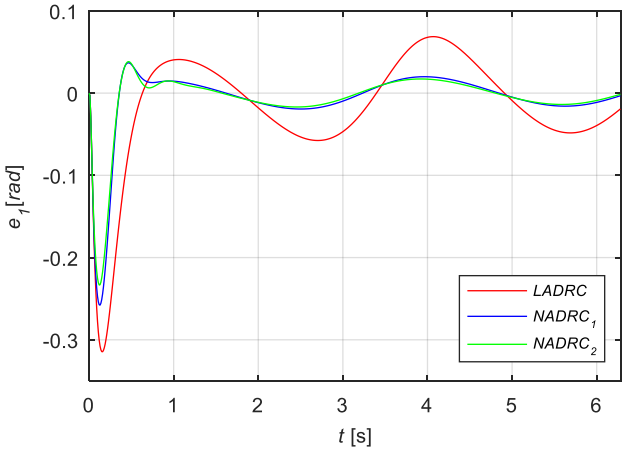
gde ω_c=10 *rad/s* predstavlja željeni propusni opseg sistema sa zatvorenom povratnom spregom.

Simulacije su sprovedene kroz tri različita scenarija koja obuhvataju ugaono pozicioniranje kraka planarnog manipulatora, u prisustvu spoljašnjih poremećaja, neodređenosti parametara, šuma merenja i ograničenja maksimalnih vrednosti upravljačkih signala.

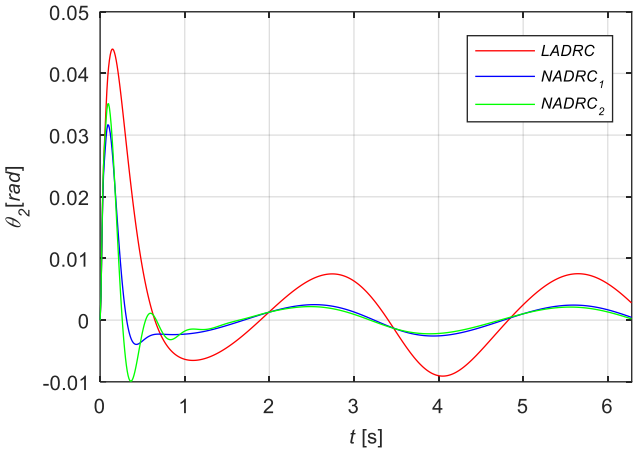
U okviru prvog scenarija je pretpostavljeno da je u potpunosti poznata vrednost parametara b_i, odnosno $\hat{b}_{o1} = b_{o1}$ i $\hat{b}_{o2} = b_{o2}$. Simulirani su odzivi sistema na referentnu pobudu $\theta_{r1} = \sin(2\pi t)$ dovedenu na prvi krak manipulatora. Dok je na drugi krak dovedena pobuda $\theta_{r2} = 0$. Performanse praćenja za sva tri tipa regulatora prikazane su na Sl. 3, dok su greške praćenja date na Sl. 4. Uticaj poremećaja na drugom kraku, koji je posledica unakrsnih veza prikazan je na Sl. 5.



Sl. 3. Performanse praćenja referentnog signala prvog kraka za scenario 1



Sl. 4. Greške praćenja referentnog signala prvog kraka za scenario 1



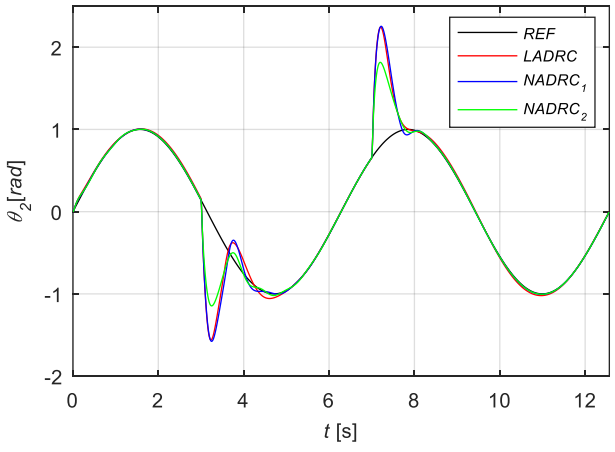
Sl. 5. Performanse praćenja referentnog signala drugog kraka za scenario 1

Sa slika se može uočiti da kod praćenja reference NADRC$_1$ i NADRC$_2$ imaju približno iste performanse sa aspekta brzine odziva, preskoka i vremena smirenja, dok LADRC ima lošije performanse. Takođe, može se uočiti da NADRC$_2$ ima nešto lošije performanse od NADRC$_1$ u toku prelaznog perioda kod potiskivanja poremećaja na drugom kraku manipulatora.

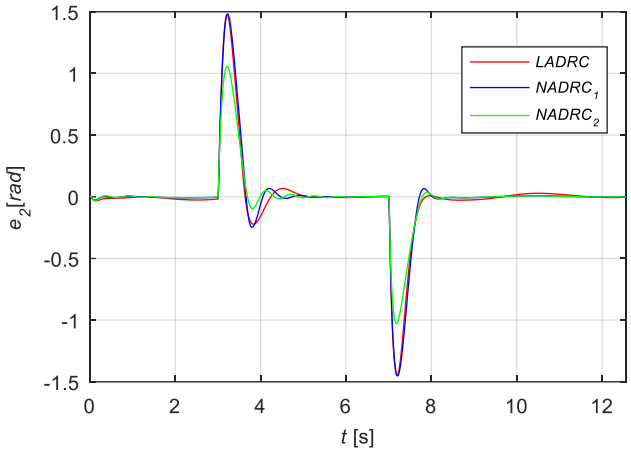
U okviru drugog scenarija je pretpostavljeno da je nepoznat model parametara b_i ($\hat{b}_{o1} = 2b_{o1}$ i $\hat{b}_{o2} = 2b_{o2}$) i simulirani odzivi na referentnu pobudu $\theta_{r2} = \sin(2\pi t)$ dovedenu na drugi krak manipulatora, a za prvi krak je podešeno $\theta_{r1} = 0$. Pored toga na oba kraka planarnog manipulatora je dodat poremećajni moment τ_{zi}

$$\tau_{zi} = \begin{cases} 5, & 3s \le t \le 7s \\ -1, & 7s < t \end{cases}. \tag{16}$$

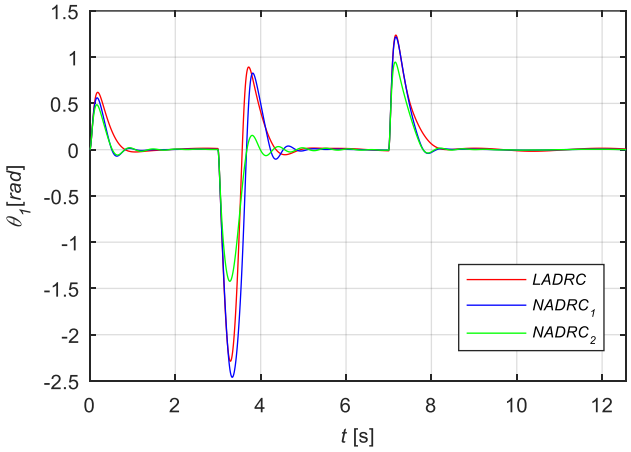
Performanse praćenja i greške praćenja date su na Sl. 6 i Sl. 7 respektivno, dok je uticaj poremećaja na prvom kraku prikazan na Sl. 8.



Sl. 6. Performanse praćenja referentnog signala drugog kraka za scenario 2



Sl. 7. Greške praćenja referentnog signala drugog kraka za scenario 2



Sl. 8. Performanse praćenja referentnog signala prvogog kraka za scenario 2

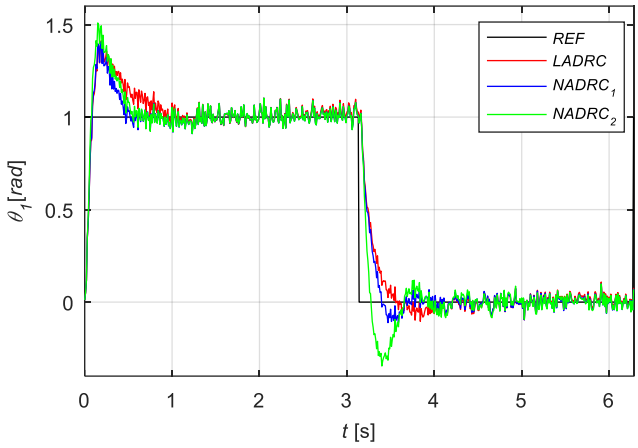
Sa slika se može uočiti da sva tri tipa regulatora zadržavaju zadovoljavajuće performanse uprkos značajnoj varijaciji parametara sistema. Takođe primećujemo da NADRC$_2$ sistem obezbeđuje najbolje potiskivanje poremećaja odskočnog tipa (najmanji preskok i najkraće vreme smirenja), što je posledica uvedenih nelinearnosti u diferencijalnom dejstvu regulatora.

Treći scenario je koncipiran tako da je zadržano nepoznavanje modela parametara b_i ($\hat{b}_{o1} = 2b_{o1}$ i $\hat{b}_{o2} = 2b_{o2}$), a simulirano je ponašanje sistema na referentne pobude

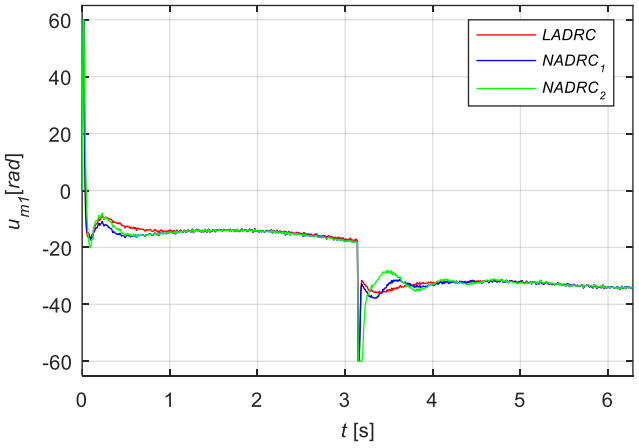
$$\theta_{r1} = \begin{cases} 1, & t \le T/2 \\ 0, & T/2 < t \le T \end{cases}, \; gde\ je\ T = 2\pi, \qquad (17)$$
$$\theta_{r2} = \sin(2\pi t).$$

Pored toga da bi uslove što više približili realnom sistemu dodat je šum merenja sa varijansom $\sigma_v^2 = 10^{-7}\, rad/s$ na oba kraka planarnog manipulatora i zasićenje upravljačkih signala aktuatora $\max(|u_{m1}|) = \max(|u_{m2}|) = \pm 60V$.

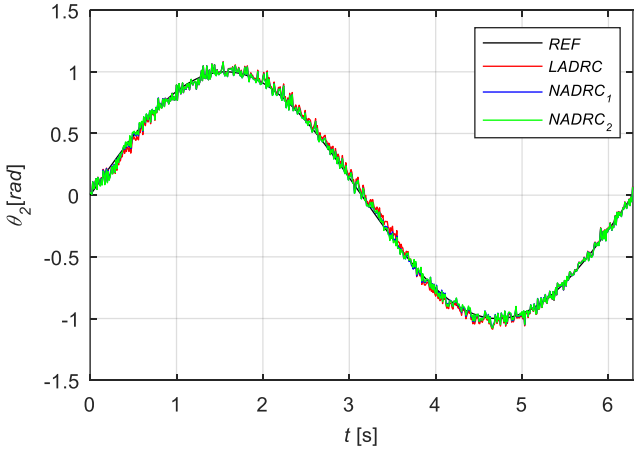
Karakteristike praćenja referentne pozicije prvog kraka date su na Sl. 9, a vrednosti upravljačkih signal odgovarajućih aktuatora na Sl. 10. Performanse praćenja i upravljački signali za drugi krak predstavljeni su na Sl. 11 i Sl. 12, respektivno.



Sl. 9. Performanse praćenja referentnog signala prvog kraka za scenario 3



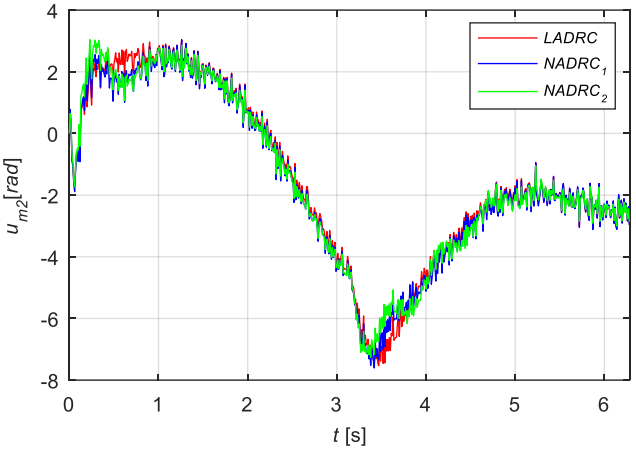
Sl. 10. Upravljački signal prvog kraka za scenario 3



Sl. 11. Performanse praćenja referentnog signala drugog kraka za scenario 3

Na osnovu izgleda upravljačkih signala (Sl. 10 i Sl. 12) se može zaključiti da regulatori imaju približno jednaku

osetljivost na šum merenja. U drugu ruku, ograničenje upravljačkih signala aktuatora ostvarilo je najveći uticaj na $NADRC_2$ (povećan preskok, duže vreme smirenja) i to u slučaju spoljašnjih odskočnih poremećaja, koji zahtevaju velike vrednosti upravljačkih signala.



Sl. 12. Upravljački signal drugog kraka za scenario 3

V. ZAKLJUČAK

U radu je izvršena analiza mogućnosti upravljanja planarnim manipulatorom primenom nelinearnog ADRC regulatora. Projektovanje upravljanja je realizovano pod pretpostavkom minimalnog poznavanja modela sistema. Detaljna simulaciona analiza je sprovedena kroz više upravljačkih scenarija za različite vrednosti parametara uvedenih nelinearnih funkcija. Rezultati su potvrdili prednosti nelinearnih algoritama u odnosu na linearne ADRC algoritme, kako u praćenju željene pozicije, tako i pri potiskivanju spoljašnjih poremećaja. Buduća istraživanja biće usmerena ka praktičnoj realizaciji razmatranih algoritama upravljanja, kao i na projektovanju složenijih proširenih opservera kako bi omogućilo potpuno potiskivanje šire klase totalnih poremećaja.

DODATAK

Parametri planarnog manipulatora:

L_1 =0.25 m L_2 =0.18 m
m_1 =0. 5 kg m_2 =0. 2 kg
η_1 =1/36 η_2 =1/20.25
J_1 =0.1 kg m^2 J_2 =0.1 kg m^2
F_1 =0.05 Nms/rad F_2 =0.05 Nms/rad

Parametri aktuatora:

R_i =20 Ω J_{mi} =0.01kg m^2 kg
k_{Ii} =1.5 Nm/A k_{ei} =1.5 V/rad/s

ABSTRACT

In this paper, Nonlinear Active Disturbance Rejection Control (NADRC) of planar robotic manipulator is proposed. Appalling ADRC approach, the complex nonlinear model of two inputs-two outputs planar manipulator system is transformed into two single input-single output (SISO) systems, including the cross-coupled dynamics in the total disturbance of two independent SISO systems. Further, the considered tracking problem is reformulated to regulation problem, and it is enabled the simpler structure of error-based NADRC controller. The detailed simulation analysis is shown the influence of the controller parameter setup on control performances.

Nonlinear Active Disturbance Rejection Control of Planar Robot Manipulator

Stabilnost linearnih dinamičkih sistema sa vremenskim kašnjenjem

Vukan Turkulov, Milan R. Rapaić, Rachid Malti

***Apstrakt*—U ovom radu bavimo se problemom određivanja oblasti stabilnosti linearnih, vremenski invarijantnih sistema sa višestrukim vremenskim kašnjenjima. Prikazani metod je iterativan, a zasniva se na primeni Rošeove teoreme i fundamentalne teoreme matematičke analize. Izlaganja su ilustrovana primerom.**

***Ključne reči*: stabilnost; analiza sistema; vremensko kašnjenje.**

I. Uvod

Stabilnost je jedna od osnovnih karakteristika dinamičkih sistema. Stabilnost linearnih, vremenski invarijantnih (Linear Time Invariant, LTI) sistema konačne dimenzije može se odrediti pomoću nula karakteristične jednačine sistema. Sistemi beskonačne dimenzije, kako im i samo ime kaže, imaju neograničen broj rešenja karakteristične jednačine. Otuda je za ovakve sisteme nepogodno, a najčešće i nemoguće, ispitivati stabilnosti direktnom proverom položaja svakog pola.

Među najčešće sretanim sistemima beskonačne dimenzije su sistemi sa vremenskim kašnjenjem. Karakteristična funkcija ovakvih sistema može se u opštem obliku zapisati kao

$$f(s, e^{-s\tau_1}, e^{-s\tau_2}, \ldots, e^{-s\tau_n}), \tag{1}$$

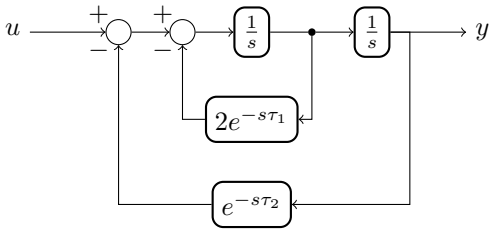
gde vrednosti $\tau_1, \tau_2, \ldots, \tau_n$ predstavljaju čista vremenska kašnjenja prisutna u sistemu. Pogodno je sva kašnjenja predstaviti jednim vektorom $\boldsymbol{\tau} = [\tau_1, \tau_2, \ldots, \tau_n]$. Od značaja je ispitati stabilnost sistema u zavisnosti od parametara $\boldsymbol{\tau}$, odnosno odrediti oblast stabilnosti sistema u prostoru parametara $\boldsymbol{\tau}$.

Ukoliko sistem poseduje vremensko kašnjenje isključivo na ulazu i/ili izlazu, funkcija prenosa sistema je oblika $G_0(s) = G(s)e^{-s\tau}$, gde je $G(s)$ racionalna funkcija prenosa. Stabilnost takvih sistema konvencionalno se ispituje Nikvistovim kriterijumom [1]. Metode za analizu nekih klasa sistema sa kašnjenjem predstavljene su u [2] [3] [4] i [5]. Interesantan alternativan pristup koji se zasniva na GMK prikazan je u [6].

Cilj ovog rada je uvođenje opšteg iterativnog postupka (algoritma) za analizu stabilnosti LTI sistema sa višestrukim vremenskim kašnjenjima. Bez gubitka opštosti, u ovom radu ćemo postupak primeniti na primer sistema sa višestrukim kašnjenjem opisan sledećim matematičkim modelom u prostoru stanja

$$\begin{aligned} \dot{x_1} &= -2x_1(t-\tau_1) - x_2(t-\tau_2) + u \\ \dot{x_2} &= x_1 \\ y &= x_2 \end{aligned} \tag{2}$$

gde je t vreme, x_1 i x_2 promenljive stanja sistema, u ulazni signal, y izlazni signal, a τ_1 i τ_2 čista vremenska kašnjenja. Blok dijagram sistema opisanog ovim modelom prikazan je na slici 1.



Slika 1. Blok dijagram sistema opisanog modelom (2).

Prilagodićemo pristup razvijen za analizu stabilnosti frakcionih sistema predložen u [7] i [8]. Postupak se zasniva na poznavanju neke određene vrednosti parametara $\boldsymbol{\tau^0}$ za koje je sistem stabilan. Počevši od date vrednosti $\boldsymbol{\tau^0}$, iterativno određujemo vrednosti $\boldsymbol{\tau}$ za koje je sistem takođe stabilan. Na ovaj način pravimo "skokove" po određenoj pravoj u prostoru parametara $\boldsymbol{\tau}$, garantujući da je sistem stabilan na svakom "preskočenom" intervalu.

Rad je podeljen u sledeće celine. U poglavlju II prikazana je matematička osnova predloženog postupka. U poglavlju III nalazi se primena predloženog postupka na sistem opisan modelom 2. Zaključak je dat u poglavlju IV.

II. Opis algoritma

Predloženi postupak vrši analizu stabilnosti sistema duž odabrane prave u prostoru parametara $\boldsymbol{\tau}$. Pogodno je kretanje po odabranoj pravoj opisati jednim realnim parametrom θ kao

$$\boldsymbol{\tau} = \boldsymbol{\tau_0} + \theta\boldsymbol{\tau_p} \tag{3}$$

gde je $\boldsymbol{\tau_0}$ tačka kroz koju prolazi odabrana prava, a $\boldsymbol{\tau_p}$ jedinični vektor paralelan sa odabranom pravom. Stabilnost sistema dalje možemo diskutovati u zavisnosti od parametra θ. Postupak možemo potom primenjivati na proizvoljan broj pravih u prostoru parametara $\boldsymbol{\tau}$, analizirajući stabilnost duž svake od njih.

Slika 2. Grafički prikaz konture $\mathcal{C}$ u kompleksnoj s ravni

Na odabranoj pravoj, karakterističnu funkciju sistema možemo preko novouvedenog parametra θ izraziti kao $f(s,\theta)$. Pretpostavka postupka je poznavanje neke vrednosti θ_0 za koju je sistem stabilan. Za takvo θ_0, funkcija $f(s,\theta_0)$ nema nijednu nulu u desnoj kompleksnoj poluravni. Takođe, pretpostavljamo da je funkcija $f(s,\theta)$ analitička u desnoj kompleksnoj poluravni za svaku vrednost parametra θ.

Predloženi postupak se oslanja na Rošeovu teoremu [9], koja je formulisana na sledeći način:

Teorema 1. Ukoliko za dve kompleksne funkcije f i g koje su holomorfne unutar zatvorene konture $\mathcal{K}$ važi $|g(s)| < |f(s)|$ za svako s na konturi $\mathcal{K}$, onda funkcije f i $f+g$ imaju isti broj nula unutar konture $\mathcal{K}$.

Rošeovu teoremu možemo primeniti na karakterističnu funkciju $f(s,\theta)$ i konturu $\mathcal{C}$ koja obuhvata celu desnu poluravan, kao što je prikazano na slici 2. Kontura $\mathcal{C}$ se sastoji iz dva segmenta - imaginarne ose gde je $s = j\omega$ za $\omega \in \mathbb{R}$, i polukruga beskonačnog poluprečnika gde je $s = \rho e^{j\varphi}$ za $\rho \to \infty, \varphi \in [-\frac{\pi}{2}, \frac{\pi}{2}]$.

Ukoliko je $|f(s,\theta) - f(s,\theta_0)| < |f(s,\theta_0)|$ za svako $s \in \mathcal{C}$, onda $f(s,\theta)$ i $f(s,\theta_0)$ imaju isti broj nula u desnoj poluravni. S obzirom na to da $f(s,\theta_0)$ nema nijednu nulu u desnoj poluravni, ovaj uslov bi garantovao da ni $f(s,\theta)$ nema nijednu nulu u desnoj poluravni. Dakle, sistem je sigurno stabilan za one vrednosti parametra θ za koje važi

$$|f(s,\theta) - f(s,\theta_0)| < |f(s,\theta_0)|, \forall s \in \mathcal{C}. \tag{4}$$

U interesu nam je da pronađemo što veću vrednost θ za koju važi uslov (4). Pored toga, uslov (4) predstavlja konzervativnu granicu stabilnosti, što ćemo ilustrovati sledećim primerom: recimo da postoji θ_1 takvo da nejednakost (4) važi za $\theta \in [\theta_0, \theta_1]$, a ne važi za $\theta > \theta_1$. Drugim rečima, θ_1 je najveća vrednost parametra θ za koju je uslov Rošeove teoreme ispunjen. Na osnovu te činjenice možemo zaključiti da je sistem sigurno stabilan za $\theta \in [\theta_0, \theta_1]$. Međutim, moguće je da postoji neko $\theta > \theta_1$ za koju je sistem takođe stabilan, iako uslov (4) nije ispunjen. Upravo je ovo razlog zbog kog je predloženi postupak iterativan. Kada pronađemo vrednost θ_1 za koju je sistem sigurno stabilan, ponavljamo postupak tražeći novu vrednost θ_2 za koju važi nejednakost $|f(s,\theta_2) - f(s,\theta_1)| < |f(s,\theta_1)|, \forall s \in \mathcal{C}$. Na ovaj način iterativno pravimo korake kroz prostor parametara, pri čemu možemo sa sigurnošću da tvrdimo da je sistem stabilan u svakom pređenom koraku.

Posmatrajmo sada uslov (4). Jednostavno je dokazati da data nejednakost važi na kružnom luku konture $\mathcal{C}$ ukoliko koeficijent uz najveći stepen promenljive s karakteristične funkcije sistema ne zavisi od parametra θ. Izazov je pokazati za koju vrednost θ data nejednakost važi na segmentu konture koji se poklapa sa imaginarnom osom. Primetimo da je funkcija $f(s,\theta)$ simetrična u odnosu na realnu osu za sve sisteme sa realnim koeficijentima. Zbog toga je dovoljno proveriti da li je uslov Rošeove teoreme ispunjen na gornjoj polovini imaginarne ose. Ovime se problem svodi na određivanje vrednosti θ za koje važi

$$|f(j\omega,\theta) - f(j\omega,\theta_0)| < |f(j\omega,\theta_0)|, \forall \omega \in \mathbb{R}^+. \tag{5}$$

Nažalost, kao što ćemo pokazati u poglavlju III, nejednakosti ovog oblika uglavnom nisu pogodne za rad. Iskoristićemo fundamentalnu teoremu analize [10] kako bismo dobili nejednakosti koje su konzervativnije, ali pogodnije za rad.

Teorema 2. Neka su $f(x)$ i $F(x)$ funkcije realne promenljive na zatvorenom intervalu $[a,b]$, tako da važi

$$F'(x) = f(x). \tag{6}$$

Ukoliko je funkcija f integrabilna na intervalu $[a,b]$, onda važi

$$\int_a^b f(x)dx = F(b) - F(a). \tag{7}$$

Fundamentalnu teoremu analize ćemo primeniti na levu stranu nejednakosti (5). Iako je f kompleksna funkcija, duž imaginarne ose je možemo posmatrati kao funkciju realne promenljive ω, koristeći zapis

$$f(j\omega,\theta) = f(\omega,\theta) = f_R(\omega,\theta) + jf_I(\omega,\theta) \tag{8}$$

gde su $f_R(\omega,\theta)$ i $f_I(\omega,\theta)$ realni i imaginarni delovi funkcije $f(\omega,\theta)$. Primenom fundamentalne teoreme na izraz sa leve strane nejednakosti (5) dobijamo

$$f(j\omega,\theta) - f(j\omega,\theta_0) = \int_{\theta_0}^{\theta} \frac{\partial f_R}{\partial \theta}(\omega,\beta)d\beta + j\int_{\theta_0}^{\theta} \frac{\partial f_I}{\partial \theta}(\omega,\beta)d\beta = \int_{\theta_0}^{\theta} \frac{\partial f}{\partial \theta}(\omega,\beta)d\beta \tag{9}$$

Uvrštavanjem dobijenog izraza, nejednakost (5) postaje

$$\left| \int_{\theta_0}^{\theta} \frac{\partial f}{\partial \theta}(j\omega,\beta)d\beta \right| < |f(j\omega,\theta_0)|, \forall \omega \in \mathbb{R}^+. \tag{10}$$

Iako nam je u interesu da pronađemo što veće θ za koje nejednakost važi, možemo radi jednostavnosti uzeti konzervativniju vrednost θ za koju možemo da tvrdimo da nejednakost važi. Kao posledica korišćenja konzervativnih vrednosti i nejednakosti, "skokovi" koje vršimo duž posmatrane prave biće manji. Drugim rečima, što konzervativnije vrednosti uzimamo, biće potrebno više iteracija da "pređemo" isti interval duž posmatrane prave.

Uzimajući to u obzir, levu stranu nejednakosti (10) možemo zameniti konzervativnijim izrazima

$$\left| \int_{\theta_0}^{\theta} \frac{\partial f}{\partial \theta}(j\omega, \beta) d\beta \right| \leq \int_{\theta_0}^{\theta} \left| \frac{\partial f}{\partial \theta}(j\omega, \beta) \right| d\beta \tag{11}$$

$$\int_{\theta_0}^{\theta} \left| \frac{\partial f}{\partial \theta}(j\omega, \beta) \right| d\beta \leq \left(\max_{\theta_0 \leq \beta \leq \theta} \left| \frac{\partial f}{\partial \theta}(j\omega, \beta) \right| \right) (\theta - \theta_0). \tag{12}$$

Uvođenjem smene $\Delta\theta = \theta - \theta_0$ koja predstavlja promenu ili "pomeraj" parametra θ i primenom konzervativnijih granica, nejednakost (10) postaje

$$\Delta\theta < \frac{|f(j\omega, \theta_0)|}{\max\limits_{\theta_0 \leq \beta \leq \theta} \left| \frac{\partial f}{\partial \theta}(j\omega, \beta) \right|}, \forall \omega \in \mathbb{R}^+. \tag{13}$$

Dakle, ako nejednakost (13) važi za neki pomeraj $\Delta\theta$, sistem će biti stabilan za $\theta = \theta_0 + \Delta\theta$. Pošto nejednakost mora da važi za svako $\omega \in \mathbb{R}^+$, "dozvoljene" korake možemo izraziti uzimajući u obzir najmanju moguću vrednost izraza sa desne strane nejednakosti:

$$\Delta\theta < \min_{\omega} \frac{|f(j\omega, \theta_0)|}{\max\limits_{\theta_0 \leq \beta \leq \theta} \left| \frac{\partial f}{\partial \theta}(j\omega, \beta) \right|} \tag{14}$$

Opšti pregled postupka za analizu stabilnosti sistema sa karakterističnom funkcijom $f(s, \theta)$ prikazan je kao Algoritam 1. Promenljiva ε koristi se kao kriterijum zaustavljanja algoritma.

Algoritam 1: Opšti pregled algoritma

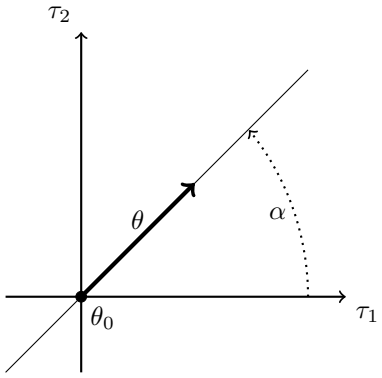
$\theta_k = \theta_0$;
$\Delta\theta = \infty$;
while $\Delta\theta > \varepsilon$ **do**
  $\Delta\theta = \min\limits_{\omega} \dfrac{|f(j\omega, \theta_k)|}{\max_{\theta_k \leq \beta \leq \theta} \left| \frac{\partial f}{\partial \theta}(j\omega, \beta) \right|}$;
  $\theta_k = \theta_k + \Delta\theta$;

III. Primer

Postupak ćemo primeniti na sistem sa karakterističnom funkcijom

$$f(s, \tau_1, \tau_2) = s^2 + 2se^{-s\tau_1} + e^{-s\tau_2}. \tag{15}$$

Stabilnost ispitujemo duž jedne prave u ravni parametara $\tau_1 O \tau_2$, kao što je prikazano na slici 3. Prava prolazi kroz



Slika 3. Ravan parametara $\tau_1 O \tau_2$

koordinatni početak, i određena je uglom α. Kretanje po pravoj opisujemo parametrom θ, tako da važi

$$\begin{aligned} \tau_1 &= \theta \cos(\alpha) \\ \tau_2 &= \theta \sin(\alpha) \end{aligned} \tag{16}$$

Radi preglednijeg zapisa, koristićemo oznake $a_1 = \cos(\alpha)$ i $a_2 = \sin(\alpha)$. Karakteristični polinom sistema izražen u zavisnosti od parametra θ je

$$f(s, \theta) = s^2 + 2se^{-sa_1\theta} + e^{-sa_2\theta}. \tag{17}$$

Za $\theta_0 = 0$, lako je utvrditi da je sistem stabilan. Za primenu algoritma neophodno je dokazati da nejednakost (4) važi na luku konture $\mathcal{C}$. U našem primer, nejednakost (4) postaje

$$\begin{aligned} &\left| 2s\left(e^{-sa_1\theta} - e^{-sa_1\theta_0}\right) + \left(e^{-sa_2\theta} - e^{-sa_2\theta_0}\right) \right| \\ &\qquad < \left| s^2 + 2se^{-sa_1\theta_0} + e^{-sa_2\theta_0} \right|. \end{aligned} \tag{18}$$

Smenom $s = \rho e^{j\varphi}$ za $\rho \to \infty, \varphi \in [-\frac{\pi}{2}, \frac{\pi}{2}]$, nejednakost (18) je očigledno ispunjena za bilo koju vrednost parametara θ i α zbog većeg stepena promenljive s u desnoj strani nejednakosti u odnosu na levu.

Ovde ukazujemo na razlog za korišćenje fundamentalne teoreme analize. Dokazivanje nejednakosti (18) na imaginarnoj osi za $s = j\omega$ nije jednostavno. Primenom fundamentalne teoreme analize dobijamo nejednakosti sa kojima je jednostavnije raditi. U skladu sa tim, dozvoljeni korak $\Delta\theta$ određujemo iz nejednakosti (14) umesto direktno iz (18).

Naravno, veličina koraka u opštem slučaju zavisi od parametara θ i α. Prvo ćemo da posmatramo imenilac iz nejednakosti (14) koji možemo označiti sa

$$c = \frac{1}{\max_{\theta_0 \leq \beta \leq \theta} \left| \frac{\partial f}{\partial \theta}(j\omega, \beta) \right|}. \tag{19}$$

Diferenciranjem funkcije $f(s, \theta)$ i smenom $s = j\omega$ dobijamo

$$\frac{\partial f}{\partial \theta} = 2\omega^2 a_1 e^{-j\omega a_1\theta} - j\omega a_2 e^{-j\omega a_2\theta}. \tag{20}$$

Apsolutna vrednost ovog izraza je

$$\left| \frac{\partial f}{\partial \theta} \right| = \sqrt{A^2 + B^2}, \tag{21}$$

gde je

$$\begin{aligned} A &= 2\omega^2 a_1 \cos(\omega a_1 \theta) - \omega a_2 \sin(\omega a_2 \theta) \\ B &= -2\omega^2 a_1 \sin(\omega a_1 \theta) - \omega a_2 \cos(\omega a_2 \theta) \end{aligned} \tag{22}$$

Dalje računamo vrednost c određenu izrazom (19). Pošto vrednost c figuriše u izrazu čiju minimalnu vrednost tražimo, možemo umesto tačne vrednosti promenljive c koristiti njenu konzervativniju granicu:

$$\begin{aligned} c &= \frac{1}{\max_{\theta_0 \le \beta \le \theta} \left| \frac{\partial f}{\partial \theta}(j\omega, \beta) \right|} \\ &\ge \frac{1}{\max_{\beta \in \mathbb{R}} \left| \frac{\partial f}{\partial \theta}(j\omega, \beta) \right|} \\ &\ge \frac{1}{\left| 2\omega^2 a_1 + \omega a_2 + j(2\omega^2 a_1 + \omega a_2) \right|} \\ &= \frac{1}{\sqrt{2}(2a_1\omega^2 + a_2\omega)} \end{aligned} \tag{23}$$

Sada nejednakost (14) postaje

$$\Delta\theta < \frac{1}{\sqrt{2}} \min_{\omega} \frac{|f(j\omega, \theta_0)|}{2a_1\omega^2 + a_2\omega}. \tag{24}$$

Računanjem apsolutne vrednosti u brojiocu, nejednakost postaje

$$\Delta\theta < \frac{1}{\sqrt{2}} \min_{\omega} \frac{(\omega^4 - 4\omega^3 s_1 + \omega^2(4 - 2c_2) + 4\omega s_\alpha + 1)^{\frac{1}{2}}}{2a_1\omega^2 + a_2\omega}. \tag{25}$$

gde je $s_1 = \sin(a_1\omega\theta_0)$, $c_2 = \cos(a_2\omega\theta_0)$ i $s_\alpha = \sin(\sqrt{2}\omega\theta_0 \cos(\alpha + \frac{\pi}{4}))$. Traženje minimuma ovog izraza bi u opštem slučaju bilo složeno, te ćemo opet tražiti konzervativniju granicu minimuma. Primetimo da za izraz od kog tražimo minimum važi

$$\begin{aligned} &\frac{(\omega^4 - 4\omega^3 s_1 + \omega^2(4 - 2c_2) + 4\omega s_\alpha + 1)^{\frac{1}{2}}}{2a_1\omega^2 + a_2\omega} \\ &\ge \frac{(\omega^4 - 4\omega^3 + 2\omega^2 - 4\omega + 1)^{\frac{1}{2}}}{2\omega^2 + \omega} = g(\omega). \end{aligned} \tag{26}$$

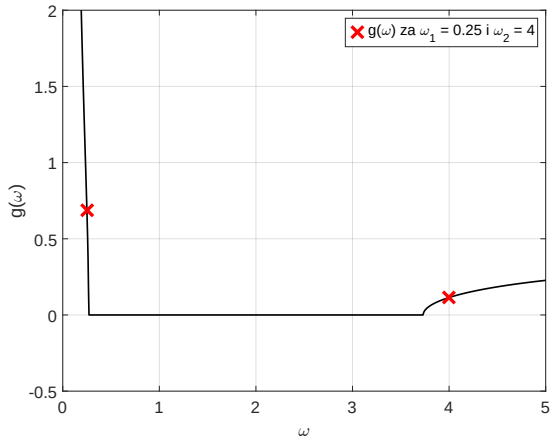
Nejednakost je dobijena uzimajući u obzir činjenicu da sinusne i kosinusne funkcije uzimaju vrednosti u intervalu $[-1, 1]$ (podsećamo da su a_1 i a_2 takođe prostoperiodične funkcije).

Lako je utvrditi da za $\omega \in (0, \frac{1}{4}] \cup [4, \infty)$ važi

$$\frac{(\omega^4 - 4\omega^3 + \omega^2 - 4\omega + 1)^{\frac{1}{2}}}{2\omega^2 + \omega} > 0.1. \tag{27}$$

Ovo tvrđenje je ilustrovano slikom 4. Skrećemo pažnju na činjenicu da je izraz pod korenom brojioca u (25) sigurno nenegativan. Uzimanjem najmanjih mogućih vrednosti trigonometrijskih funkcija, u korenu brojioca funkcije $g(\omega)$ dobijen je polinom koji je negativan za neke vrednosti promenljive ω. Zbog toga vrednost funkcije $g(\omega)$ može biti kompleksna. Prilikom crtanja ove funkcije, na mestima gde funkcija poprima kompleksne vrednosti nacrtana je vrednost 0.

Na osnovu (27) zaključujemo da je i vrednost izraza pod minimumom u nejednakosti (25) veća od 0.1 za $\omega \in (0, \frac{1}{4}] \cup [4, \infty)$. Dalje ćemo minimum tražiti na intervalu $\omega \in [\frac{1}{4}, 4]$. Zbog ograničenosti intervala, možemo uvesti gornje ograničenje na vrednost imenioca i tvrditi



Slika 4. Prikaz funkcije $g(\omega)$

$$\begin{aligned} &\frac{1}{\sqrt{2}} \min_{\omega \in [\frac{1}{4}, 4]} \frac{(\omega^4 - 4\omega^3 s_1 + \omega^2(4 - 2c_2) + 4\omega s_\alpha + 1)^{\frac{1}{2}}}{2a_1\omega^2 + a_2\omega} \ge \\ &\frac{1}{36\sqrt{2}} \Big(\min_{\omega \in [\frac{1}{4}, 4]} (\omega^4 - 4\omega^3 s_1 + \omega^2(4 - 2c_2) + 4\omega s_\alpha + 1) \Big)^{\frac{1}{2}}. \end{aligned} \tag{28}$$

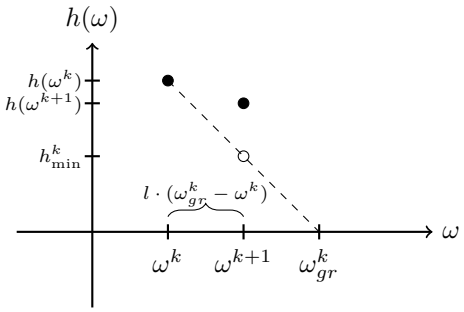
Problem se sada svodi na određivanje minimuma izraza $h(\omega) = \omega^4 - 4\omega^3 s_1 + \omega^2(4 - 2c_2) + 4\omega s_\alpha + 1$ na intervalu $\omega \in [\frac{1}{4}, 4]$. Zbog ograničenosti intervala, moguće je pronaći gornju granicu za vrednost izvoda funkcije h na posmatranom intervalu:

$$\max_{\omega \in [\frac{1}{4}, 4]} \left| \frac{dh}{d\omega} \right| \le 500 + |\theta_0|(256a_1 + 32a_2 + 16\sqrt{2}|a_3|) \tag{29}$$

Izvedenu gornju granicu izvoda funkcije h ćemo označiti simbolom γ. Koristeći ovu činjenicu, moguće je numerički pronaći donju granicu minimuma funkcije $h(\omega)$ na intervalu $\omega \in [\frac{1}{4}, 4]$. Počnimo od tačke $\omega = \frac{1}{4}$. Računanjem vrednosti funkcije u toj tački (koja je sigurno pozitivna) i poznavajući gornju granicu izvoda funkcije na datom intervalu, zaključujemo da je funkcija $h(\omega)$ sigurno veća ili jednaka nuli na intervalu $\omega \in [\frac{1}{4}, \frac{h(\frac{1}{4})}{\gamma}]$. Najveću vrednost ω za koju možemo da tvrdimo da važi $h(\omega) \ge 0$ označićemo sa $\omega_{gr} = \frac{h(\frac{1}{4})}{\gamma}$. Možemo uzeti proizvoljan broj iz intervala $[\frac{1}{4}, \omega_{gr})$ kao novu vrednost promenljive ω, i ponoviti postupak. Na ovaj način iterativno prelazimo interval $[\frac{1}{4}, 4]$, uvek birajući novu vrednost promenljive ω po pravilu

$$\omega^{k+1} = \omega^k + l(\omega_{gr}^k - \omega^k), \tag{30}$$

gde promenljiva $l \in (0, 1)$ određuje na koji način biramo novu vrednost ω^{k+1} iz dozvoljenog intervala $[\omega^k, \omega_{gr}^k]$.



Slika 5. Grafički prikaz numeričkog traženja minimuma

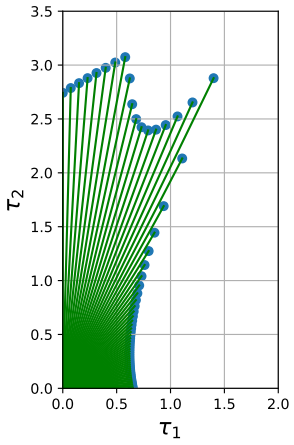
Donju granicu minimuma prilikom svakog koraka ažuriramo po pravilu

$$h^k_{\min} = \min\left(h^{k-1}_{\min},\ (1-l)h(\omega^k)\right). \tag{31}$$

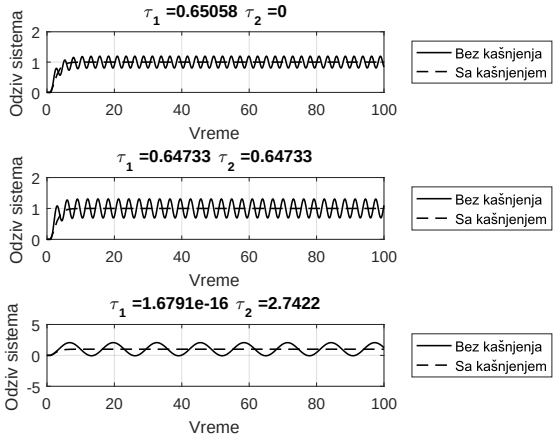
Jedna iteracija ovog postupka grafički je prikazana na slici 5. Zanimljivo je proučiti uticaj parametra l na efikasnost algoritma. Što je l veće, broj iteracija neophodnih da se "pređe" interval $[\frac{1}{4}, 4]$ biće manji, ali će dobijena donja granica minimuma biti konzervativnija. Tokom eksperimenata smo za vrednost ovog parametra koristili $l = \frac{1}{2}$.

Koristeći navedene postupke, moguće je implementirati Algoritam 1 za primer koji smo analizirali u ovom radu. Dati algoritam pronalazi granicu stabilnosti duž jedne prave u ravni parametara $\tau_1 O \tau_2$. Na slici 6 nalazi se grafički prikaz rezultata algoritma primenjenog na više prava u ravni parametara, koristeći kriterijum zaustavljanja $\varepsilon = 10^{-5}$. Računarski kod koji reprodukuje dobijene rezultate javno je dostupan na repozitorijumu https://github.com/Moon-Raven/stability_analysis. Numeričkom simulacijom moguće je proveriti stabilnost krajnje tačke sa svake prave, kako bi se utvrdio ispravan rad algoritma. Rezultati simulacije za tri takve tačke prikazani su na slici 7. Za svaku tačku dat je uporedan prikaz odziva sistema bez kašnjenja i sa kašnjenjima odgovarajućim za tu tačku. U svim slučajevima sistem je pobuđen step funkcijom $u(t) = h(t)$.

U ovom relativno jednostavnom primeru, stabilnost je moguće ispitati i iterativnom primenom Nikvistovog kriterijuma. Diskutovaćemo dobijene rezultate i na ovaj način, u cilju dodatne verifikacije dobijene oblasti stabilnosti. Posmatrani sistem sadrži unutrašnju i spoljašnju petlju, kao što se vidi na slici 1. Zbog toga je neophodno Nikvistov kriterijum primeniti prvo na unutrašnju petlju sistema, potom na spoljašnju. Na slici 8 prikazani su Nikvistovi dijagrami za tri odabrane tačke iz ravni parametara. Sve tri tačke pripadaju pravoj određenoj uglom $\alpha = \frac{\pi}{4}$ i za svaku tačku su prikazani dijagrami unutrašnje i spoljašnje petlje. Na osnovu skicirane oblasti stabilnosti sa slike 6, očekivano je da se prva tačka nalazi unutar oblasti stabilnosti, da je druga tačka bliska granici stabilnosti i da je treća tačka nestabilna. Prikazani Nikvistovi dijagrami potvrđuju očekivane rezultate; unutrašnja petlja sistema je uvek stabilna, ali je spoljašnja petlja granično stabilna za drugu i nestabilna za treću tačku.



Slika 6. Grafički prikaz rezultata

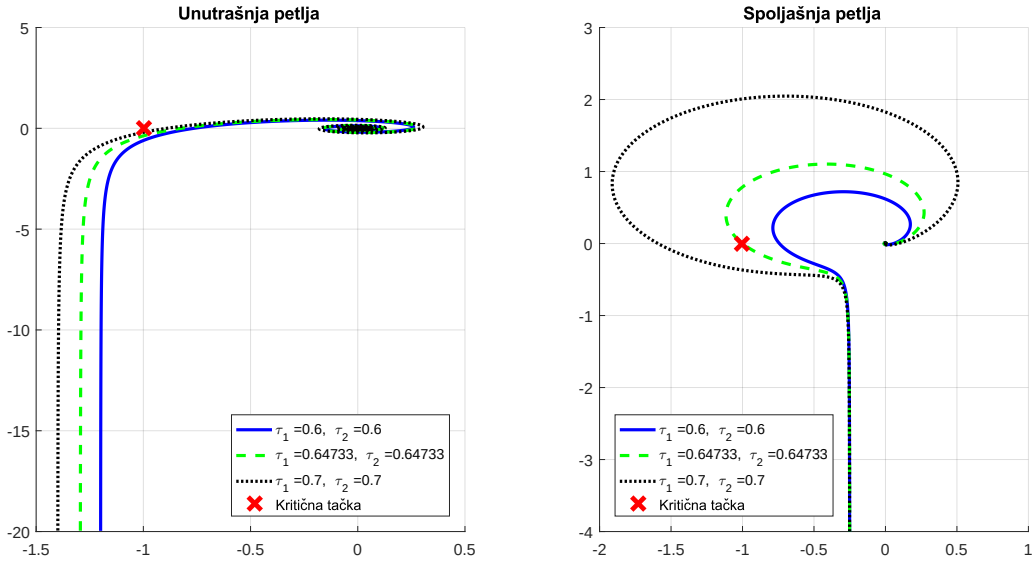


Slika 7. Numerička simulacija krajnjih tačaka intervala

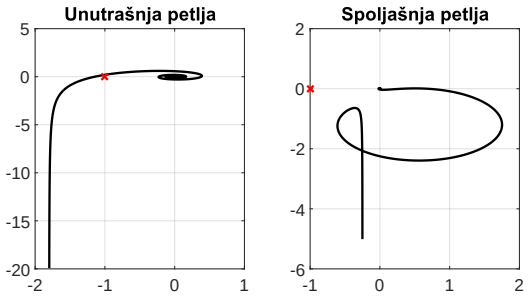
Ovde ukazujemo i na činjenicu da je za diskusiju Nikvistovog dijagrama spoljašnje petlje potrebno poznavati broj nestabilnih polova unutrašnje petlje. Drugim rečima, neophodno je porediti broj obuhvata oko kritične tačke za spoljašnju i unutrašnju petlju. Ovo ćemo ilustrovati Nikvistovim dijagramima posmatranog sistema za kašnjenja $\tau_1 = \tau_2 = 0.8$. Odgovarajući dijagrami su prikazani na slici 9. Činjenica da Nikvistova kriva spoljašnje petlje ne obuhvata kritičnu tačku $-1 + 0j$ nam ukazuje na to da je sistem nestabilan, zbog toga što Nikvistova kriva unutrašnje petlje obuhvata kritičnu tačku jednom.

IV. Zaključak

U ovom radu smo prikazali algoritam za ispitivanje stabilnosti dinamičkih sistema sa višestrukim vremenskim kašnjenjima. Iako je postupak ilustrovan na primeru sistema sa dva vremenska kašnjenja, jasno je da se na direktan način može proširiti i na sisteme sa većim brojem kašnjenja. Prikazanim postupkom, stabilnost se ispituje duž fiksiranih



Slika 8. Nikvistovi dijagrami spoljašnje i unutrašnje petlje za tri odabrane tačke iz ravni parametara



Slika 9. Nikvistovi dijagrami sistema za $\tau_1 = \tau_2 = 0.8$

pravaca u prostoru kašnjenja. Međutim, kao što je pokazano u radu, uzastopnom primenom na niz ovakvih pravaca moguće je skicirati oblik oblasti stabilnosti.

U daljem radu, bavićemo se proširenjem prikazanog algoritma. Konkretno, bavićemo se stabilnošću šire klase sistema sa beskonačno stepeni slobode, uključujući i sisteme sa distribuiranim parametrima. Takođe, po ugledu na [7] i [8], bavićemo se proširenjem algoritma kojom se stabilnosti direktno garantuje u oblasti, a ne samo duž pravca.

Abstract

This paper focuses on the problem of obtaining a stability region of linear, time-invariant systems with multiple time delays. The presented method is iterative and is based on the application of the Rouché's theorem and the fundamental theorem of calculus. The method is illustrated with an example.

Stability of linear dynamical sistems with time delays

***Apstrakt*—U radu se razmatra problem podešavanja dinamike u kliznom režimu višeg reda kod linearnih sistema sa jednim ulazom. Predložena je metoda izbora klizne površi koja istovremeno obezbeđuje neophodni relativni red klizne promenljive za željeni klizni režim višeg reda, kao i željenu dinamiku po uspostavljanju datog kliznog režima. Pokazano je da je rešenje ovog problema jedinstveno i dat jednostavan način za njegovo nalaženje. Teorijski dobijeni rezultati su potvrđeni na numeričkim primerima i ilustrovani simulacionim rezultatima.**

***Ključne reči*—Klizni režimi višeg reda; Projektovanje klizne površi; Dinamika sistema u kliznom režimu; Podešavanje polova.**

I. Uvod

Sistemi upravljanja promenljive strukture (SUPS) sa kliznim radnim režimom (KR) [1,2] su jedna od značajnijih tehnika robusnog upravljanja zbog teorijske invarijantnosti u KR na poremećaje koji deluju u prostoru vektora upravljanja [3]. Ova osobina se u praktičnim realizacijama svodi na veliku robusnost sistema na parametarske i spoljne poremećaje. Osnovna prepreka širokoj primeni ove upravljačke tehnike je pojava tzv. četeringa usled neidelanosti prekidačkih elemenata u sistemu i nemodelovane dinamike. Ovaj neželjeni efekat se ispoljava kroz pojavu visokofrekvencijskih oscilacija, nedopustivih u nekim primenama.

U sklopu pokušaja pronalaženja načina za redukciju četeringa nastao je koncept KR višeg reda [4]. KR višeg reda su najpre razmatrani u sistemima sa jednim ulazom, a potom u sistemima sa više ulaza kao i u sistemima sa vremenski diskretnom obradom informacija [5-8]. Najznačajni rezultati su postignuti kod KR drugog reda [9,10].

Prvi korak u projektovanju SUPS je izbor klizne površi, tj. klizne promenljive. Ovim izborom se definiše željena dinamika sistema u KR duž te površi. Kod konvencionalnih KR (KR prvog reda) relativni red klizne promenljive mora biti jednak jedinici. Predloženo je nekoliko metoda izbora klizne promenljive koja obezbeđuje željenu dinamiku u KR prvog reda. Jedan pristup je transformacija sistema u tzv. regularnu formu [2] u kojoj je redukovana dinamika kliznog režima jasno uočljiva. U slučaju sistema sa jednim ulazom, moguće je projektovati kliznu površ bez transformacije sistema na način koji se bazira na primeni Akermanove formule [11]. Međutim, razvijena je i sveobuhvatna metoda kojom se takođe bez tranformacije sistema jodnostavno projektuje klizna površ za sisteme sa jednim ili više ulaza [12,13].

U slučaju KR višeg reda, relativni red klizne promenljive mora biti jednak redu KR. Dakle, u projektovanju klizne površi treba ostvariti dvojaki zadatak. Obezbediti željenu dinamiku redukovanog reda u KR i istovremeno zadovoljiti preduslov potrebnog relativnog reda klizne promenljive. Mali je broj radova koji tretiraju ovu problematiku, i do sada su posmatrani sistemi sa jednim ulazom. Generalizacija formule Akerman-Utkin [11] za projektovanje klizne površi proizvoljnog relativnog reda sa ciljem podešavanja dinamike sistema izvršena je u [14,15].

U ovom radu je predložen još jedan način projektovanja klizne površi KR višeg reda u sistemima sa jednim ulazom. Ova metoda se bazira na pristupu [12,13] koji se zasniva na analogiji sa projektovanjem standardne povratne sprege po stanju. Pored zahteva da se KR r-tog reda ostvari predefinisana redukovana dinamika $(n-r)$-tog reda zadavanjem željenog spektra polova, izbor klizne promenljive mora da zadovolji i preduslov da je njen relativni red r. U radu je pokazano da je kod sistema n-tog reda sa jednim ulazom moguće istovremeno zadovoljiti oba zahteva. Štaviše dokazano je da se formirani sistem jednačina sastoji od n linearno nezavisnih jednačina sa n nepoznatih, tj. da postoji jedinstveno rešenje za izbor klizne promenljive. Ovo omogućava da se do tog rešenja dođe na jednostavan način primenom pseudoinverzije matrica, koja će u ovom slučaju dovesti do ispravnog rešenja. Validnost predloženog rešenja je potvrđena na numeričkim primerima i ilustrovana simulacionim rezultatima.

II. Postavka problema

Posmatrajmo linearni sistem upravljanja sa skalarnim upravljanjem, čiji je model u prostoru stanja dat sa

$$\dot{x} = Ax + b(u + d). \qquad (1)$$

$x \in \mathbb{R}^n$ je raspoloživi vektor stanja, a $u, d \in \mathbb{R}$ su upravljanje i nepoznati ograničeni poremećaj, respektivno. A i b su konstantne matrice odgovarajućih dimenzija i sistem je kontrolabilan, tj. matrica kontrolabilnosti $Q_c = [b \;\; Ab \;\; \cdots \;\; A^{n-1}b]$ ima puni rang $(\mathrm{rank}Q_c = n)$. Očigledno je da poremećaj zadovoljava uslove poklapanja, tj.

Branislava Draženović i Senad Huseinbegović – Elektrotehnički fakultet, Univerzitet u Sarajevu, Sarajevo, Bosna i Hercegovina (e-mails: brana_p@hotmail.com, shuseinbegovic@etf.unsa.ba).

Rezultati prikazani u radu su deo istraživanja u okviru projekta III44004 Ministarstva prosvete, nauke i tehnološkog razvoja Republike Srbije.

deluje na sistem kroz upravljački kanal. Treba primetiti da su sve promenljive u (1) funkcije vremena, ali da su vremenski argumenti radi kraće notacije tu i nadalje izostavljeni. Zadatak je organizovati KR r-tog reda u sitemu (1) pri čemu je potrebno ostvariti željenu dinamiku u kliznom režimu.

Neka je klizna promenljiva $g \in \mathbb{R}$ definisana kao

$$g = cx, c \in \mathbb{R}^{1\times n}. \quad (2)$$

Kretanje sistema (1), (2) u potprostoru definisanog sa

$$g = \dot{g} = \ddot{g} = \cdots = g^{(r-1)} = 0 \quad (3)$$

se naziva KR r-tog reda, [4]. Upravljanje koje obezbeđuje da se u sistemu (1), (2) za konačno vreme ostvari uslov (3) mora biti diskontinualno, barem na skupu (3), [6], uz uslov da klizna promenljiva bude relativnog reda r u odnosu na upravljanje. To znači da se upravljanje pojavljuje tek u r-tom izvodu g, tj. u $g^{(r)}$. Za r-ti izvod klizne promenljive se dobija

$$g^{(r)} = cA^r x + \sum_{j=0}^{r-1} cA^{r-1-j} b(u^{(i)} + d^{(i)}). \quad (4)$$

Uslov da klizna promenljiva ima zahtevani relativni red se može iskazati kao

$$c \cdot [b \quad Ab \quad \cdots \quad A^{r-2}b] = 0_{1\times(r-1)}, \quad (5)$$

$$cA^{r-1}b \neq 0. \quad (6)$$

Tada r-ti izvod klizne promenljive (4) postaje

$$g^{(r)} = cA^r x + cA^{r-1}b(u + d). \quad (7)$$

Dinamika sistema u KR r-tog reda je $(n-r)$-tog reda [7]. Ona se može naći korišćenjem ekvivalentnog upravljanja, koje se može odrediti iz uslova

$$g^{(r)}\big|_{u=u_{eq}} = 0, \quad (8)$$

što daje

$$u_{eq} = -(cA^{r-1}b)^{-1}cA^r x - d. \quad (9)$$

Zamenom ekvivalentnog upravljanja u (1) dobija se opis sistema u KR r-tog reda

$$\dot{x} = Ax + b(u + d)|_{u=u_{eq}} = [I - b(cA^{r-1}b)^{-1}cA^{r-1}]Ax = PAx = A_{eq}x. \quad (10)$$

Iz dinamike sistema u (idealnom) KR r-tog reda (10) se vidi da nema uticaja poremećaja d, te je sistem invarijantan na dejstvo poremećaja koji zadovoljavaju uslove poklapanja. Naravno, ekvivalentno upravljanje (9) je nemoguće fizički ostvariti, budući da zahteva poznavanje poremećaja. Takođe, lako se može uočiti da je matrica P idempotentna matrica, tj. da važi $P^2 = P$. To znači da P predstavlja projektor. Na osnovu osobina projektorskih matrica [16], nalazi se da je $\mathrm{rank}(P) = n - 1$. Onda sledi da je $\mathrm{rank}(A_{eq}) = \mathrm{rank}(PA) < n$, što znači da je $\det(A_{eq}) = 0$ te A_{eq} predstavlja singularnu matricu. Očigledno je da sopstvene vrednosti matrice A_{eq} definišu dinamiku posmatranog sistema u KR, koja treba biti stabilna.

Dakle, potrebno je odrediti vektor c koji će obezbediti željenu dinamiku sistema (10) u KR r-tog reda, kao i zahtevani relativni red r klizne promenljive (2). Jednostavan način izbora c predložen je u narednoj sekciji.

III. Projektovanje klizne površi

Kako je upravljanje (9) linearno, može se sagledati kao tradicionalna povratna sprega po stanju. Naime, model (10) koji opisuje dinamiku u KR se može predstaviti kao

$$\dot{x} = A_{eq}x = (A - b(cA^{r-1}b)^{-1}cA^r)x = (A - bk)x, \quad (11)$$

gde je $k \in \mathbb{R}^{1\times n}$ vektor pojačanja povratne sprege po stanju $u = -kx$. Kako je dinamika sistema u KR redukovanog reda, u slucaju KR r-tog reda dinamiku odlikuje r nultih sopstvenih vrednosti i $n - r$ sopstvenih vrednosti različitih od nule. Nenulte sopstvene vrednosti $\lambda_1, \lambda_2, \ldots, \lambda_{n-r}$ treba izabrati da budu stabilne i da definišu željenu dinamiku sistema u KR, koja se može opisati sledećim karakterističnim polinomom

$$\phi(s) = s^r(s - \lambda_1)(s - \lambda_2)\cdots(s - \lambda_{n-r}) = s^n + \beta_1 s^{n-1} + \cdots + \beta_{n-r}s^r. \quad (12)$$

Iz teorije je poznato da se može naći jedinstveni vektor pojačanja povratne sprege k u kontrolabilnom sistemu (11) koji će obezbediti željenu dinamiku (12). Jedan od načina nalaženja k je primena Akermanove formule

$$k = e_1 Q_c^{-1}\phi(A), e_1 = [0_{1\times(n-1)} \quad 1]. \quad (13)$$

Tako određeno k se može iskoristiti za nalaženje nepoznatog vektora c. Na osnovu (11) se može uspostaviti veza između c i k koja je data relacijom $(cA^{r-1}b)^{-1}cA^r = k$, koja se može posle sređivanja iskazati jednačinom $cA^{r-1}(A - bk) = 0_{1\times n}$. Vektor c koji zadovoljava ovu jednačinu obezbediće željenu dinamiku (12) sistema u KR r-tog reda. Međutim, pored ovog zahteva, c mora da obezbedi i traženi relativni red klizne promenljive u odnosu na upravljanje (5) i (6). Često se uslov (6) bira u obliku $cA^{r-1}b = 1$ radi daljeg uprošćavanja. Dakle, c mora da zadovolji sledeće jednačine

$$cA^{r-1}(A - bk) = 0_{1\times n}, \quad (14)$$

$$c \cdot [b \quad Ab \quad \cdots \quad A^{r-2}b] = 0_{1\times(r-1)}, \quad (15)$$

$$cA^{r-1}b = 1. \quad (16)$$

Sistem jednačina koji se formira na osnovu (14)-(16) se sastoji od $n + r$ skalarnih jednačina sa n nepoznatih elemenata vektora c. Ovaj sistem jednačina se može u matričnom obliku predstaviti kao

$$c[A^{r-1}(A - bk) \quad b \quad Ab \quad \cdots \quad A^{r-2}b \quad A^{r-1}b] = [0_{1\times n} \quad 0_{1\times(r-1)} \quad 1] \quad (17)$$

Sledećom teoremom je dato jedinstveno rešenje datog sistema jednačina.

Teorema 1: U kontolabilnom sistemu (1), vektor c koji predstavlja jedinstveno rešenje sistema jednačina (14)-(16) se može naći kao

$$c = [k \quad 0_{1\times(r-1)} \quad 1] \cdot [A^r \quad b \quad Ab \quad \cdots \quad A^{r-1}b]^{\dagger}, \quad (18)$$

gde simbol † označava pseudoinverziju.

Dokaz: Kako je sistem (1) kontrolabilan, postoji nesingularna matrica transformacije T $(x = T\hat{x})$ koja transformiše sistem u kontrolabilnu kanoničku formu, koja je opisana matricama

$$\hat{A} = T^{-1}AT = \begin{bmatrix} 0_{(n-1)\times 1} & I_{n-1} \\ -a_n & -a \end{bmatrix}, \hat{b} = T^{-1}b = \begin{bmatrix} 0_{(n-1)\times 1} \\ 1 \end{bmatrix},$$
$$a = [a_{n-1} \quad a_{n-2} \quad \cdots \quad a_1],$$
$$\det(sI - A) = s^n + a_1 s^{n-1} + \cdots + a_{n-1}s + a_n. \quad (19)$$

Uzimajući u obzir relacije

$$A = T\hat{A}T^{-1}, b = T\hat{b}, c = \hat{c}T^{-1}, k = \hat{k}T^{-1}, \quad (20)$$

lako se može pokazati da je sistem jednačina (14)-(16) ekvivalentan sledećem sistemu jednačina

$$\hat{c}\hat{A}^{r-1}(\hat{A} - \hat{b}\hat{k}) = 0_{1\times n}, \quad (21)$$

$$\hat{c} \cdot [\hat{b} \quad \hat{A}\hat{b} \quad \cdots \quad \hat{A}^{r-2}\hat{b}] = 0_{1\times(r-1)}, \quad (22)$$

$$\hat{c}\hat{A}^{r-1}\hat{b} = 1. \quad (23)$$

Vektor pojačanja povratne sprege $\hat{k}$ transformisanog sistema koji će obezbediti željenu dinamiku (12) se može naći primenom Akermanove formule

$$\hat{k} = e_1\hat{Q}_c^{-1}\phi(\hat{A}), \quad (24)$$

gde je $\hat{Q}_c = [\hat{b} \quad \hat{A}\hat{b} \quad \cdots \quad \hat{A}^{n-1}\hat{b}]$. Poznato je iz [17] da važi

$$e_1\hat{Q}_c^{-1} = e = [1 \quad 0_{1\times(n-1)}],$$
$$e\hat{A}^i = [0_{1\times i} \quad 1 \quad 0_{1\times(n-1-i)}], r \le i < n, \quad (25)$$
$$e\hat{A}^n = [-a_n \quad -a].$$

Korišćenjem (24), (19) i (12) uz osobinu (25), za $\hat{k}$ se dobija

$$\hat{k} = [-a_n \quad \cdots \quad -a_{n-r+1} \quad -(a_{n-r} - \beta_{n-r}) \quad \cdots \quad -(a_1 - \beta_1)]. \quad (26)$$

Ekvivalentna matrica spregnutog sistema $\hat{A}_{eq} = \hat{A} - \hat{b}\hat{k}$ za ovako dobijeno $\hat{k}$ se dobija kao

$$\hat{A}_{eq} = \hat{A} - \hat{b}\hat{k} = \begin{bmatrix} 0_{(n-1)\times 1} & I_{n-1} \\ 0 & \gamma \end{bmatrix}, \quad (27)$$
$$\gamma = [0_{1\times(r-1)} \quad -\beta], \ \beta = [\beta_{n-r} \quad \cdots \quad \beta_1].$$

Po ugledu na (17), sistem jednačina (21)-(23) se može zapisati u obliku

$$\hat{c}\hat{L} = [0_{1\times n} \quad 0_{1\times(r-1)} \quad 1],$$
$$\hat{L} = \left[\hat{A}^{r-1}(\hat{A} - \hat{b}\hat{k}) \quad \hat{b} \quad \hat{A}\hat{b} \quad \cdots \quad \hat{A}^{r-2}\hat{b} \quad \hat{A}^{r-1}\hat{b}\right]. \quad (28)$$

Množenjem (27) sa $\hat{A}^{r-1}$ sa leve strane može se pokazati da prva submatrica $\hat{A}^{r-1}(\hat{A} - \hat{b}\hat{k})$ matrice $\hat{L}$ ima stukturu

$$\hat{A}^{r-1}(\hat{A} - \hat{b}\hat{k}) = \begin{bmatrix} 0_{(n-r)\times 1} & 0_{(n-r)\times(r-1)} & I_{n-r} \\ 0 & 0_{1\times(r-1)} & -\beta \\ 0_{(r-1)\times 1} & M(a_n, a)_{(r-1)\times(r-1)} & N(a,\beta)_{(r-1)\times(n-r)} \end{bmatrix} \quad (29)$$

Takođe, može se pokazati da ostali elementi (kolone) matrice $\hat{L}$ imaju strukturu opisanu sa

$$\hat{A}^{\mathrm{i}}\hat{b} = \begin{bmatrix} 0_{(n-i-1)\times 1} \\ 1 \\ H(a)_{i\times 1} \end{bmatrix}, i = 0,1,\dots,r-1. \quad (30)$$

Da bi se moglo suditi o rešivosti sistema jednačina (21)-(23), tj. (28), potrebno je analizirati rang matrice $\hat{L}$. Najpre se polazi od submatrica $\hat{A}^{r-1}(\hat{A} - \hat{b}\hat{k})$. Na osnovu strukture (29) može se uočiti da rang ove matrice određuju njeni elementi I_{n-r} i $M(a_n, a)$, tj.

$$\mathrm{rank}\left(\hat{A}^{r-1}(\hat{A} - \hat{b}\hat{k})\right) = \mathrm{rank}(I_{n-r}) + \mathrm{rank}(M(a_n,a)) =$$
$$n - r + \mathrm{rank}(M(a_n,a)). \quad (31)$$

U slučaju kada su svi koeficijenti polinoma $\det(sI - A)$ jednaki nuli ($a_n = 0, \quad a = 0_{1\times(n-1)}$) tada je $\mathrm{rank}\left(M(0, 0_{1\times(n-1)})\right) = 0$, pa je $\mathrm{rank}\left(\hat{A}^{r-1}(\hat{A} - \hat{b}\hat{k})\right) = n - r$. Takođe, maksimalni mogući rang $M(a_n, a)$ je $\mathrm{rank}(M(a_n,a)) = r - 1$. To znači da se rang matrice (29) na osnovu (31) nalazi u opsegu

$$n - r \le \mathrm{rank}\left(\hat{A}^{r-1}(\hat{A} - \hat{b}\hat{k})\right) \le n - 1. \quad (32)$$

U slučaju kada matrica $M(a_n, a)$ ima puni rang $r - 1$, na osnovu (30) se može zaključiti da nijedna od $r - 1$ kolona $\hat{A}^{\mathrm{i}}\hat{b}, i = 0,1,\dots,r-2$ matrice $\hat{L}$ ne može doprineti povećanju ranga matrice $\hat{L}$. Sa druge strane kada je $\mathrm{rank}(M(a_n,a)) = r - 1 - j$, $j = 1,2,\dots,r-1$, tada svaka od j kolona $\hat{A}^{\mathrm{i}}\hat{b}, i = 0,1,\dots,j-1$ će povećati rang matrice $\hat{L}$ za jedan. To znači da će deficit ranga matrice $M(a_n, a)$ nadoknaditi određeni broj kolona $\hat{A}^{\mathrm{i}}\hat{b}, i = 0,1,\dots,r-2$ koje slede iza $\hat{A}^{r-1}(\hat{A} - \hat{b}\hat{k})$ u matrici $\hat{L}$. Dakle, može se pisati da je

$$\mathrm{rank}\left(\left[\hat{A}^{r-1}(\hat{A} - \hat{b}\hat{k}) \quad \hat{b} \quad \hat{A}\hat{b} \quad \cdots \quad \hat{A}^{r-2}\hat{b}\right]\right) = n - 1 \quad (33)$$

Poslednja kolona matrice $\hat{L}$ je $\hat{A}^{r-1}\hat{b}$, koja je na osnovu (30) oblika

$$\hat{A}^{\mathrm{r}-1}\hat{b} = \begin{bmatrix} 0_{(n-r)\times 1} \\ 1 \\ H(a)_{(r-1)\times 1} \end{bmatrix}, i = 0,1,\dots,r-1. \quad (34)$$

Može se videti na osnovu strukture (29) matrice $\hat{A}^{r-1}(\hat{A} - \hat{b}\hat{k})$ da će kolona $\hat{A}^{\mathrm{r}-1}\hat{b}$ povećati rang ove matrice za jedan, bez obzira na rang matrice $M(a_n, a)$. Uzimajući u obzir (33), dolazi se do zaključka da je

$$\mathrm{rank}(\hat{L}) = n, \quad (35)$$

te sistem jednačina (28), odnosno (21)-(23), sa n nepoznatih ima jedinstveno rešenje. Samim tim i ekvivalentni sistem jednačina (14)-(16) ima jedinstveno rešenje, tj. postoji jedinstvni vektor c koji zadovoljava sve tri jednačine.

Ako jednačinu (16) uvrstimo u (14), jednačina (14) se tada modifikuje u prostiji oblik

$$cA^r = k. \quad (36)$$

Onda se sistem koga čine jednačine (36), (15) i (16) može zapisati kao

$$c \cdot [A^r \quad b \quad Ab \quad \cdots \quad A^{r-1}b] = [k \quad 0_{1\times(r-1)} \quad 1]. \quad (37)$$

Budući da je ovaj sistem punog ranga, tj. ima n linearno nezavisnih jednačina sa n nepoznatih, do ispravnog jedinstvenog rešenja se može doći korišćenjem pseudoinverzije matrica, na način (18). Ovim je kompletiran dokaz.■

IV. Izbor algoritma upravljanja

Pokazano je u [6] da upravljanje u sistemu (1), (2) koje obezbeđuje da se za konačno vreme ostvari uslov (3) mora biti diskontinualno, barem na skupu (3). Ukoliko je adekvatnim izborom c ova dinamika stabilna, trajektorija sistema asimptotski konvergira duž (3) u koordinatni početak ($x \to 0$ za $t \to \infty$), uprkos dejstvu poremećaja koji zadovoljava uslove poklapanja.

Kako je projektovanjem c obezbeđeno da važi (16), r-ti izvod klizne promenljive (7) postaje

$$g^{(r)} = cA^r x + u + d. \quad (38)$$

Ako se upravljanje u sistemu (1), (2) formira kao u [7]

$$u = -cA^r x - \gamma(\xi), \ \xi = \left(g, \dot{g}, \dots, g^{(r-1)}\right), \quad (39)$$

r-ti izvod po vremenu od g postaje

$$g^{(r)} = -\gamma(\xi) + d. \quad (40)$$

Levant je predložio u [6] skup kvazi-kontinualnih funkcija $\gamma(\xi)$ za uspostavljanje kliznog režima r-tog reda za nelinearne sisteme sa skalarnim upravljanjem. Kompleksnost ovih funkcija raste sa porastom reda r, dok se četering redukuje. Ove funkcije se lako mogu primeniti za linearni slučaj (40).

Funkcije $\gamma(\xi)$ koje garantuju klizni režim višeg reda u konačnom vremenu se mogu izabrati kao nelinearne funkcije date u [5,6]. Na primer, funkcije $\gamma(\xi)$ za $r = 1,2,3$ su

respektivno date kao

$$\gamma(\xi) = \alpha \frac{g}{|g|}, \tag{41}$$

$$\gamma(\xi) = \alpha \frac{\dot{g} + \beta_1 |g|^{\frac{1}{2}} \text{sign}(g)}{|\dot{g}| + \beta_1 |g|^{\frac{1}{2}}}, \tag{42}$$

$$\gamma(\xi) = \alpha \frac{\ddot{g} + \beta_2 \left(|\dot{g}| + \beta_1 |g|^{\frac{2}{3}} \right)^{-\frac{1}{2}} \left(\dot{g} + \beta_1 |g|^{\frac{2}{3}} \text{sign}(g) \right)}{|\ddot{g}| + \beta_2 \left(|\dot{g}| + \beta_1 |g|^{\frac{2}{3}} \right)^{\frac{1}{2}}}, \tag{43}$$

gde su $\alpha, \beta_1, \beta_2 > 0$ izabrani da budu dovoljno veliki.

Treba istaći da je za formiranje upravljanja potrebno poznavanje sukcesivnih izvoda klizne promenljive, tj. $g^{(i)}$, $i = 0,1,\dots,r-1$. Međutim, u sistemima na koje deluju poremećaji koji zadovoljavaju uslove poklapanja, ovi izvodi se na osnovu (4) i (5) mogu dobiti kao

$$g^{(i)} = cA^i x,\ i = 0,1,\dots,r-1. \tag{44}$$

V. Ilustrativni primeri i simulacioni rezultati

Ispravnost predložene metode projektovanja klizne površi u slučaju KR višeg reda je proverena na numeričkim primerima i potkrepljena je simulacionim rezultatima. Posmatra se potpuno kontrolabilni sistem (1) petog reda čije su matrice

$$A = \begin{bmatrix} -1.129 & -2.262 & 2.21 & 0.465 & 1.663 \\ 1.829 & -0.743 & -1.344 & -3.802 & -6.199 \\ -1.06 & 1.87 & -1.375 & -2.324 & 0.181 \\ 0.399 & 4.190 & 1.258 & -1.062 & 0.908 \\ -2.89 & 5.645 & 1.334 & 0.24 & -1.45 \end{bmatrix},$$

$b^{\mathrm{T}} = [0.4136 \quad 0 \quad 0.144 \quad 0 \quad -0.7601]$.

Na sistem deluje složeni poremećaj $d(t) = 2\sin(4\pi t) + 2h(t-3)$. Zadatak upravljanja je da se sistem uprkos dejstvu poremećaja dovede iz početnog stanja $x(0) = [10 \quad -5 \quad 0 \quad -10 \quad 5]^{\mathrm{T}}$ u koordinatni početak organizovanjem kliznog režima drugog reda. Kako je u ovom slučaju $n = 5$ a $r = 2$, dinamika sistema u kliznom režimu je $n - r = 3$ reda. Neka je željena dinamika sistema definisana spektrom polova $p = [0 \quad 0 \quad -3 \quad -3 \quad -3]$. Korišćenjem (13) za pojačanja povratne sprege k se dobija

$k = [4.2365 \quad -12.9816 \quad -3.4063 \quad -0.8998 \quad -2.6053]$

Ovde treba uočiti da je matrica A punog ranga, te je matrica $A^{r-1}(A - bk)$ maksimalnog ranga $n - 1 = 4$. Primenom formule (18) dolazi se do tražene vrednosti vektora c

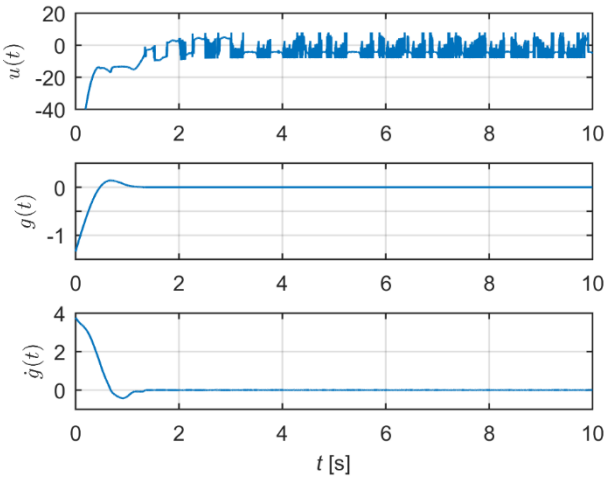
$$c = [0.052 \quad 0.2238 \quad 0.101 \quad 0.0976 \quad 0.0474].$$

Proverom je potvrđeno da dobijeno c zadovoljava jednačine (14)-(16) i da matrica $(A - b(cA^{r-1}b)^{-1}cA^r)$ iz (11) ima spektar sopstvenih vrednosti p.

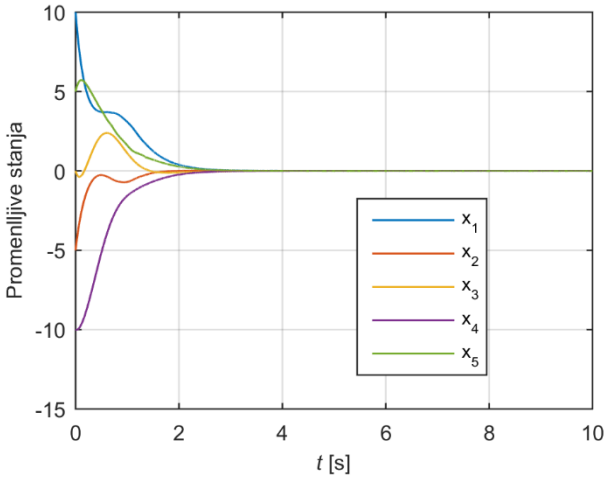
Navedena izračunavanja se lako mogu sprovesti u okviru MATLAB-a izvršavanjem sledećeg seta naredbi:

```
p=[0 0 -3 -3 -3]
k=acker(A,B,p)
c=[k 0 1]*pinv([A^2 B A*B])
```

Upravljanje koje u posmatranom sistemu obezbeđuje nastanak KR drugog reda je dato sa (39) i (42), pri čemu se izvod klizne promenljive $\dot{d}$ dobija korišćenjem (44). Za parametre regulatora je izabrano $\alpha = 8$ i $\beta_1 = 1$. Na Sl. 1 su prikazani upravljački signal $u(t)$, klizna promenljiva $g(t)$ i njen izvod $\dot{g}(t)$. Vidi se da upravljanje obezbeđuje $g = \dot{g} = 0$, tj. Nastanak KR drugog reda za konačno vreme uprkos dejstvu spoljnog poremećaja. Sl. 2 pokazuje da promenljive stanja asimptotski konvergiraju ka koordinatnom početku nakon nastanka KR, sa dinamikom definisanom spektrom polova p.



Sl. 1. Upravljački signal, klizna promenljiva i njen izvod



Sl. 2. Promenljive stanja

Na sledećem primeru se testira slučaj kada je matrica A singularna. Kao objekat upravljanja se posmatra serijska veza pet integratora, čiji model (1) karakterišu matrice

$$A = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix},\ b = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 20 \end{bmatrix}.$$

Model je u kontrolabilnoj kanoničkoj formi, pri čemu su koeficijenti polinoma $\det(sI - A)$ dati sa $a_1 = a_2 = a_3 = a_4 = a_5 = 0$. U slučaju KR drugog reda, rang matrice $A^{r-1}(A - bk)$ je tada minimalan, tj. $n - r = 3$. Neka kao u prethodnom primeru, na sistem deluje isti spoljni poremećaj i ima istu željenu dinamiku u KR. Za pojačanje povratne sprege se sada na osnovu (13) dobija

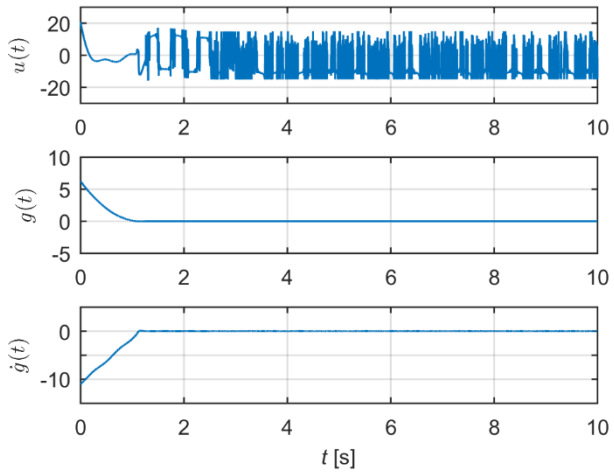
$$k = [0 \quad 0 \quad 1.35 \quad 1.35 \quad 0.45].$$

Korišćenjem (18) za c se dobija

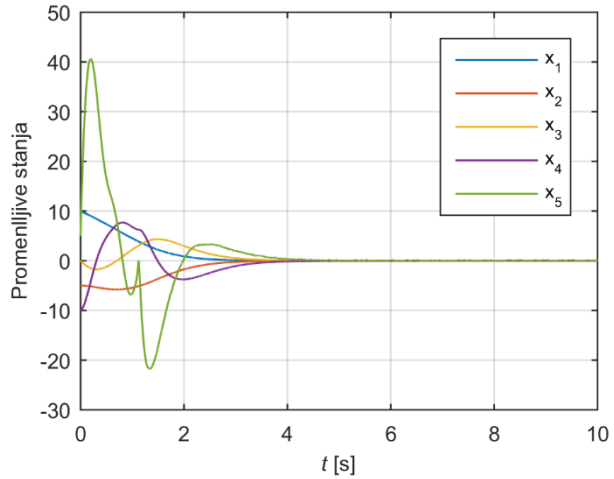
$$c = [1.35 \quad 1.35 \quad 0.45 \quad 0.05 \quad 0],$$

koje zadovoljava jednačine (14)-(16) i obezbeđuje da matrica $(A - b(cA^{r-1}b)^{-1}cA^r)$ ima spektar sopstvenih vrednosti p. Ovo pokazuje da i kada matrica $A^{r-1}(A - bk)$ ima najveći

mogući deficit ranga, formula (18) daje ispravno rešenje.



Sl. 3. Upravljački signal, klizna promenljiva i njen izvod



Sl. 4. Promenljive stanja

I ovde je primenjen isti algoritam upravljanja (39), (42) i (44) gde je $\alpha = 15$ i $\beta_1 = 1$. Simulacioni rezultati prikazani na Sl. 3 i Sl. 4 potvrđuju, da i u ovom slučaju dobijeni vektor klizne promenljive uz odgovarajući upravljački signal obezbeđuju nastanak KR drugog reda sa željenom dinamikom.

VI. Zaključak

U radu je pokazano da se princip projektovanja konvencionalne povratne sprege po stanju može iskoristiti prilikom projektovanja dinamike KR višeg reda u slučaju sistema sa jednim ulazom. Predložena metoda projektovanja klizne površi za slučaj KR višeg reda je jednostavna i ne zahteva velika izračunavanja. Dokazano je da isprojektovani vektor c obezbeđuje željenu dinamiku sistema u KR, kao i neophodni relativni red klizne promenljive koji je preduslov za uspostavljanje KR višeg reda. Validnost analitički dobijenog rešenja je potvrđena kroz numeričke primere i simulacione rezultate.

Dati prilaz projektovanja klizne površi se može u potpunosti primeniti i na diskretne KR r-tog reda dok se problem dosezanja i robusnosti mora rešavati na drugi način, što će biti predmet narednog istraživanja.

Abstract

The paper considers higher-order sliding mode dynamics design in single-input linear systems. The proposed method of sliding manifold selection simultaneously provides necessary relative degree of the sliding variable for a specific sliding mode order and desired system dynamics after establishing that sliding mode. It is shown that the solution of this problem is unique and a simple way of finding it is suggested. Theoretically obtained results are validated through numerical examples and illustrated by digital simulations.

Higher-Order Sliding Mode Dynamics Design in Single-Input Linear Systems

Prepoznavanje govora iz ograničenog rečnika primenom neuralne mreže

Emilija Kisić, Slobodan Drašković i Vera Petrović

Apstrakt— **Cilj ovog rada je da se pokaže kako se jednom efikasnom i kompleksnom obradom govornih signala i pravilnim izborom arhitekture neuralne mreže može napraviti sistem za prepoznavanje govora iz ograničenog rečnika koji će raditi sa velikom tačnošću. U ovom radu prikazan je kompletan postupak pravljenja sistema za prepoznavanje reči iz ograničenog rečnika i pokazano je da su neuralne mreže u kombinaciji sa poznatim metodama za modelovanje i obradu govornog signala jedan veoma moćan alat za prepoznavanje govora.**

***Ključne reči*—neuralne mreže; prepoznavanje govora; obrada signala.**

I. UVOD

Već decenijama predmet istraživanja brojnih naučnika je automatsko prepoznavanje govora (eng. *Automatic Speech Recognition*). Ova oblast doživljava puni razvoj tek prelaskom sa analognih na digitalne sisteme, a poslednjih godina, obeleženih opštim tehnološkim razvojem, dobija primenu u velikom broju aplikacija koje se mogu sresti u svakodnevnom životu [1], [2].

U ovom radu dat je detaljan opis pravljenja sistema za prepoznavanje govora primenom neuralnih mreža [3], [4]. Pravljenje sistema sastojalo se iz više koraka. Najpre je izvršeno snimanje govornih signala kako bi se oformila baza na osnovu koje će se obučavati neuralna mreža, zatim je usledila predobrada snimljenih signala koja se sastoji od *pre-emphazis* filtriranja, eliminisanja jednosmerne komponente iz signala i filtriranja na osnovni opseg govorne učestanosti [5]. Potom je napravljen efikasan algoritam koji određuje početak i kraj reči, kako bi se eliminisali početni i krajnji deo snimljene sekvence koji su „prazni“, odnosno u njima se nalazi samo termički šum, a zadržao se samo onaj deo signala koji nosi informaciju o reči. Nakon što je cela baza isečena, prelazi se na formiranje vektora karakterističnih obeležja kako bi se dala predstava posmatranih reči u višedimenzionalnom prostoru karakterističnih obeležja. Prvo je izračunat spektrogram govornog signala [8], a nakon toga je formirana pravougaona mreža kojom se spektrogram deli na *N*X*M* pravougaonih delova. Na kraju se prelazi na obučavanje neuralne mreže na bazi isečenih govornih signala koji su predstavljeni odgovarajućim vektorima karakterističnih obeležja. Svi algoritmi su implementirani u *Matlab* softverskom paketu. Na Sl. 1 dat je prikaz algoritma koji opisuje sve korake potrebne za pravljenje ovog sistema.

Sl. 1. Algoritam za prepoznavanje govora iz ograničenog rečnika primenom neuralne mreže

II. FORMIRANJE BAZE ZA OBUČAVANJE NEURALNE MREŽE

Prvi korak u razvoju sistema za prepoznavanje govora bio je snimanje baze koja će služiti za obučavanje neuralne mreže. Sistem je obučavan na ograničenom rečniku i za početak su izabrane reči koje će se u njemu nalaziti. Za elemente rečnika odabrane su cifre nula, jedan, dva, tri, četiri, pet, šest, sedam, osam i devet i reči napred, nazad, kreni, stani, levo i desno. Nakon što je odlučeno da dimenzija rečnika bude 16, obavilo se snimanje govornih signala. Za bazu je dalo glas 10 muških i 10 ženskih govornika, pri čemu je svako od njih izgovorio svaku od 16 reči po 10 puta. Na taj način, oformljena je baza od 3200 govornih signala, odnosno, od po 200 glasova za svaku klasu. Naravno, bilo bi bolje da je baza bila veća, jer bi na taj način sistem bio obučen za još više različitih glasova, ali i 3200 govornih signala predstavlja sasvim zadovoljavajući broj da se sistem kvalitetno obuči.

Svi govorni signali snimljeni su sa frekvencijom odabiranja od 8 kHz kako bi se zadovoljila Šenonova teorema [5]. S obzirom da je opseg učestanosti govornog signala u kome je sadržana gotovo sva informacija koja obezbeđuje potpunu razumljivost govorne poruke i većinu informacija o identitetu govornika od 250 Hz do 4kHz, za njegovu vernu reprezentaciju potrebno je vršiti odabiranje sa učestanošću od 8 kHz. Svi govorni signali snimljeni su u trajanju od 2s, što je bilo sasvim dovoljno da se zabeleže sve bitne informacije i omogući kvalitetno formiranje baze.

Za vreme snimanja govornih signala vodilo se računa o uslovima pri kojima se vrši snimanje. Naime, u zavisnosti od opreme (mikrofona i podešavanja računara) i buke za vreme snimanja koja potiče od okoline zavisi i kvalitet snimljenog signala. Zbog toga se nastojalo da se snimanje

Emilija Kisić– Visoka škola elektrotehnike i računarstva strukovnih studija, Vojvode Stepe 273, 11000 Beograd, Srbija (e-mail: emilija.kisic@viser.edu.rs).

Slobodan Drašković – Visoka škola elektrotehnike i računarstva strukovnih studija, Vojvode Stepe 273, 11000 Beograd, Srbija (e-mail: slobodan.draskovic@viser.edu.rs).

Vera Petrović – Visoka škola elektrotehnike i računarstva strukovnih studija, Vojvode Stepe 273, 11000 Beograd, Srbija (e-mail: vera.petrovic@viser.edu.rs).

vrši u prostoriji gde nema nijednog izvora buke, a za slučaj da se za vreme snimanja javio neki veći šum ili buka koja potiče spolja, snimanje se ponavljalo, u cilju formiranja što kvalitetnije baze. Takođe, veoma važno je bilo kako se drži mikrofon prilikom snimanja, da bude na dovoljnom odstojanju, da se vodi računa o pravilnom disanju, da se mikrofon ne trese i da se reči izgovaraju što spontanije (da se ne viče, ne priča pretiho), itd.

Svi signali snimljeni su u *Matlab*-u, pomoću naredbe *wavrecord*, a zatim su sačuvani kao *.wav* fajlovi. U slučaju da je došlo do pojave koja se zove clipp-ovanje, odnosno ako su određeni odbirci prešli maksimalnu vrednost koju oprema za snimanje dozvoljava, pa im je dodeljena maksimalna dozvoljena vrednost umesto njihove prave vrednosti, takvi signali su izbačeni i snimanje je ponovljeno.

III. PREDOBRADA SIGNALA

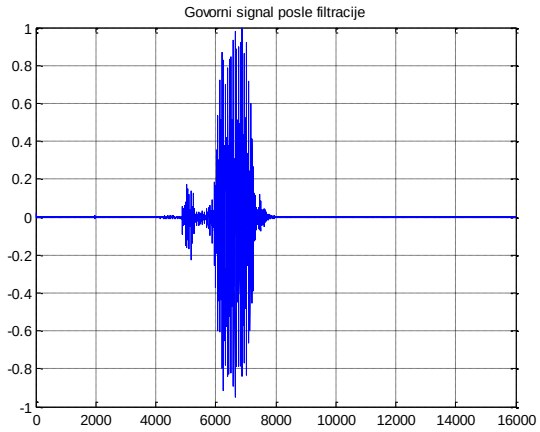
Nakon formiranje baze, sledeći korak je bio predobrada snimljenih signala. Za početak objasnićemo kako su govorni signali bili predstavljeni. Fizički posmatrano govorni signal predstavlja seriju promena vazdušnog pritiska u medijumu između zvučnog izvora i slušaoca. Najčešća i najjednostavnija predstava govornog signala je preko tzv. talasnog oblika. Horizontalna osa predstavlja vremensku osu, dok se na vertikalnoj osi može videti kako se pritisak povećava i smanjuje sa protokom vremena. Svi signali iz baze predstavljeni su u talasnom obliku, a na Sl. 2 nalazi se talasni oblik reči dva.

Svi signali najpre su prošli kroz *pre-emphasis* filtar. Naime, kada posmatramo raspored spektralnih komponenti po frekvencijama možemo uočiti da je njihov intenzitet na učestanostima iznad 1 kHz dosta mali. Međutim ako zanemarimo ove komponente i na primer signal propustimo kroz niskopropusni filtar učinićemo veliku grešku i izgubiti bitne informacije o govornom signalu. Jedna od metoda koja omogućava uspešno modelovanje formanata različitih intenziteta jeste *pre-emphasis*. Ideja je da se energija ulaznog govornog signala poveća za neku promenljivu vrednost u zavisnosti od učestanosti. Na taj način se smanjuje veliki opseg intenziteta u spektru govornog signala i „izravnjava“ spektar, čime se kasnija obrada govornog signala čini robusnijom i manje podložnom na uticaj konačne preciznosti pri računanju. Drugim rečima, *pre-emphasis* omogućava da informacije smeštene na višim učestanostima dođu do izražaja u kasnijoj analizi signala. Ravnanje spektra se realizuje dodavanjem nule u spektar signala, čime se parira padu signala od -12dB/oktava, do koga inače dolazi usled procesa nastanka govornog signala. *Pre-emphasis* filtar se definiše preko vrednosti konstante α. Kada se *pre-emhasis* filtriranje primeni na ulazni govorni signal dobija se:

$$y[n] = s[n] - \alpha s[n-1] \tag{1}$$

Za vrednost konstante α izabrana je vrednost 0.97 za koju se pokazalo da daje dobre rezultate.Nakon propuštanja kroz *pre-emphasis* filtar izvršeno je filtriranje Čebiševljevim VF filtrom šestog reda kako bi se odseklo prvih 250 Hz koji nam nisu potrebni za dalju obradu i kako bi se eliminisali neželjeni efekti nastali prilikom snimanja.

Na kraju je izvršena normalizacija signala tako da maksimalna vrednost apsolutne vrednosti odbirka bude 1 i eliminisana je jednosmerna komponenta koja se javlja na 50 Hz kao signal smetnje uzrokovan gradskom mrežom. Neutralizacija jednosmerne komponente je izvršena tako što je izračunata srednja vrednost svih odbiraka, a zatim je vrednost svakog odbirka umanjena za tu vrednost. Na Sl. 2 prikazan je talasni oblik reči „dva“ nakon celokupne predobrade.



Sl. 2. Talasni oblik reči „dva“ nakon celokupne predobrade

IV. ODREĐIVANJE POČETKA I KRAJA REČI

U procesu snimanja signala rešeno je da svi signali budu snimani u trajanju od 2s. Na taj način pored središnjeg dela snimljene sekvence u kome se nalazi govorna informacija, postoje i početni i krajnji deo koji su „prazni“, odnosno u njima se nalazi samo termički šum. Da bi algoritam mogao da vrši efikasno prepoznavanje reči potrebno je prvo iz snimljenog signala izdvojiti onaj deo signala koji nosi informaciju o reči, od termičkog šuma.

Postoji više načina da se ovaj problem reši. Prva ideja je bila da se pokuša segmentacija signala na osnovu njegove energije. Ovaj pristup izuzev što je jednostavan nema nekih posebnih prednosti, a rezultati koji su dobijeni nisu bili zadovoljavajući. Najveći problem predstavljala je detekcija kraja reči koje sadrže slovo T (pet, šest, devet). Problem sa ovim pristupom je što se na krajevima nekih reči nalaze visokofrekventne komponente u kojima se nalazi informacija o samoj reči, pri čemu je energija sadržana u tom delu govornog signala, dosta manja u odnosu na energiju niskofrekventnih delova signala. Stoga je određivanje granica reči u tim slučajevima jako teško, a često i nemoguće izvršiti samo na osnovu energije signala.

Nešto drugačiji pristup rešavanju ovog problema jeste korišćenje tzv. *Teager* energije za predstavu signala [6].
U [7] je pokazano da korišćenje *Teager* energije daje jako dobre rezultate kada je u pitanju detekcija „slabog“ početka i kraja reči u prisustvu šuma koji ima veću energiju od početka i kraja izgovorene reči. Osnovna ideja upotrebe *Teager* energije je da se istaknu komponente signala na višim frekvencijama. To je ostvareno množenjem odgovarajućih spektralnih komponenti kvadratom frekvencije.

Procedura računanja *Teager* energije se sastoji od nekoliko koraka. Prvo se signal podeli na preklapajuće segmente (okvire) dužine *W*. Za svaki od segmenata računa se *FFT*:

$$X(w) = \sum_{i=-\infty}^{\infty} s_i e^{-jwi} \tag{2}$$

gde je s_i vrednost odbirka signala u posmatranom segmentu.
Amplitude spektralnih komponenti se potom skaliraju vrednošću kvadrata odgovarajuće učestanosti :

$$f_k = w_k^2 X(w_k) \tag{3}$$

gde je sa f_k označena odgovarajuća *Teager* spektralna komponenta, a sa w_k njoj odgovarajuća učestanost. Na kraju se *Teager* energija signala dobija po formuli:

$$T_i = \left(\sum_{k=1}^{K} f_k \right)^{1/2} \tag{4}$$

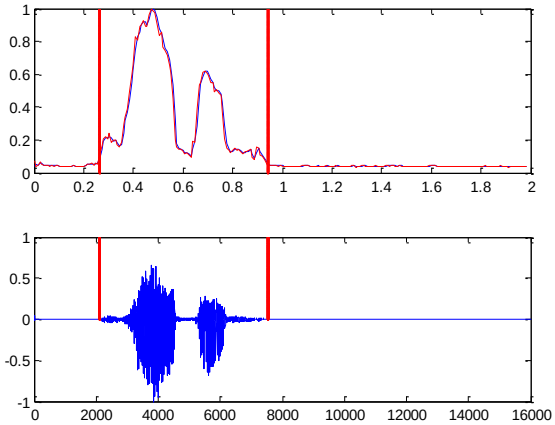
gde je *K* broj tačaka u kojima se računaju spektralne komponente.

Računanje *Teager* energije signala realizovano je je u *Matlab*-u. Prva dva koraka opisanog algoritma predstavljaju računanje spektrograma signala. Za to je korišćena *Matlab* funkcija *spectrogram*. Za širinu prozora uzeto je *W*=128, za veličinu preklapanja izabrana je vrednost *K*=*W*/2, a za broj tačaka u kojima se računa *FFT (Fast Fourier Transform)* uzeto je *M*=512. Izbor vrednosti za navedene parametre može da utiče na rezultat algoritma.

Nakon formiranja spektrograma, vrednost dobijenih spektralnih komponenti su pomnožene sa kvadratom učestanosti. Na taj način dobijena je *Teager* predstava signala, a zatim se *Teager* energija određenog segmenta dobija kao koren sume *Teager* spektralnih komponenti koje pripadaju tom segmentu. Dobijena predstava signala je prilično dinamična kriva sa velikim skokovima, pa je potrebno dodatno je isfiltrirati da bi se smanjila verovatnoća pogrešne detekcije granica reči. To je urađeno usrednjavanjem krive na prozoru dužine *N* (u ovom slučaju za vrednost *N* izabrana je *N*=2).

Sada treba dobijenu predstavu signala iskoristiti za određivanje granice reči. Ideja je da se definišu vrednosti pragova sa obe strane snimljenog signala (sa početka P_L i kraja P_R) i da se odrede uslovi pod kojim se proglašava početak/kraj reči. Algoritam se izvršava poređenjem nivoa *Teager* energije snimljenog signala sa odabranim pragovima. Leva granica se određuje kao trenutak t_L kada signal posmatran od početka ka kraju nadmaši vrednost levog praga. Slično tome desna granica se postavlja u trenutku t_R kad signal posmatran od kraja ka početku nadmaši vrednost desnog praga. Na Sl. 3 dat je prikaz *Teager* energije i talasnog oblika reči jedan sa pragovima t_L i t_R.

Vrednost pragova detekcije je određena na osnovu procenjenog nivoa šuma i usvojena je da bude jednaka *Teager* energiji šuma uvećanoj za 4% od maksimalne vrednosti energije. Ovakav izbor vrednosti praga je utvrđen eksperimentalno i predstavlja neku vrstu kompromisa. Smanjenjem vrednosti praga svakako bi se smanjio procenat nedetektovanih delova problematičnih reči, ali sa druge strane sistem bi bio manje robustan i jako osetljiv na smetnje koje se mogu pojaviti prilikom snimanja signala.



Sl. 3. *Teager* energija i talasni oblik reči "jedan" sa eksperimentalno određenim pragovima t_L i t_R.

Procenjeni nivo šuma je karakterisan *Teager* energijom signala na početku i na kraju snimljene sekvence. Podrazumevano je da se korisni signal nalazi u centralnom delu snimljenog niza, odnosno da se na krajevima niza nalazi samo termički šum.

Problem sa opisanim načinom detekcije granica reči je u tome što je jako teško izabrati veličinu praga koja bi odgovarala svim glasovima iz baze. Kao moguće rešenje za ovaj problem za svaku stranu detekcije postavljena su po dva praga umesto jednog. Vrednost većeg praga (P_{LH} i P_{RH}) je postavljena dovoljno visoko, tako da u svim slučajevima kada je nadmašena, sa sigurnošću možemo reći da je to usled postojanja govornog signala, a ne kao posledica varijacija termičkog šuma. Analogno tome vrednost manjeg praga (P_{LL} i P_{RL}) se postavlja da bude u stanju da detektuje najmanje varijacije u *Teager* energiji govornog signala. Trenuci u kojima se detektuje da je po prvi put nadmašena vrednost praga označeni su sa t_{LH} i t_{LL} za levu stranu i sa t_{RH} i t_{RL} za desnu stranu. Postavljen je i dodatni uslov, a to je da vrednost rastojanja između trenutaka kada su nadmašeni viši i niži prag mora biti manja od neke unapred definisane maksimalne vrednosti ($t_{L\max}$ i $t_{R\max}$). Odnosno taj uslov se može napisati kao:

$$t_{LH} - t_{LL} < t_{L\max} \tag{5}$$

$$t_{RH} - t_{RL} < t_{R\max} \tag{6}$$

Algoritam kojim se određuje početak i kraj reči se izvršava tako što se prvo odredi tačka u kojoj *Teager* energija signala postaje veća od višeg praga (t_{LH}), a potom se pretraga vrati za $t_{L\max}$ trenutaka unazad i počev od te pozicije treba naći momenat u kome je nadmašena vrednost nižeg praga (t_{LL}). Trenutak t_{LL} je proglašen za početak reči $t_L = t_{LL}$. Ukoliko postoji potreba moguće je još preciznije određivanje početka i kraja reči. U tom slučaju obično se računa i neka druga predstava signala i definiše se dodatna vrednost praga P_D u odnosu na tu predstavu signala. Potom se na intervalu $t_{LL} - t_{LH}$ traži trenutak kada je vrednost tog praga nadmašena. Na sličan način se određuje i kraj reči, sa razlikom što u tom slučaju pretraga počinje od kraja snimljene sekvence.

Sve vrednosti pragova su određene eksperimentalno, tako da daju dobre rezultate za postojeću bazu signala. Pri tome se naročito vodilo računa o osobenostima elemenata baze, pa tako na primer $t_{R\max}$ mora biti dovoljno dugačko da se ne bi odseklo slovo T iz pojedinih reči (devet, pet,...), odnosno prag t_{LL} mora biti dovoljno nizak da detektuje početak reči koje počinju bezvučnim samoglasnikom (sedam, šest,...).

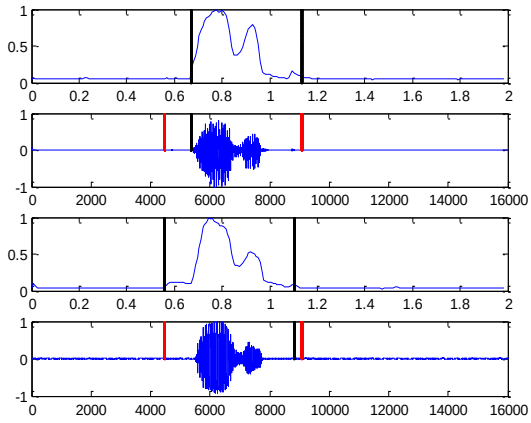
Prethodnim algoritmom ispravljena je većina nedostataka raznih drugih metoda koja se odnosila na lošu detekciju visokofrekfentnih komponenti i dobijeni su dosta dobri rezultati. Međutim, ostao je problem sa kasnom detekcijom početka nekih reči (dva, devet,...). Rešenje koje je primenjeno u ovom radu je da se opisani algoritam primeni dva puta. Prvi put, kao što je to i do sada bio slučaj, algoritam se primenjuje na govorni signal u osnovnom opsegu učestanosti (250Hz-4kHz), dok se u drugom slučaju algoritam primenjuje na signal koji je prethodno propušten kroz filtar propusnik opega učestanosti (250Hz-550Hz). Na taj način dobijaju se dva para granica reči (t_{L1}, t_{L2}) i (t_{R1}, t_{R2}) na osnovu kojih se donosi konačna odluka. Primenjen je sledeći princip odlučivanja:

$$t_L = \min\{t_{L1}, t_{L2}\} \tag{7}$$

$$t_R = \min\{t_{R1}, t_{R2}\} \tag{8}$$

gde su t_L i t_R granice reči.

Na Sl. 4 prikazano je ponašanje algoritma u slučaju izgovorene reči "devet". Reč se posmatra jer ilustruje dva bitna problema: detekciju kraja reči koje se završavaju na T i detekciju početka reči koje počinju na D. U gornjoj polovini Sl. 4 nalazi se grafik *Teager* energije signala i njegov talasni oblik, dok se na donjoj polovini nalazi prikaz *Teager* energije signala filtriranog na opseg 250-550 Hz i odgovarajući talasni oblik.

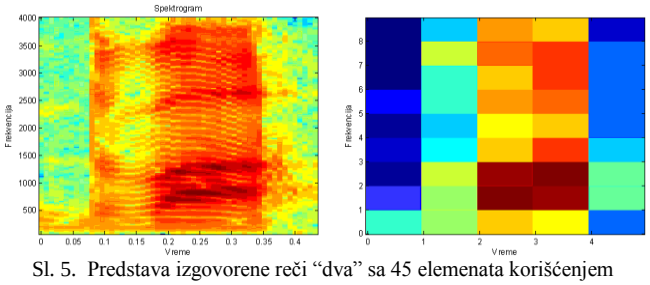


Sl. 4. Ilustracija *Teager* algoritma za izgovorenu reč "devet"

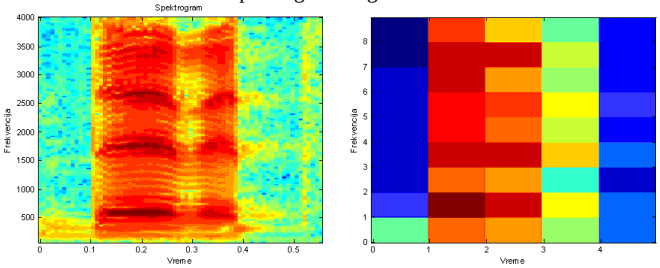
Na graficima *Teager* energije crnim vertikalnim linijama označene su granice reči onako kako to vidi algoritam za pojedinačne slučajeve signala. Kombinacijom ta dva rezultata opisan u (5) i (6) dobijaju se granice reči koje se mogu videti na slikama talasnih oblika gde su označene crvenim vertikalnim linijama. Kao što se može videti korekcija je neophodna bez obzira koji signal posmatrali. Algoritam opisan u ovom poglavlju primenjen je na sve signale iz baze i na taj način je dobijena baza skraćenih signala, na kojoj će se vršiti obučavanje neuralne mreže.

V. IZBOR KARAKTERISTIČNIH OBELEŽJA

Vektor karakterističnih obeležja daje predstavu posmatrane reči u višedimenzionalnom prostoru karakterističnih obeležja. Dimezije tog prostora i izbor samih obeležja zavise od mnogih faktora, a tačnost algoritma za prepoznavanje reči je u velikoj meri uslovljena dobrim izborom obleležja. Vektor karakterističnih obležja formiran je korišćenjem spektrograma signala. Nakon toga se formira pravougaona mreža kojom se spektrogram deli na *N*x*M* pravougaonih delova. Dimenzije mreže, odnosno izbor vremenske i frekvencijske rezolucije podele spektrograma, može značajno da utiče na tačnost sistema za prepoznavanje. Kada se odrede vrednosti za *N* i *M*, za svaki od pravougaonih segmenata treba izračunati srednju vrednost logaritama spektralnih komponenti unutar njega. Na ovaj način dobija se karakterističan vektor čija je dimenzija *N*x*M* elemenata. Kao što će kasnije biti pokazano, najbolji rezultati dobijeni su za vrednosti *N*=9 i *M*=5. Do ovog rezultata došlo se eksperimentalnim putem, tako što se neuralna mreža obučavala na bazi isečenih govornih signala koji su predstavljeni odgovarajućim vektorom karakterističnih obeležja za različite vrednosti *N* i *M*, pa je uzeta ona vrednost za koju je neuralna mreža dala najmanju grešku. Osim srednje vrednosti logaritama spektralnih komponenti, računat je i maksimum spektralnih komponenti unutar pravougaonih segmenata, kako bi se videlo u kom slučaju se dobijaju bolji rezultati. Eksperimentalnim putem utvrđeno je da se mnogo bolji rezultati dobijaju kada se računa srednja vrednost, tako da je za optimalnu podelu spektrograma izabrano 9X5 elemenata, pri čemu je vrednost svakog od ovih elemenata zapravo srednja vrednost logaritama spektralnih komponenti unutar odgovarajućeg pravougaonog segmenta. Na Sl. 5 data je predstava izgovorene reči "dva" pomoću spektrograma (levo) i vektora obeležja sa 45 elemenata (desno). Na Sl. 6 data je predstava izgovorene reči "devet" pomoću spektrograma (levo) i vektora obeležja sa 45 elemenata (desno).



Sl. 5. Predstava izgovorene reči "dva" sa 45 elemenata korišćenjem spektrograma signala.



Sl. 6. Predstava izgovorene reči "devet"sa 45 elemenata korišćenjem spektrograma signala.

Sa slika se vidi da se spektrogrami za ove dve reči veoma jasno razlikuju. Drugim rečima, predstave govornih signala na ovaj način biće veoma slične za govorne signale iz iste klase, a razlikovaće se za govorne signale iz različitih klasa. Kada svi govorni signali budu bili predstavljeni na ovaj način dobiće se baza na kojoj će se neuralna mreža obučiti.

VI. DIZAJNIRANJE NEURALNE MREŽE I DOBIJENI REZULTATI

Kao što je ranije rečeno, veoma je bitno koje su vrednosti uzete za vremensku i frekvencijsku rezoluciju, odnosno na koliko pravougaonih segmenata će spektrogram biti podeljen. Kako za *N* i *M* ne treba uzeti ni previše male, a ni previše velike vrednosti, odlučeno je da se izvrši analiza za sledeća tri slučaja: *N*=8 i *M*=6, *N*=8 i *M*=7 i *N*=9 i *M*=5. Neuralna mreža koja je korišćena za problem prepoznavanja izgovorenih reči iz ograničenog rečnika je višeslojna *feedforward* mreža. Ovakav tip mreže izabran je zbog višedimenzionalnog problema koji jednoslojna mreža ne bi mogla adekvatno da reši [3,4]. Ako bi se izabrala prva podela, mreža bi imala 48 ulaza, za drugu podelu bi imala 56 ulaza, a za treću podelu bi imala 45 ulaza. Svaki od ulaza ima po 3200 vrednosti, po 200 za svaku od 16 reči, a svaka vrednost predstavlja odgovarajući pravougani segment spektrograma. Za obučavanje neuralne mreže primenjeno je obučavanje sa nadzorom, jer je broj klasa unapred definisan, odnosno u svakom trenutku mreža zna šta bi trebalo da bude na izlazu (jedna od 16 izgovorenih reči). Kod obučavanja sa nadgledanjem (supervizorskog obučavanja), u svakom diskretnom trenutku vremena, kada je određeni signal na ulazu, odgovarajući željeni izlaz je dat. Tada neuralna mreža tačno zna šta treba da bude na izlazu [9]. Algoritam koji je korišćen za obučavanje mreže jeste algoritam propagacije greške unazad (eng. *backpropagation)* [3]. Na ulaz neuralne mreže dovodi se obrađena baza na način koji je opisan u prethodnim poglavljima. Svaka izgovorena reč predstavljena je vektorom karakterističnih obeležja, na način koji je opisan u prethodnom poglavlju.

Kako bi se došlo do zaključka koja struktura mreže daje najbolje rezultate, mreža je obučavana tako što se pravilo krosvalidaciono okruženje [9]. To znači da se obučavajući skup (raspoloživa baza izgovorenih reči) deli u određenom procentu na obučavajući i testirajući (validacioni) skup (u ovom radu uzeto je 50% za obučavanje, 50% za testiranje). Obavlja se 2 iteracije algoritma, tako što se u prvoj iteraciji uzima polovina podataka za potrebe validacije, a druga polovina se koristi za učenje, a u drugoj iteraciji obrnuto. U obe iteracije algoritma uzima se ista struktura mreže. Pri svakoj iteraciji računa se greška, odnosno koliko je reči pogrešno klasifikovano. Na kraju se računa prosečna uspešnost (greška) na nivou obe iteracije, jer tako izračunate mere uspešnosti daju bolju sliku o performansama algoritma. Mera uspešnosti, odnosno izračunata greška daje informaciju o tome koliko je reči pogrešno klasifikovano, odnosno koliko uspešno je algoritam klasifikovao reči iz baze. Kada se izabere optimalna struktura, neuralna mreža se obučava na celom skupu.

Da bi se izabrala optimalna struktura mreže koja dovodi do najmanje greške, najpre se uzela siromašna struktura mreže (jedan sakriveni sloj sa pet čvorova), broj epoha bio je 100, konstanta obučavanja 0.1, a algoritam propagacije unazad *traingd* (*Gradient descent backpropagation*) i dobila se greška od 90.19%. U svim strukturama koristile su se *purelin* i *tansig* aktivacione funkcije [3]. Zatim se broj skrivenih slojeva i čvorova povećavao (najviše se uzimalo četiri skrivena sloja do 50 čvorova). Menjao se broj epoha obučavanja (od 100 do 1500). Menjala se i vrednost konstante obučavanja (od 0.1 do 10). Sa povećanjem broja epoha, skrivenih slojeva i čvorova kao i konstante obučavanja greška se smanjivala, dok se nije došlo do najmanje greške. Takođe, korišćeni su različiti algoritmi propagacije unazad koji su davali različite rezultate. Za strukturu od 4 skrivena sloja sa po 48,30,48,30 čvorova, 1500 epoha, algoritam propagacije unazad *traincgp* (*Conjugate gradient backpropagation with Polak-Ribiere updates*), primenjena je regularizacija [3] i konstanta obučavanja je 2, greška je 5.63%. Za strukturu od 4 skrivena sloja sa po 45 čvorova, 1500 epoha, algoritam propagacije unazad *trainoss* (*One step secant backpropagation*), primenjena je regularizacija i konstanta obučavanja je 7, greška je 4.5%. Nakon detaljne analize različitih struktura mreže kojih je bilo mnogo, pa se ne mogu sve navesti, došlo se do zaključka da najmanju grešku od 3.41% daje struktura gde je izabrano 4 skrivena sloja sa po 45 čvorova, 1500 epoha, algoritam propagacije unazad *traincgb* (*Conjugate gradient backpropagation with Powell-Beale restarts*) [10], primenjena je regularizacija i konstanta obučavanja je 7. Kada se uporede najmanje greške koje se dobijaju za tri različite podele (4.03%, 5.34% i 3.41%) vidi se da se najbolji rezultat dobija za podelu *N*=9 i *M*=5 i gore izabranu strukturu. Takođe, bolji rezultati (manja greška) dobila se kada se vektor karakterističnih obeležja deli na 45 pravougaonih segmenata koji se računaju kao srednja vrednost logaritamskih vrednosti na odgovarajućem segmentu.

Nakon što je izabrana optimalna struktura, mreža je obučena na celoj bazi. Da bi se videlo kolika je tačnost rada ovog sistema za prepoznavanje govora iz ograničenog rečnika, sistem je najpre testiran na skupu na kojem je obučen. Od dobijenih rezultata pravi se matrica konfuzije koja je data u vidu tabele. Matrica konfuzije daje tačan prikaz koliko je svaka reč tačno klasifikovana, i za slučaj da je došlo do greške, vidi se kako je sistem prepoznao reč, odnosno u koju klasu je pogrešno klasifikovao [9]. Jasno je da je idealna matrica konfuzije dijagonalna, što znači da su sve reči pravilno klasifikovane. Kada je sistem testiran na istom skupu na kojem je i obučen, dobijena je greška od 0% (odnosno dijagonalna matrica konfuzije) što je očekivan i veoma zadovoljavajuć rezultat.

Zatim, sistem je testiran na 3 govornika koji se nalaze u bazi na kojoj je sistem obučen. Govornici su po 5 puta ponovo rekli svaku reč iz ograničenog rečnika, i dobijeni rezultati dati su u Tabeli 1. Na kraju, u Tabeli 2 dati su rezultati kada je sistem testiran na govornicima koji nisu bili u bazi.

Klase u matricama konfuzije obeležene su na sledeći način: Klasa 1-Nula, Klasa 2- Jedan, Klasa 3-Dva, Klasa 4-Tri, Klasa 5-Četiri, Klasa 6-Pet, Klasa 7-Šest, Klasa 8-Sedam, Klasa 9-Osam, Klasa 10-Devet, Klasa 11-Napred, Klasa 12-Nazad, Klasa 13-Kreni, Klasa 14-Stani, Klasa 15-Levo, Klasa 16-Desno. Matrica konfuzije u Tabeli 1 nije dijagonalna. Greška klasifikacije od 2.5% nije velika greška, tako da je dobijeni rezultat sasvim dobar. Sistem je od 240 reči 6 reči pogrešno klasifikovao. Dva puta je prepoznao reč „dva“ kao „nula“, jednom reč „sedam“ kao „jedan“, jednom reč „napred“ kao „levo“, jednom reč „stani“ kao „devet“ i

jednom reč „stani“ kao „nazad“. U svim ostalim slučajevima reči su tačno prepoznate

6	0	0	0	0	0	17	0	0	0	0	0	0	0	0	0	0
7	0	0	0	0	0	0	12	0	0	0	0	0	0	0	0	0
8	0	0	0	0	0	0	0	19	0	0	0	0	0	0	0	0
9	0	0	0	0	0	0	0	0	19	0	0	0	0	0	0	0
10	0	0	0	0	0	0	0	0	0	22	0	0	0	3	0	0
11	0	0	0	0	0	0	0	0	0	0	22	0	0	0	0	0
12	0	0	0	1	0	0	0	1	0	0	0	25	0	0	0	0
13	0	0	0	0	0	0	0	0	0	0	0	0	28	0	0	0
14	0	0	0	0	0	0	0	0	0	0	0	0	0	13	0	0
15	0	0	0	0	0	0	0	0	0	0	0	0	3	0	23	0
16	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	27

Matrica konfuzije u Tabeli 2 je najvažnija matrica, jer prikazuje sa kolikom tačnošću sistem prepoznaje reči koje su izgovorili govornici van baze. Od 322 izgovorene reči sistem je pogrešno klasifikovao 9 reči, a sve ostale je tačno prepoznao. Dobijena je greška od 2,8% što je veoma zadovoljavajuć rezultat koji pokazuje da je sistem dobro obučen da prepoznaje reči koje izgovaraju govornici koji se ne nalaze u bazi na kojoj je sistem obučen.

VII. ZAKLJUČAK

Dobijeni rezultati u ovom radu su sasvim zadovoljavajući i pokazuju da se efikasnim algoritmom za predobradu govornih signala i pravilnim izborom arhitekture neuralne mreže može napraviti sistem za prepoznavanje reči iz ograničenog rečnika koji će raditi sa velikom tačnošću, uz sva ograničenja koja se na sistem nameću i umanjuju tačnost klasifikacije.

Prvi problem koji se javlja jesu uslovi pod kojima se reči snimaju. U slučaju da postoji neki izvor buke koji potiče ili od bliže okoline, ili da dolazi spolja, ili od same opreme pomoću koje se vrši snimanje, sistem će ga registrovati kao šum ili će ga protumačiti kao deo reči, a svakako će umanjiti razumljivost same reči.

Drugi problem koji se javlja jeste način na koji govornici izgovaraju reči. S obzirom da je ovo sistem koji je nezavistan od govornika, odnosno nije pravljen da prepoznaje jednog govornika, nego je pravljen da prepoznaje razne govornike, način na koji se izgovaraju reči je veoma bitan. Iz ovih razloga veoma je teško napraviti jedinstven algoritam koji klasifikuje reči nezavisno od toga koji je govornik izgovorio reč. Sa povećanjem broja govornika u obučavajućem skupu svakako da bi se poboljšao kvalitet dobijenih rezultata.

I pored gore navedenih ograničenja i problema na koje se nailazilo prilikom projektovanja jednog ovakvog sistema, dizajniran sistem za prepoznavanje govora iz ograničenog rečnika daje veoma zadovoljavajuće rezultate. Neuralne mreže su zbog svojih osobina i danas veoma atraktivne za naučnike i istraživače kada je u pitanju prepoznavanje govora [11].

ABSTRACT

The goal of this paper is to show how effective and complex speech signals processing with the correct choice of neural network architecture can make a speech recognition system from a limited vocabulary that will work with great accuracy. This paper presents the complete procedure for creating a word recognition system from a limited vocabulary and it has been shown that neural networks combined with well-known methods for modeling and speech signal processing are a very powerful speech recognition tool.

TECHNOLOGY-SUPPORTED THERAPEUTIC APPROACHES FOR STROKE REHABILITATION: FROM DESIGN TO CLINICAL TRANSLATION (INVITED PAPER)

Emilia Ambrosini, NearLab, Department of Electronics, Information and Bioengineering, Politecnico di Milano, Milan, Italy

ABSTRACT

Stroke is the third most common cause of death and the main cause of acquired adult disability in high-income countries. Hemiparesis, which is motor impairment of one side of the body, affects about 80% of stroke survivors. Restoration of gait and gait-related activities is one of the main goals of stroke rehabilitation, while the recovery of arm functions is crucial for the capability to perform activities of daily life (ADL), which increases independence and quality of life.

Neuroplasticity is the basic mechanism for functional recovery after stroke. Rehabilitative interventions should make effective use of neuroplasticity, proposing high-intensity, repetitive, task-specific, interactive and individualized training. Technology-supported therapeutic approaches are emerging as a solution to support therapists in providing such training for a long duration, allowing the participants to progress in task difficulty, so as to increase their motivation.

In the last thirty years, several robotic devices for both lower and upper-limb rehabilitation have become commercially available. Robot-assisted gait training, supporting (partially or totally) the body weight and the movement of patients, allow intensive and highly repetitive training of complex gait cycles, with a reduced effort for the therapists. A recent Cochrane review showed that robotic gait training in combination with physiotherapy might improve recovery of independent walking in stroke survivors. Leg cycling training may represent a low-cost and safe alternative to robot-assisted gait training. Indeed, cycling shares a similar locomotor pattern with walking and can be performed safely with a sufficient intensity soon after stroke since it does not require standing balance.

Robotic devices have been strongly proposed also to support upper limb stroke rehabilitation and recent systematic reviews demonstrated that stroke patients who receive electromechanical and robot-assisted arm and hand training might improve ADL, arm and hand function and strength.

To increase the therapeutic benefits of robotic rehabilitation, other approaches have been combined with robots, such as Functional Electrical Stimulation (FES) and Virtual Reality (VR); these combined approaches can make robotic based-interventions more functional and engaging. FES has been strongly used to enhance functional recovery of the paretic arm or leg. The combination of FES with robotic devices helps overcome one of the main limits of FES, e.g., the early onset of muscle fatigue. VR is instead used to provide an interactive and individualized training modality, which can provide sensorimotor training in enriched environments, so as to maximize patient's engagement.

This talk will provide an overview of the main technology-supported therapeutic approaches for upper and lower limb stroke rehabilitation. The main training elements, which technology should guarantee in order to maximize cortical plasticity and consequently motor re-learning, will be summarized. Interventions for both upper and lower limb recovery will be mentioned. Special focus will be given to active-assistive control modalities of robotic devices which implement "assisted-as-needed" rehabilitation therapy aimed at maximizing patient's involvement and self-esteem. Finally, the importance of the design of randomized controlled trials (RCT) to evaluate the efficacy of technology-supported therapeutic approaches with respect to usual care will be highlighted. The examples of two RCTs recently conducted by our group will be also provided. Specifically, one RCT recruited a population of 68 subacute stroke survivors and evaluated the effects of a biofeedback training involving FES-augmented cycling training and balance exercises on motor recovery and walking ability. The second RCT was a multi-center clinical trial conducted within the European project RETRAINER and evaluated the efficacy of training with the support of a hybrid robotic system, consisting of an anti-gravity arm exoskeleton combined with EMG-triggered FES, on a sample of 68 post-acute stroke patients.

Rules for Estimation of Gait Phases from Data Acquired by the Gait Teacher Insoles

Vladimir Džepina, Aleksandar Gogić, Dejan B. Popović, *Member, IEEE*

***Abstract*—The task of this study was to develop a user-friendly method for estimation of gait events from the sensor's data integrated into the wearable system called Gait Teacher. Ten pressure sensors and two six-axis inertial measurement sensors built into a pair of insoles wirelessly send signals to the host computer sampled at 100 Hz. We collected and processed data by a custom-designed software developed in LabVIEW. We heuristically segmented the gait cycle to the phases typically used for the gait analysis (*Toes off, Terminal swing, Heel contact, Foot flat and Heel off,*) and then applied the automatic segmentation of data. The performance of the method was tested by comparing the heuristic and automated segmentation. The results suggest that the averaged accuracy of the segmentation reached almost 100% for all four healthy subjects who participated in the study. These results indicate that Gait Teacher could be used for evaluation of the gait performance in sports, recreation, and rehabilitation.**

***Index Terms*—Gait; Insole; Inertial measurement unit (IMU); Ground Reaction Force (GRF); Gait segmentation.**

I. Introduction

The description of the gait is of interest to clinicians for assessing the patient's course of recovery during the rehabilitation [1]. Therefore, it is essential to provide clinicians with a system that would allow gait data acquisition and processing. Two different types of gait data recording systems are: 1) camera-based laboratory system with force plates [2, 3] and 2) wearable sensors with instrumented insoles [4, 5]. The complexity of use and the price make wearable systems much more attractive for clinical applications.

Wearable sensors need to acquire the ground reaction forces and kinematics of bodily segments. The kinematics can be assessed by inertial measurement units (IMU) which integrate accelerometers, gyroscopes, and magnetometers. Today, these sensors are miniature, have low power consumption and generate a reproducible digital signal that characterizes the motion of the bodily segments on which they are mounted. These sensors need a power supply and need to be linked to a wireless communication chip, to send data to a computer. There are systems at the market which satisfy most of the requirements [e.g., 6, 7, 8, 9]. The ground reaction force is delicate to measure information, and no wearable system can generate comparable precision to the one from the force platform. The sensory systems available on the market use piezoelectric or piezoresistive material on distributed over shoe insoles [e.g., 10, 11, 12, 13]. One of the systems that we single out because it is by the intention of an application similar to the Gait Teacher is the Gait Tutor [14]. The Gait Tutor uses separate IMU positioned at the body segments for biofeedback and monitoring of the gait performance.

The new instrument (Gait Teacher) used in this study comprises in each insole one IMU unit (3D gyroscope and 3D accelerometer) and five ground reaction pressure transducers and all 2 x 11 raw signals are synchronously sent via a specific protocol to the host computer [15]. The system is the successor of the Walky system [16] that has been used in combination with IMU in several clinical studies. The construction of the Walky system is very similar to the Gait Tutor. The target of the investigation was to establish a method for sequencing the gait cycle into phases determined by specific gait events. To clarify the objective, we show a sketch of the gait cycle (Fig. 1). The movements of the left and right legs are time-shifted for 50% of the gait cycle.

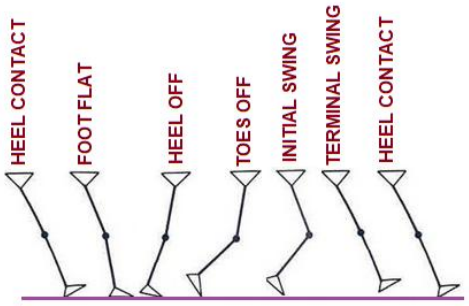

Fig. 1: The events segmenting the gait cycle to phases

II. The Methods

A. Instrumentation

We have used a custom designed system Gait Teacher [15]. The system comprises two insoles instrumented with five industrial pressure sensors and one inertial measurement unit (IMU) per insole. Position of pressure sensors and the orientation of the IMU axis are shown in Fig. 2. Z-axis is positioned towards the ground.

Aleksandar Gogić is a Ph.D. student at the School of Electrical Engineering, University of Belgrade, Bulevar kralja Aleksandra 73, 11000 Belgrade, Serbia, (e-mail: gogicaleksandar@yahoo.com).

Dejan B. Popović is with the Serbian Academy of Sciences and Arts, Knez Mihailova 35, 11000 Belgrade, Serbia, and Aalborg University, Aalborg, Denmark (e-mail: dbp@etf.rs).

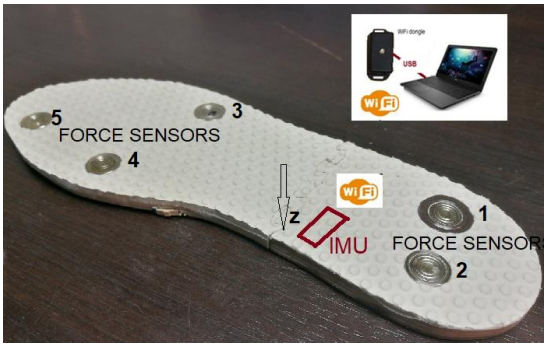

Fig. 2: Gait Teacher insole comprising five pressure sensors, a six-axis digital IMU, Bluetooth communication chip and the battery [15]

Signals from insoles are sent wirelessly to the host PC and read with custom acquisition software. This application was designed in LabVIEW [17] software. It has options to show, calibrate, and log signals acquired from insoles. There is no preprocessing of the raw signals.

B. Subjects and procedure

We recorded data for four healthy subjects with no known history of neuromuscular disorders. All subjects signed Informed Consent approved by the Local Ethics Committee. All subjects were females, with a shoe size of 39 (same size of insoles for all subjects).

Insoles were placed in both shoes of subjects. Subjects were asked to lift feet from the ground one by one, to set the zero for pressure sensors (calibration).

Subjects were then asked to walk along the straight 10m long path with the self-selected comfortable speed. The test was repeated in total four times for each subject.

C. Data processing

Signals were processed offline in LabVIEW 2015 software. We reduced the number of signals for this analysis. The heuristics were based on the evidence gained from the observation that some sensors provide redundant information.

We decided to segment the gait cycle into five consecutive phases. The phases were determined with the gait events as defined below:

- *Toes off* – event when a subject lifts the foot from the ground and starts the swing
- *Terminal swing* – event when the foot is approaching the ground
- *Heel contact* – event when the subject contacts the ground with the heel at the beginning of the stance
- *Foot flat* – a phase where both the heel and toes are in contact with the ground
- *Heel off* – event when the subject lifts the heel, and the support remains only on the tarsus and toes.

After a thorough analysis of recorded data, we have heuristically selected rules for three models that we used for segmentation of the gait cycle events. The signals used in the models are in Table 1.

TABLE 1
LIST OF SIGNALS WITH POSITION AND ORIENTATION OF SENSORS

SIGNAL	DESCRIPTION
P1 HEEL	PRESSURE SENSOR ON THE HEEL (1 IN FIG. 2)
P2 HEEL	PRESSURE SENSOR ON THE HEEL (2 IN FIG. 2)
P1 META	PRESSURE SENSOR ON METATARSAL (3 IN FIG. 2)
P2 META	PRESSURE SENSOR ON METATARSAL (4 IN FIG. 2)
P TOE	PRESSURE SENSOR ON THE TOE (5 IN FIG. 2)
AX	ACCELERATION OF IMU ON THE X-AXIS
AY	ACCELERATION OF IMU ON THE Y-AXIS
AZ	ACCELERATION OF IMU ON THE Z-AXIS
WX	ANGULAR VELOCITY OF IMU ON THE X-AXIS (ROLL)
WY	ANGULAR VELOCITY OF IMU ON THE Y-AXIS (PITCH)
WZ	ANGULAR VELOCITY OF IMU ON THE Z-AXIS (YAW)

The terms used in the tables to follow are the following: dwy/dt is the first derivative of wy, Treshold1 and Treshold2 are the minimal offsets of the pressure signals used to eliminate error caused by noise, Max and Min are maximum and minimum of values inside the brackets, respectively. OR and AND are Boolean operators.

TABLE 2
RULES FOR MODEL 1

GAIT PHASE	RULES
TOES OFF	DWY/DT<0 AND AX>0 AND AZ≤1
TERMINAL SWING	DWY/DT>0 AND AX<0 AND AZ>1
HEEL CONTACT	P1 HEEL>TRESHOLD1 OR P2 HEEL>TRESHOLD1
FOOT FLAT	MAX(P1 META,P2 META)>MIN(P1 HEEL,P2 HEEL)
HEEL OFF	MAX(P1 HEEL, P2 HEEL)<THRESHOLD1 AND P TOE>THRESOLD2

TABLE
RULES FOR MODEL 2

GAIT PHASE	RULES
TOES OFF	DWY/DT<0
TERMINAL SWING	DWY/DT>0
HEEL CONTACT	P1 HEEL>TRESHOLD1 OR P2 HEEL>TRESHOLD1
FOOT FLAT	MAX(P1 META,P2 META)>MIN(P1 HEEL,P2 HEEL)
HEEL OFF	MAX(P1 HEEL, P2 HEEL)<THRESHOLD1 AND P TOE>THRESOLD2

TABLE 4
RULES FOR MODEL 3

GAIT PHASE	RULES
TOES OFF	DWY/DT<0 AND MAX(P1 HEEL, P2 HEEL, P1 META, P2 META,P TOE)<TRESHOLD1
TERMINAL SWING	DWY/DT [K]>0 AND DWY/DT [K-1]≤0
HEEL CONTACT	P1 HEEL>TRESHOLD1 OR P2 HEEL>TRESHOLD1
FOOT FLAT	MAX(P1 META,P2 META)>MIN(P1 HEEL,P2 HEEL)
HEEL OFF	MAX(P1HEEL, P2HEEL)<THRESHOLD1 AND PTOE>THRESHOLD2

Rules for models 1, 2 and 3 are shown in Tables 2, 3 and 4, respectively. In the first two models, phases can switch only in sequential order, the same as the order in the table. In the third model, skip of heel-off is made possible.

III. Results

All signals recorded from one foot are in Fig. 3. The stance phase is denoted by a yellow background, while the swing phase by white for more natural visual perception. Fig. 4 shows one gait cycle extracted from the signal in Fig 3.

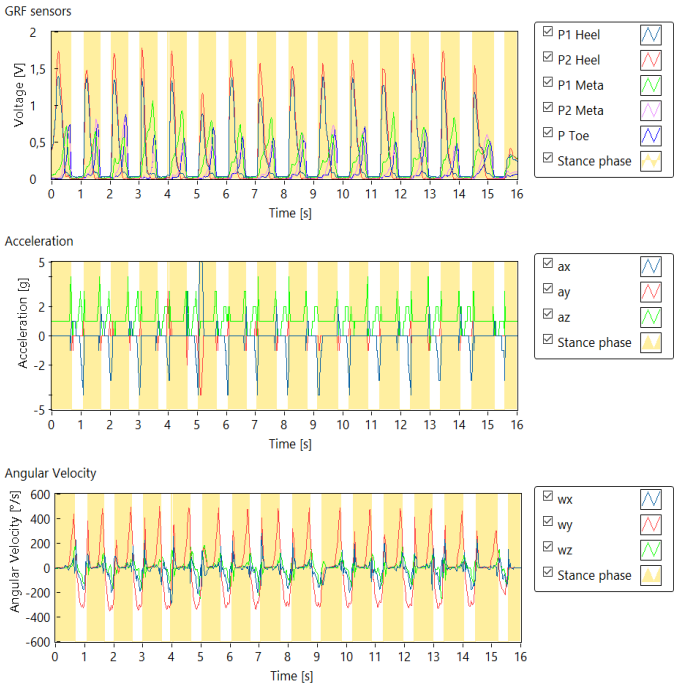

Fig. 3: Signals of one foot during one 10m walk

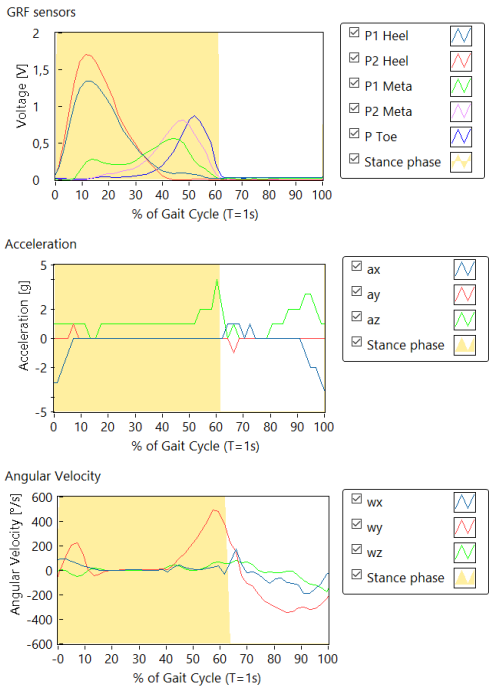

Fig. 4: A typical gait cycle extracted from Fig. 3

The results from the four clinical tests are presented in tables 5, 6 and 7.

TABLE 5
THIS NUMBER OF GAIT PHASES IS ESTIMATED BY HEURISTICS AND FROM MODEL 1 AUTOMATICALLY.

	Toes off	Terminal swing	Heel contact	Foot flat	Heel off
# of phases Heuristics	300	300	300	300	300
# of phases Automatic	289	289	289	289	289

TABLE 6
THIS NUMBER OF GAIT PHASES IS ESTIMATED BY HEURISTICS AND FROM MODEL 2 AUTOMATICALLY.

	Toes off	Terminal swing	Heel contact	Foot flat	Heel off

# of phases Automatic	300	300	300	300	300

Column chart (Fig. 5) is showing the percentage of successful individual gait phase recognitions. Every color of a bar represents one model that was used for classification.

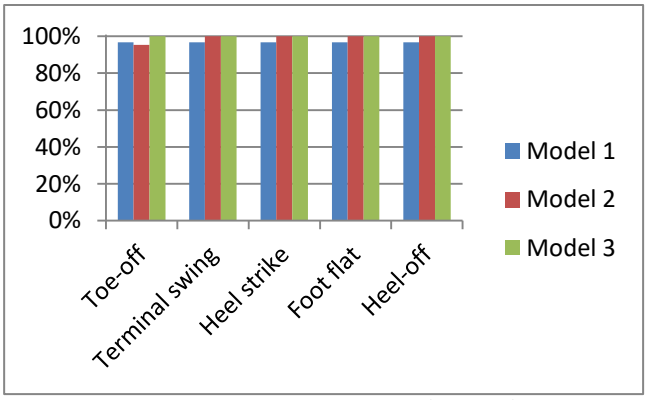

Fig. 5: Bar diagram showing the percent of successful automatic gait event/phase recognitions for the three models tested

IV. Discussion

Model 1 gives acceptable results (Fig. 5). Almost every phase is recognized. Problem is in the duration of phase *Toes off*. Also, there is a problem of not "recognizing" the steps within some of the tests. The problem occurred most likely due to sometimes unreliable acceleration data (noise) that has

been acquired from IMU. This measurement was not reproducible at the level necessary. Therefore, rules that implement accelerometer data can “miss” the gait event that would be seen by heuristics.

Classification model 2 gave better results compared to the results from model 1 for all phases except the phase *Toes off* (Fig. 5). There are two reasons for the decrease in accuracy. One possible problem for missing the *Toes off* event in the initial step comes from the actual modality of movement of a subject (lifting the foot in the air and moving it forward compared to leaning forward and pushing the contralateral leg). The error might also occur since some subjects tend to slightly swing their foot in front at the beginning of *Toes off*. Therefore, the system could falsely register *Terminal swing* phase. Heuristics do not miss all of this, but it is lost by automatic segmentation. Model 3 gives perfect segmentation when compared to heuristics for all phases (Fig. 5).

V. Conclusion

Gait Teacher provides accurate real-time ground reaction force information from only one per leg wireless gadget. The donning and doffing of the system is trivial since the self-contained insole with the small LiI battery allowing eight hours of operation between recharging is identical to many insoles available and uses only wireless communication. The data can be presented to the user online and off-line, or sent to a remote evaluator allowing the feedback based gait training. An example of a possible application is the detection of freezing of gait (FOG) in patients with Parkinsonian disease [18].

The analysis of the system performance suggested that it is appropriate to estimate the length and variability of each gait phase (not shown in this paper). Analyzing the signals used for segmentation defined by model 3, we found approaches for reducing the number of signals that need to be acquired. This conclusion comes from the analysis of level walking. Future studies need to increase the population size and consider perturbations and change in the gait modality (level walking, slope, steps, side walking, backward stepping, etc.).

For future improvement of hardware and classification methods, we are planning to design a smartphone application (Android, iOS) to provide online feedback in sports, recreation, and rehabilitation.

Acknowledgment

Authors would like to thank all volunteers for participation in this study. The work was partly supported by the Serbian Academy of Sciences and Arts, project F-137

Authors would like to thank Vladimir Kojić and the company Rehabshop doo [15] for developing and providing the Gait Teacher system for the tests.

Multi-sensor acquisition system for noninvasive detection of heart failure

Aleksandar Lazović, Lana Popović-Maneski and Ljupčo Hadžievski

***Abstract*—To research the possibility of noninvasive detection of heart failure we developed an acquisition system with multiple sensors. The system synchronously measures cardiovascular pulsations, heart sounds and ECG using different types of sensors positioned only on the patient's body. The system has a modular structure with five modules: 1. Module for controlling the light source (MWLS) 2. Module for data acquisition from fiber optical sensors (FBGA) with the compact optical spectral analyzer 3. Module for the acquisition of hearth sounds (PCG) with four ports for microphones; 4. Module for the acquisition of standard ECG signals; 5. Module for data acquisition from three accelerometers and three photoplethysmography sensors (ACC/PPG).**

***Keywords*— multi-sensor device, heart failure.**

I. Introduction

Heart failure is an abnormality of cardiac structure and function leading to the incapability of the heart to deliver oxygen to maintain natural metabolic balance in the organism. The most common method for the detection of heart failure is echocardiogram in which some functional and structural changes of the heart related to heart failure can be detected [1].

One of the main reasons for the rare detection of heart failure in the early phase of the disease is non-existence of symptoms. When symptoms (weakness, fatigue, breathlessness) become noticeable, the disease has already progressed to the stage when treatment is difficult, and a chance of mortality is very high compared to the patient with early detected heart failure. Also, due to the expensive equipment and skilled personnel, the echocardiogram is typically not part of primary medical care. So, it would be very useful to find an alternative method, which would be cheaper and easier for use in primary care and available to more patients. In order to achieve that, we took the first step of the research and developed a measurement system that will eventually be transformed in such a device that preventive primary care requires. Noninvasive system for early detection of heart failure, which can be cheap and easy for use in primary care, would provide a high impact on the health care system. [2,3].

To investigate the possibility of noninvasive detection of heart failure we developed a new acquisition system for simultaneous measurement of several biomedical signals. By using this system, we will simultaneously measure different types of cardiovascular pulsations, heart sounds, and ECG signals. To measure cardiovascular pulsation, we use fiber optical sensors, accelerometers, compact semiconductor, lasers, and for measurement of heart sounds we use microphones.

In this work, we present the multi-sensor system which will be used for data acquisition of heart-related biomedical signals and data analyses of their properties for early detection of heart failure.

II. System description

Multi-sensor acquisition system, that we developed is composed of multi-sensor acquisition device and PC acquisition software. The multi-sensor acquisition device has a modular structure (Figure 1) with five different modules:

1. A module that controls a light source (MWLS) with bandwidth 1510 nm-1590 nm
2. Module for data acquisition from fiber optical sensors (FBGA) with a spectrum analyzer in the same bandwidth as the light source (1510 nm-1590 nm)
3. Module for the acquisition of heart sounds (PCG module) from up to four different microphones
4. Module for the acquisition of ECG signals with 12 channels (ECG module)
5. Module for the acquisition from three accelerometer sensors and three photoplethysmography (PPG) sensors (ACC/PPG module).

A. MWLS and FGBA module

The primary purpose of the MWLS and FBGA module is a real-time measurement of the transmitted spectrum passed through some fiber optical sensor (FBG or LPG sensor). MWLS module emits light through a fiber optical sensor in a wide bandwidth range. As optical sensors are fabricated with a grating, transmitted light spectrum on the opposite side of the sensor has resonant deeps. If the sensor is stretched or curved with a small radius, resonant deep is moving towards lower or higher frequencies linearly. This characteristic of the sensor can be used for the measurement of respiratory and cardiovascular pulsations [4,5].

Both MWLS and FBGA modules are an official product of company BaySpec. FBGA module is optical spectrum analyzer which can acquire spectrum at a maximum sampling rate of 5 KHz. Also, each spectrum sample is a group of 512

points in the spectrum range 1510 nm-1590 nm, which means that spectrum resolution is 0.15625 nm. By analyzing the spectrum of measured signals, we concluded that the sampling frequency of 500Hz is good enough. Because a large amount of data needs to be sent in real time, the system uses USB full speed communication for data transmission to PC. USB is also used for control of the MWLS module. FBGA module has a triggering ability which is crucial for synchronization between all modules.

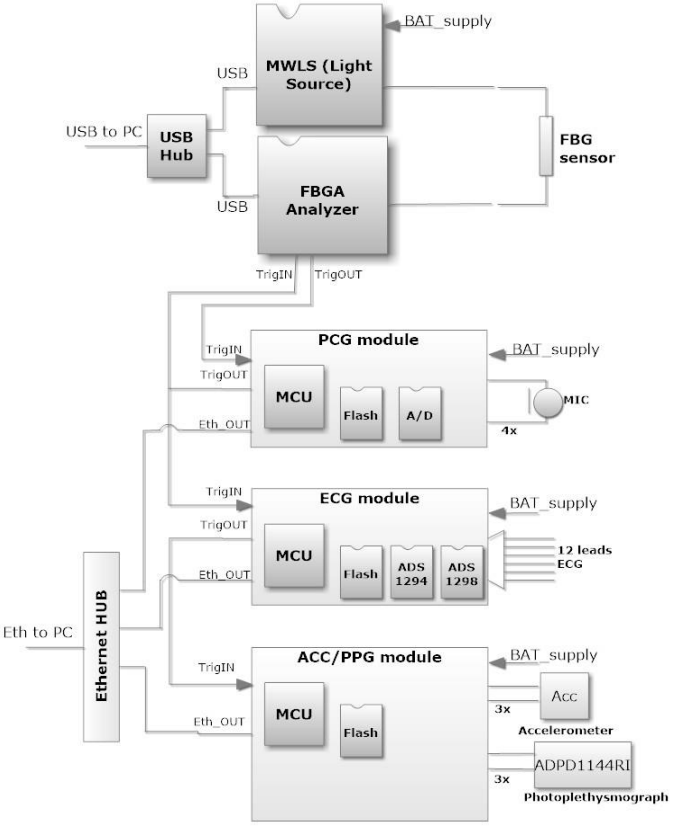

Figure 1. Schematic description of multi sensor device

B. PCG module

PCG module is a module for the acquisition of data from up to 4 different microphone sensors. The module is based on STM32F407 microcontroller which acquires data from microphones. The acquisition sample rate is 1 kHz with 16-bit A/D conversion. Sensors are MEMS microphones placed in an analog stethoscope bell. All sensors are intended to be used for the measurement of heart sounds (S1, S2, S3, S4) [6]. As significant frequency components of heart sounds are below 200 Hz, sample frequency was set to 1kHz. Also, MEMS microphones are selected to have the high sensibility and wide frequency bandwidth. PCG module is a master module for control of synchronization triggering pulses. This module transmits data to PC over Ethernet.

C. ECG module

ECG module is based on Texas Instruments' chip ADS1298. This chip has a lot of advanced functionalities necessary for easy acquisition of ECG signals. It consists of 8 channels with 8 differential amplifiers and 24bit A/D converter with a maximum sampling frequency of 32 KHz. For the regular acquisition of ECG signals we used 500 Hz sampling frequency. Some additional features of this chip are embedded antialiasing digital filter, RLD driver and lead-off detection. ECG chip is controlled by a microcontroller (STM32F407) over SPI. Data is acquired in real time and transmitted to PC over Ethernet. Electrodes are DC coupled to the inputs of ECG chip.

D. ACC/PPG module

ACC/PPG module is one common module for data acquisition from accelerometer sensors [7] and PPG sensors [8]. It consists of one microcontroller STM32F407 which acquires data from sensors over I2C. The accelerometer sampling rate is 500Hz with acceleration range +/-1g. It is possible to use up to 3 sensors from each group of sensors. PPG sensor ADPD174GGI is Analog Devices' chip with integrated all necessary components for reflective photoplethysmography measurement. It has incorporated photodiode, two green, and one infrared LED. Ambient light and offset rejection, photodiode amplifier gain control and LED intensity control are features of the sensor that simplify its usage and processing is not needed when data is acquired. The sampling frequency of the photodiode A/D converter is 100 Hz.

Data is synchronously acquired from both groups of sensors and transmitted to PC over Ethernet.

E. Power supply

The power supply of the system is a lead-acid battery of capacity 7 Ah. The battery can be charged using an external AC/DC power supply. To make the system comply with safety standards, charging is enabled only when the device is turned off. Working capacity of the device is approximately 10 hours.

F. Synchronization and communication with PC

MWLS and FBGA modules communicate with PC over USB. Other three modules communicate with PC over Ethernet. As standard PC doesn't have three Ethernet ports, an Ethernet hub is integrated inside the device. When synchronization measurement is initiated, the PCG master module transmits triggering pulses to synchronize acquisition. Data is transferred to PC independently from each module in real time in the form of packets.

G. Acquisition software

Acquisition software is realized in Visual Studio C#. When the device is connected to PC synchronous acquisition can be started and received data from each module is recorded in an independent file. When the measurement is finished, acquisition software has to merge synchronized data from separate files into one file. In real time, up to 6 different graphs from different types of sensors can be shown on the main screen giving examiner possibility to see if some electrode or sensor was not placed correctly.

III. RESULTS

On the following three pictures (Figure 2, Figure 3 and Figure 4) are shown realized acquisition device, sensors and electrodes used in measurement and example of sensor positioning on the patient.

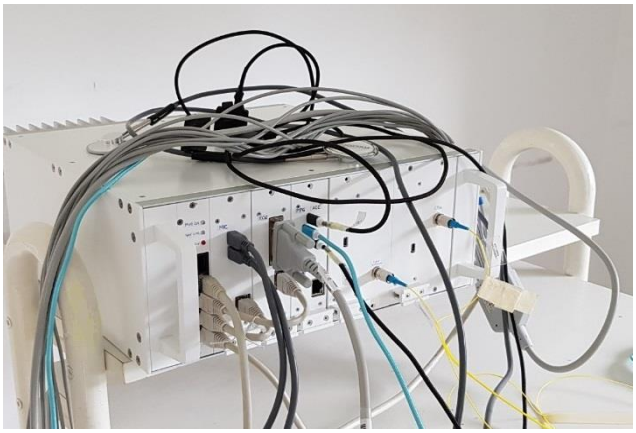

Figure 2:Realized multi-sensor acquisition device

Figure 3:Different sensors used in measurement - fiber optical sensor (up left), ECG electrode cable (up right), photoplethysmography sensor (bottom left), accelerometers (bottom center), digital stethoscope (bottom right)

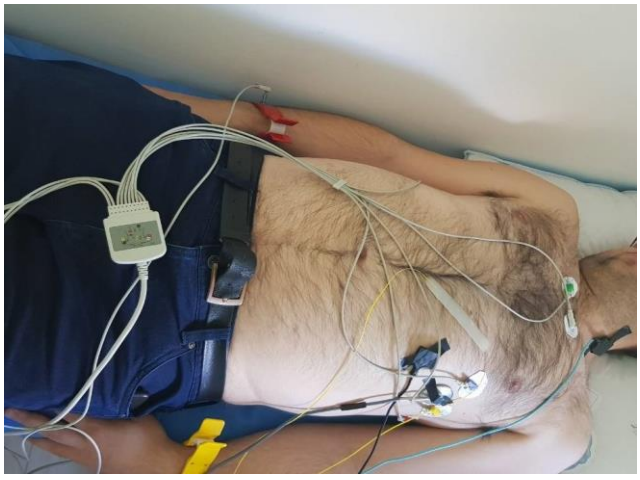

Figure 4: Electrodes and sensors placed on the patient

On the following two pictures are shown signals that were measured independently from each sensor. Figure 5 is shown signal from the microphone placed on the chest of the healthy person. It can be noticed that heart sounds S1 and S2 are visually detectable which means that the position of the microphone in stethoscope bell was adequate.

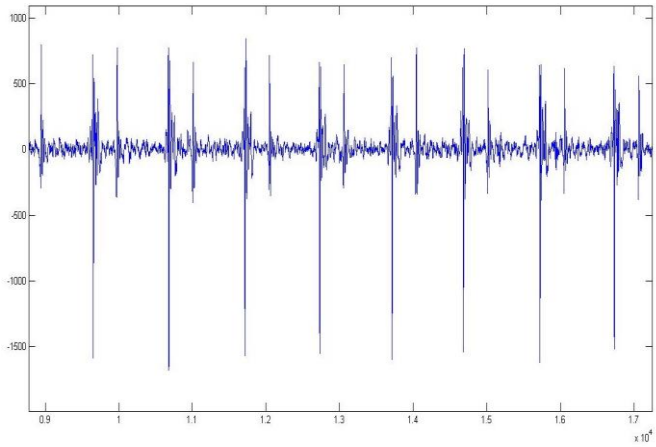

Figure 5. Signal measured from PCG sensor (digital stethoscope)

Figure 6 shows the signal measured from an accelerometer positioned on the chest of the patient below the heart. Also, Figure 6 are visible clear heartbeats with a periodic signal pattern which indicate that the measurement is successful.

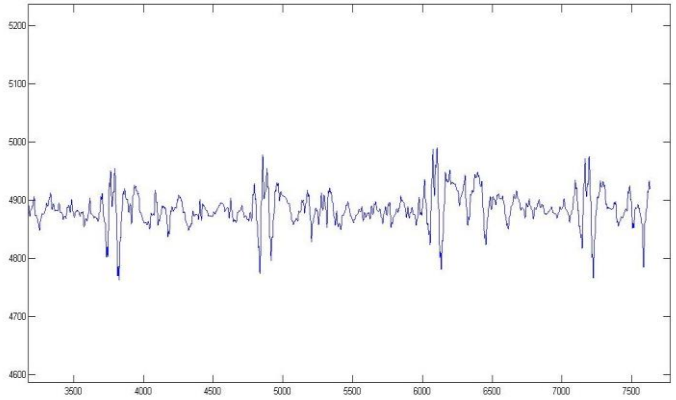

Figure 6. Signals measured from an accelerometer positioned on the chest below the heart

Figure 7 shows multiple signals from multiple different sensors measured simultaneously. This kind of measurement shows that all of the signals are well synchronized.

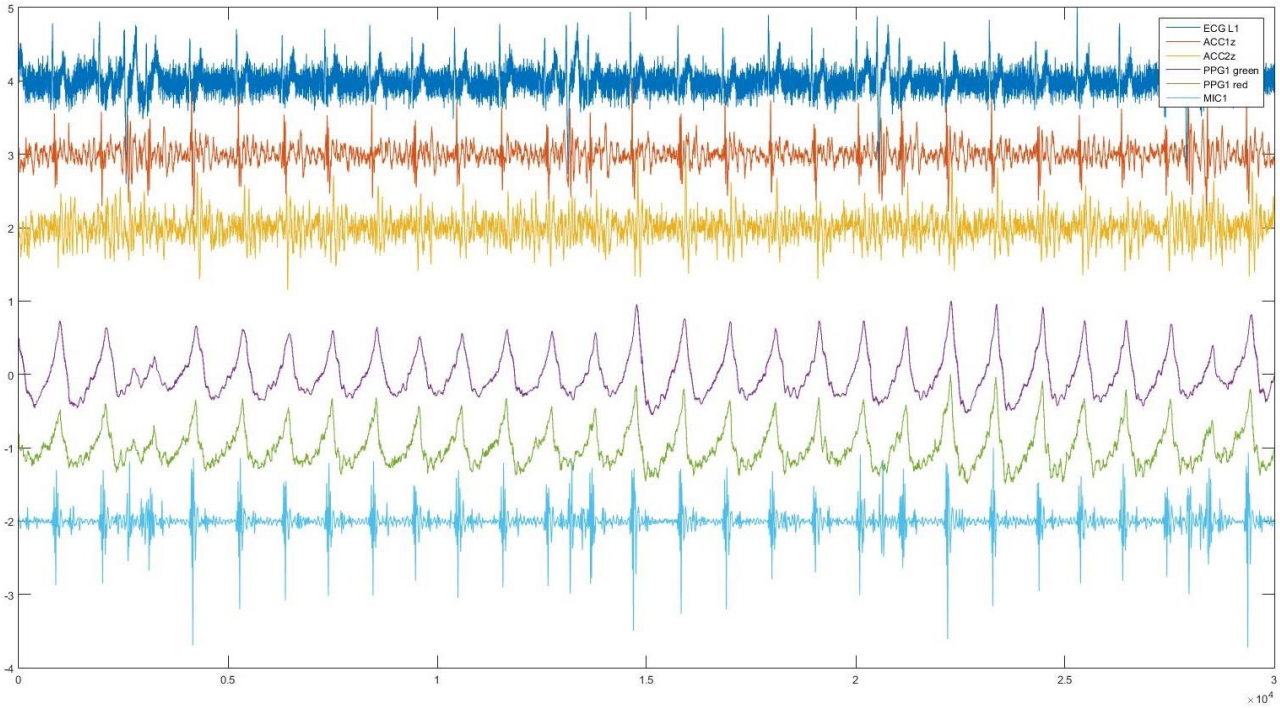

Figure 7. Simultaneous measurements of different types of signals. Shown signals are (from up to down): ECG signal channel I, two accelerometer signals from lower and upper chests, two signals from PPG sensors positioned on the carotid artery and signals measured from PCG sensors.

IV. Conclusion

Presented acquisition device will be used to record multiple heart-related mechanical, electrical and sound signals for further analyses of their properties and space and time correlations to investigate the possibility for early detection the heart failure. The first set of measurements was used to optimize the configuration and positioning of the sensors on the human body to get good quality raw signals with increased signal to noise ratio. The results show that the device is delivering well-synchronized signals from all sensors with good signal to noise ratios appropriate for further analyses. The next step is an adaptation of the multisensory device for use in a clinical study which will include patients with detected heart failure in early and progressed phases. For that purpose, we are developing user-friendly software and preprocessing algorithms to enable easy handling of the device by the medical personnel in clinical environment. Due to its modular structure and possibility to use multiple sensors, the device can be easily reconfigured for some other biomedical researches.

Drowsiness detection using machine learning approaches based on cardiopulmonary signals

Anita Lupšić, Predrag Tadić, Veljko Mihailović and Milica Janković, *Member, IEEE*

***Abstract*—Drowsiness detection systems can be behavioral-based (e.g. tracking face/eyes expressions, vehicle-based measuring) or physiological-based (monitoring features of physiological signals such as electroencephalography, electrooculography, respiration rate, electrocardiography). The aim of this paper is the development of an algorithm for the detection of drowsiness based on the variability of heart rate and breathing rate features. A group of ten healthy adults participated in the experiment in which they were exposed to multimedia content. The measurement of electrocardiography (ECG) and the respiration curve was performed using Smartex Wearable Wellness System (Pisa, Italy). The video of the subject's face was recorded as the reference signal for drowsiness. All data were acquired while subjects were awake, sleepy and in the early stage of sleep. Time, frequency and fractal feature extraction of heartrate variability and breathing rate was performed. Machine learning approaches (Support Vector Machines (SVM), k-nearest neighbors (kNN) and ensemble methods) were implemented for the multinomial classification with three output classes: "awake", "drowsy" and "fallen asleep". Unequal risks of different error types were considered because the consequences are significantly higher if the "drowsy" and "fallen asleep" classes are not properly detected, in comparison to the "awake" class. The upper accuracy of 77% and 80% was obtained in the validation and test process, respectively.**

***Index Terms*— drowsiness, ECG, respiration, support vector machine, k-nearest neighbors, ensemble method.**

I. Introduction

DROWSINESS is defined as a transitional state between wakefulness and sleep associated with a desire or inclination to sleep (sleepiness) in which the "sleep onset process" has already begun [1],[2]. Assessment tools for sleepiness include behavior measures (e.g. head movements, facial expressions, eye closing etc.), subjective rating scales (e.g. Stanford Sleepiness Scale - SSS, Karolinska Sleepiness Scale - KSS etc.) and electrophysiological measurements (Multiple Sleep Latency Test - MSLT, polysomnography, cerebral evoked potentials etc.) [3]. Measurement of sleepiness is significant from the point of view of clinical evaluation [4], [5] as well as in conditions when healthy population intends to state awake (e.g. while driving or at work).

According to the data collected by the American Automobile Association, drowsiness is one of the main causes of traffic accidents (about 20% of all) [6]. From an economical point of view, around 30 billion dollars is spent on traffic accidents caused by drivers' drowsiness. Those facts caused expansion in the development of commercial systems for drowsiness detection based on arteficial intelligance approaches performed on features extracted from vehicle behavior signals (e.g. deviation from the central lane position, steering wheel disturbance etc.), camera recordings (e.g. position of the head, yawning, degree of eye closure etc.) or physiological signals (e.g. electrocardiogram (ECG), electrooculogram (EOG), electroencephalogram (EEG), respiration curve) [7], [8], [9], [10]. The most reliable systems for sleepiness assessment are based on physiological signals, but they usually require uncomfortable contact sensors for measuring physiological state of the body. Contactless systems (e.g. radar-based systems) for precise vital signs monitoring (heartrate and breathing rate) can overcome such problems and enable using objective and reliable measurement of sleepiness based on physiological features [11], [12].

The aim of this paper is the development of a drowsiness detection algorithm based on the variability of heart rate and breathing rate features using different machine learning approaches. This type of algorithm could be further implemented for use in non-contact drowsiness detection systems which rely on the measurement of heart rate and breathing rate. In Section II we have presented the experiment setup, signal preprocessing methods, feature extraction procedure and classification methods. The classification results are reported in Section III. Finally, the conclusion and plans for future work are given in Section IV.

II. The Method

A. Experiment description

A group of ten healthy volunteers participated in the experiment (four males and six females, 26±5 years). The written informed consent form was signed. The experiment is carried out in accordance with the ethical standards of the Declaration of Helsinki. They were in a semi-seated position and exposed to multimedia content from a laptop (movie,

Predrag Tadić is with the University of Belgrade - School of Electrical Engineering, Bulevar kralja Aleksandra 73, 11120 Belgrade, Serbia (e-mail: ptadic@etf.rs).

Veljko Mihajlović is with the NovelIC L.L.C., Veljka Dugoševića 54/A3, 11000 Belgrade, Serbia (e-mail: veljko.mihajlovic@novelic.com).

Milica Janković is with the University of Belgrade - School of Electrical Engineering, Bulevar kralja Aleksandra 73, 11120 Belgrade, Serbia (e-mail: piperski@etf.rs)..

music or noise, depending on the subject's wishes). Laptop was positioned in front of the subject so that the camera could capture the face and eyes of the subject, Fig. 1. Electrocardiogram (ECG) and respiration curve were acquired using the reliable textile-based Wearable Wellness System (WWS, Italy, Pisa) that was positioned as a belt around the subject's torso [13]. WWS sends ECG and respiration data via bluetooth to the laptop where data logging is performed. A screen shot of the acquisition software for ECG and breathing monitoring is presented in Fig. 2.

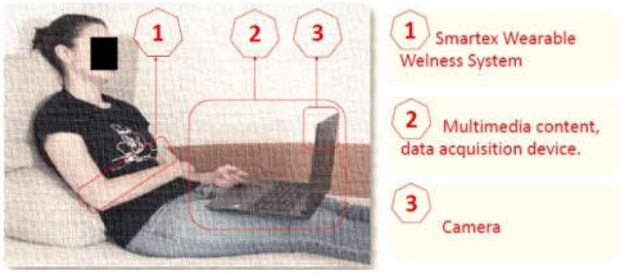

Fig. 1. Experiment setup

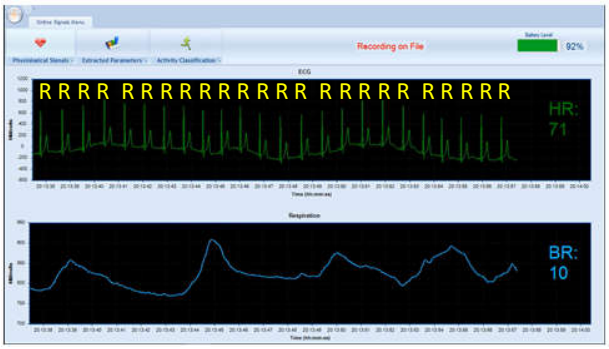

Fig. 2. A screen shot of WWS data acquisition software

B. *Signal preprocessing and feature extraction*

Sampling rates for ECG and breathing were 250Hz and 25 Hz, respectively. Beat-to-beat intervals (position of R waves in ECG) were extracted using the Pan Tompkins algorithm [14]. Time, frequency and fractal feature extraction for heart rate variability (HRV) and breathing rate parameters was performed. Table I and Table II show HRV and breathing rate parameters, respectively, selected as features for classification, as in [15].

C. *Classification*

Data labeling was performed manually, based on video recordings in three output classes: 1-"awake", 2-"drowsy" and 3-"fallen asleep". 80% of data was used for training and validation, and 20% of data was used for testing. K-fold cross-validation method (k=10) was used for evaluation of machine learning approaches [16]. Classification procedure was performed using: Support Vector Machine (SVM) with Gaussian kernel [17], k-nearest neighbors (kNN) and ensemble methods (boosted trees, bagged trees, random subspace method) [18]. Trained model needs to have two main characteristics: high classification accuracy and low risk of false alarm. After determination the optimal model, data are ones again run through the selected model for finding the optimal hyper-parameters. The final metrics, reported in Section III, were obtained by running the held-out test data through the tuned models.

TABLE I
HEART RATE VARIABILITY FEATURES

Parameters	Units	Definition
Time domain		
MeanRR	ms	Mean value of the RR intervals in the fixed time window.
STDRR	ms	Standard deviation of RR intervals in the fixed time window.
RMSSD	ms	Root mean square of RR intervals in the fixed time window.
NN50	count	Number of neighbour RR intervals with maximum differences of 50 ms.
Frequency domain		
VLF,LF,HF	ms	Absolute power of frequency ranges.
LF,HF	n.u.	Normalised power of different frequency ranges.
Non-linear parameters		
SD1	ms	Standard deviation of Poincare plot perpendicular to the line-of-identity (45° line to the normal axis).
SD2	ms	The standard deviation of Poincare plot along the line-of-identity (45° line to the normal axis)
ApEn	-	Entropy for short-time signals.

TABLE II
BREATHING RATE FEATURES

Parameters	Units	Definition
Time domain		
MeanBB	ms	Mean value of BB intervals in the fixed width time window.
STDBB	ms	Standard deviation of BB intervals in the fixed width time window.
RMSSD_BB	ms	Root mean square of BB intervals in the fixed width time window.

III. RESULTS

Confusion matrix for SVM with Gaussian kernel is presented in Fig.3. The optimization of hyper parameters was done for each model separately. A one-versus-all approach was employed – three binary classifiers were built, each of which distinguishes between one of the classes and the remaining two. Fig. 3 shows that 33% instances of the class "drowsy" is misclassified as "awake". The overall accuracy was 73%.

Fig. 3. SVC confusion matrix for Gaussian kernel

kNN was trained for different distance functions, as well as for different numbers of parameter k. The optimization was done for eleven different distance functions [19] (Spearman, Seuclidean, Mincowski, Mehalanobis, Jaccard, Hamming, Euclidean, Cosine, Correlation, Chebyshev, City block Distance) and for each function validation errors were calculated for k=1 to k=100 neighbors. Fig. 4 presents the objective function model through iterations for different distance functions and different numbers of neighbors.

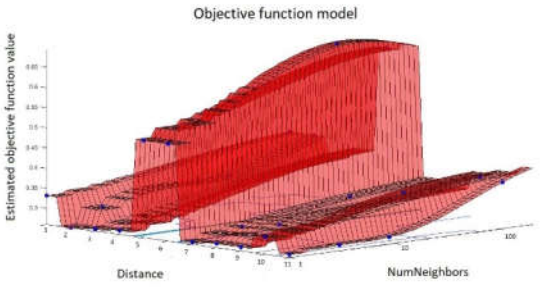

Fig. 4. kNN objective function model for eleven distance functions and k=1,100. (1-Spearman,2- Seuclidean,3- Mincowski, 4-Mehalanobis, 5-Jaccard, 6-Hamming, 7-Euclidean, 8-Cosine, 9-Correlation,10- Chebyshev, 11-City block Distance)

Optimization for these two parameters (distance function and number of neighbors k) resulted in the model with the confusion matrix presented in Fig. 5. The probability of misclassification for the "drowsy" class is 29%, 18% of instances from this class were labeled as "awake", and 10% as "fallen asleep".

New optimization was done by the weight which should be assigned to every sample. The model which gave the best results was obtained for k=10 neighbors with Euclidean distance, with reciprocal weights. 24% of instances from the "drowsy" class was misclassified: 14% was mislabeled as "awake", and 11% as "fallen asleep", Fig. 6. The overall accuracy was 75.7%.

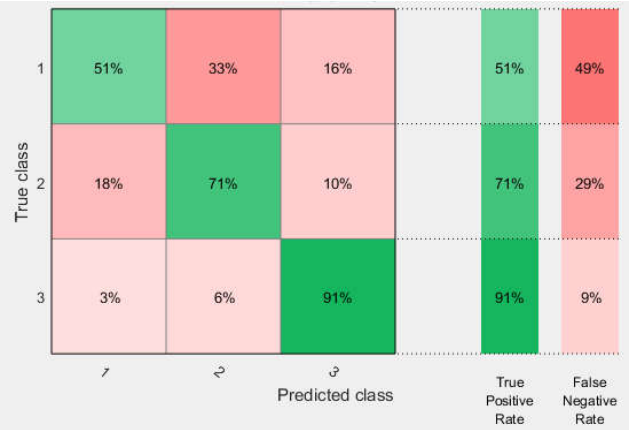

Fig. 5. kNN confusion matrix (optimized for two parameters)

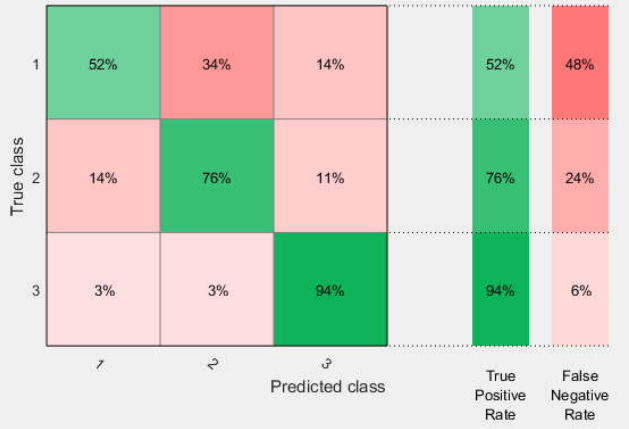

Fig. 6. kNN confusion matrix (optimized for four parameters)

Confusion matrix for different types of ensemble models (boosted tree, bagged tree and random subspace model with kNN classifiers as week learners) is presented in Fig. 7.

Boosted tree - We have optimized boosted tree model over the following hyper parameters: learning rate, number of trees and the maximum depth of each tree. Based on this the best result is achieved with model with *number of trees*=52, *maximal number of branching*=16, *learning constant*=0.1. Figure 7A shows the confusion matrix for boosting algorithm. The "drowsy" class was labeled correctly with probability 78%, while 17% of instances were labeled as "awake". The overall accuracy was 71%.

Bagged tree - Every tree is trained on a different, bootstrapped dataset, and the final decision is made by a majority vote, [20]. Figure 7B shows the confusion matrix for the bagged tree model with the learning rate of 0.1 and with 100 week learners. The overall accuracy was 74%.

Random subspace – This method was used for improving

the performance of the kNN model. kNN was used to train the weak learners, [21]. After a certain point the overall error gets bigger when the number of nearest neighbors is increased. The minimum is achieved for ten nearest neighbors, with the overall accuracy converges to 77%. The confusion matrix for this choice of parameters is represented in Fig. 7C.

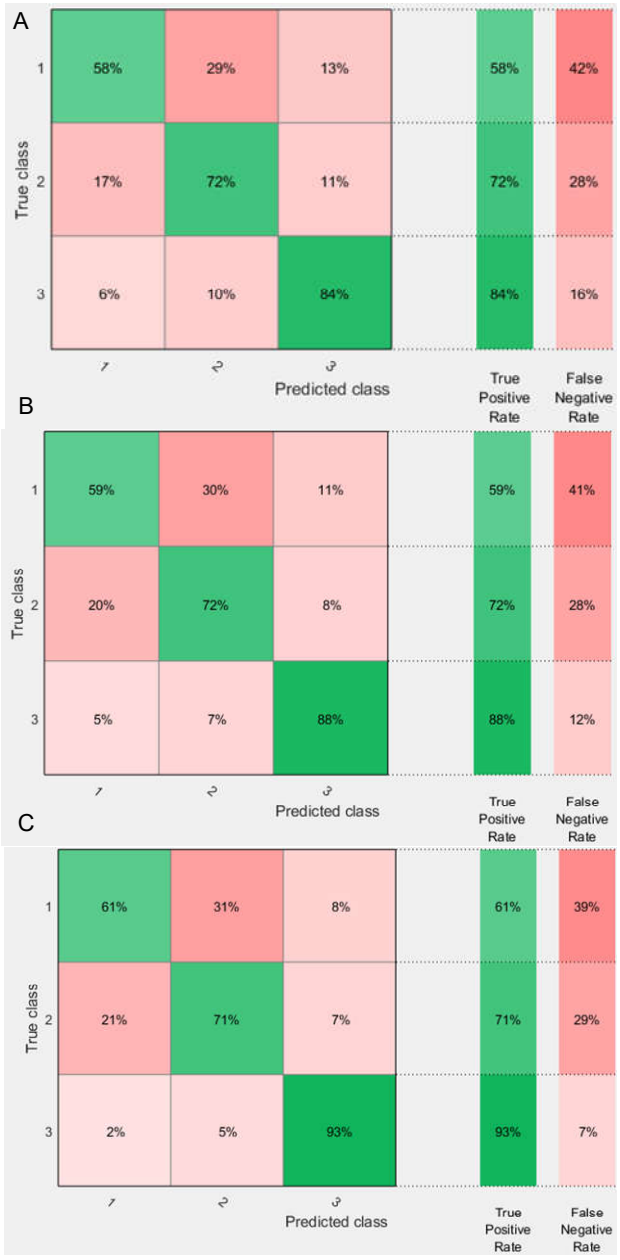

Fig. 7. Ensemble methods confusion matrix for: A) boosted trees method, B) bagged trees method, C) random subspace method

The model with the best performance was the ensemble method with kNNs as weak learners. The main problem is slightly higher error when classifying the "drowsy" class. Model which gave a slightly higher estimation of validation error, but better performance on the samples from the "drowsy" class is the kNN model (optimized for four parameters). Fig. 8 and 9 show confusion matrices on the test set for these two models.

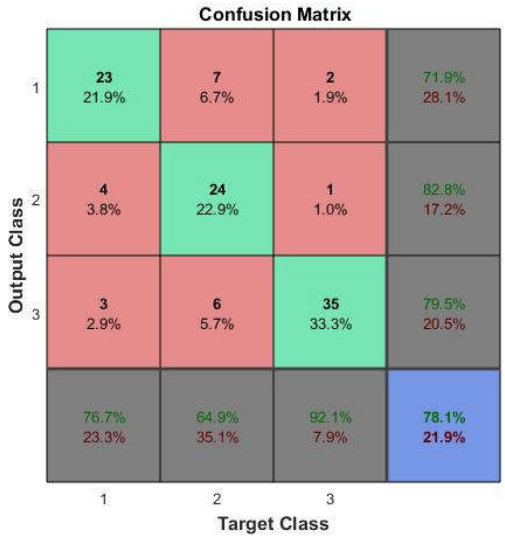

Fig. 8. Confusion matrix for random subspace model on test data

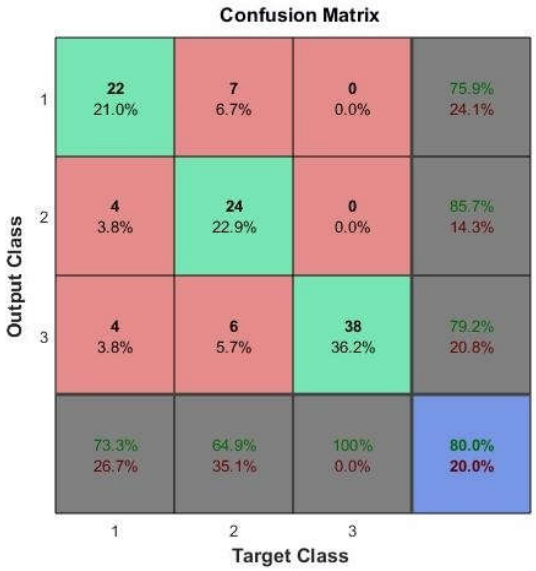

Fig. 9. Confusion matrix for kNN model on test data

IV. Conclusion

The study presented in this paper compared results of several machine learning approaches for detection the degree of alertness, based on features of cardiopulmonary signals. The upper accuracy of 77% and 80% was obtained in the validation and test process, respectively. Results could be improved by a more precise and automatic data labeling. Video reference could be replaced by electroencephalographic (EEG) recording signal that offers reliable detection of

sleeping phases from the EEG signal [22]. This approach would not only lead to the better precision, but also to the possibility of distinguishing more number of classes [23]. Also, more realistic environment for inducing subjects into sleeping phases is desirable (e.g. driving simulator in virtual reality). This would give us a much more realistic picture of the transition between the sleeping stages.

Analysis of PVC microfluidic system for antibacterial solutions delivery in dentistry

Anđela Stojanović, Jovana Jevremov, Bojan Petrović, Sanja Kojić, Jovana Lazarević and Goran Stojanović, *Member, IEEE*

Abstract- Microfluidic systems can be used for oral diagnostics but they can also provide a new approach for effective drug delivery. The aim of this investigation was to evaluate the applicability of PVC microfluidic setup for the purposes of controlled release of two antibacterial mouthwashes commonly used in dentistry and to evaluate basic physical properties of liquids within the channel of microchips. Eight PVC chips were fabricated, they were Y-channel chips without any obstacles, with the input channels set at an angle of 60 °, and the width of 500-700 μm. The analyzed parameters included the passage, speed and necessary pressure for the laminar flow of solutions. The liquid diffusion was observed with a USB camera. All chips were crossable for both tested solutions. A laminar flow for both liquids was achieved with a pressure of 40 mbar. The minimum pressure on which flow was possible was 1 mbar for Eludril and 5 mbar for Curasept. The obtained data indicate that controlled drug delivery for routine use in dental clinical practice utilizing microfluidic setups require additional preclinical confirmation, calibration of all relevant parameters and the improvement of merge of existing medical and engineering technologies.

Keywords. Mouthwash solutions; drug delivery; microfluidics; PVC chips

I. Introduction

Microfluidics offers numerous possibilities for various clinical applications since it is still young and rather underdeveloped area of engineering that allows us to control liquids on the micro and nano scale, factors enabling basic medical science to extend its diagnostic, research and innovation properties. Microfluidic setups generally consist of fluid channels through which liquids are passed, pumping units and electronics for data collection and control. During the last couple of decades, exploration of the possibilities fordesigning less invasive and more accurate diagnostic tests gained increased attention, together with the raising concern for targeted and individualized drug delivery which has intensified research into the opportunity of salivary use as a diagnostic fluid, and intraoral drug delivery as a favorable drug delivery route. It has been clearly shown that among non-invasive organic fluids, saliva is one of the most preferred and most practical samples for monitoring general and oral health because it is always easily accessible, effortlessly gathered and stored [1,2]. When analyzing the drug delivery patterns, the intraoral route is without doubt the most preferred from patients' perspective. In addition, numerous factors render the oral cavity tissues, mucosa and teeth, appealing and practical sites for systemic and local drug delivery. The mucosa of oral cavity is rather permeable with a good vascularization and innervation, and exhibits rapid healing period after trauma or damage [3,4]. However, intraoral administration of drugs has its disadvantages for both oral and general diseases, such as unpredictable patients' compliance, unstable effective concentrations, clearance within the oral cavity, mixing properties with saliva and penetration to targeted tissues and degradation within the gastrointestinal tract. All abovementioned limits encouraged the consideration of other similar tissues and mucosae as probable drug release routes and sites for drug absorption [5]. Inside the oral cavity, drug delivery is categorized into three groups: 1) sublingual delivery, 2) buccal delivery, 3) local delivery.

Chlorhexidine, especially in a form of digluconate (CHX) is an extensively assessed and commonly used antibacterial agent in dentistry, since it exhibits the potential for efficient disinfection in the oral cavity against numerous bacterial strains and also has antifungal properties. The application indications for CHX are numerous, ranging from prophylactic and preventive, preoperative and postoperative disinfection in surgical procedures, and finally, to therapeutic use for the therapy of gingivitis and periodontal disease [6]. CHX is used in various forms and concentrations for both at home and professional applications, and nowadays it is used in concentrations ranging from 0.1% up to 20%.

Studies on the controlled and slow release of antimicrobial agents, including CHX, from some polymer based systems, and the assessment of their clinical performances have been described [7]. And at the moment, various polymer systems such as fibers, micro beads, films and strips are used for oral drug delivery systems, using chemical or physical release regulation with the aim of adjusting the release level, without the possibility of automation and target delivery. When it comes to CHX, targeted tissues are condition dependent, varying from subgingival periodontal pocket, gingival surface, to exposed mucosal wound, issues that can be easily targeted with using microfluidic systems. However, at the same time it has been clearly pointed out to the fact that transitioning from the research laboratory microfluidic setups into the routine clinical applications faces some important challenges. increasing number of microfluidic devices and applications emerging for clinical use, it is mandatory to assess the selection of substrate and fabrication method in order for the product to meet biocompatibility, clinical safety and regulatory criteria, and finally to contribute to answering the question: "*when does a microfluidic device become a medical device, as opposed to a research product*" [8]. Bearing in mind that the area of microfluidic setups rapidly transfers from research laboratories to everyday clinical practice, the careful choice of materials, systems, setups that comply with medical prerequisites turn out to be very important.

The aim of this investigation was to evaluate the applicability of PVC microfluidic setup for the purposes of controlled release of two antibacterial mouthwashes commonly used in dentistry and to evaluate basic physical properties of liquids within the channel of microchips.

II. Material and methods

Microfluidic properties of two different CHX based mouthwash solutions were analyzed, and the chemical composition of the investigated liquids is presented in Table I). Eight PVC chips were fabricated, they were Y-channel chips without any obstacles inside of the channel, with the input channels set at an angle of 60 ° (to aviod turbulance) , and the width of 500-700 μm and observation field (Figure 1). The analyzed parameters included the passage, speed and necessary pressure for the laminar flow of solutions. The liquid diffusion was observed with a USB camera (Figure 2).

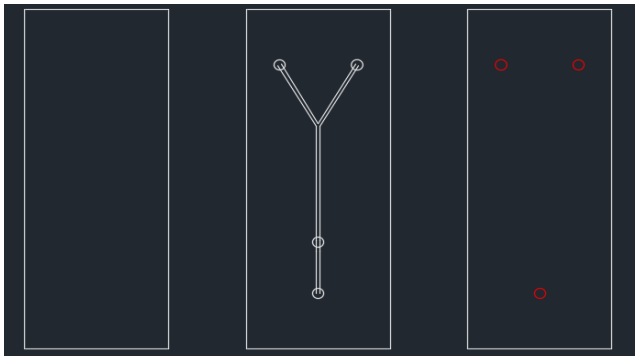

Figure 1. The scheme of the PVC chip design.

TABLE I
COMPOSITIONS OF INVESTIGATED MOUTHWASHES

Eludril	CURASEPT
Glycerin	Water
Chlorhexidine digluconate (0.1%)	Chlorhexidine digluconate (0.2%)
Water	Xylitol
Ethanol	Propylene glycol
Chlorbutanol	Hydrogenated castor oil

For the visualization purposes, tested fluids were painted with gentian violet (Figure 3). Plotter/cutter was used to cut the foils (125 microns thick) in order to manufacture the microfluidic chips. The parameters used for different layer elements are given in Table II, the same experimental and setup parameters were used in our previous reports [9,10], where for the realization of the microfluidic chips, the xurographic technique was used. In order to examine what pressure in the channel is needed for laminar flow of liquid, the fluid pressure at the inlet was changed.

TABLE II
PARAMETERS OF XUROGRAPHIC METHOD FOR CHIPS FABRICATION

	Channel Cutting Parameters	Reference values	Edge cutting parameters	Reference values
Speed	5	1-8	10	1-8
Acceleration	1	1-64	1	1-64
Force	28	1-38	28	1-38

III. Results

All fabricated microfluidic chips were passable for both tested solutions. A laminar flow for both liquids was achieved with a pressure of 40 mbar. The minimum pressure on which flow was possible was 1 mbar for Eludril and 5 mbar for Curasept. Experimental setup enabled satisfactory control, visualization of the flow and recording of the trial. The formation of the bubbles was recorded in both tested solutions but it did not significantly affect the procedure.

IV. Discussion

This study was conducted in order to assess the possibilities of integration of salivary diagnostics within the microfluidic systems. The chips, experimental setups and all employed technologies were for the first time, according to the authors' best knowledge, used for the purposes of evaluating the microfluidic behavior of the antibacterial solutions within PVC based microfluidic systems. This paper, together with previously published reports from our group [9,10], investigates the possibilities of designing optimal microfluidic system for salivary theranostics based on economic and easily fabricated PVC technology, following the criteria set for contemporary medical devices, and defined as ASSURED by WHO [11], that suggested that appliances used for routine procedures in general health monitoring need to be affordable, sensitive, specific, user-friendly, rapid and robust, without the use of complex equipment.

For more than forty years CHX have been used in preventive, prophylactic and therapeutical procedures in dentistry, and its efficiency has been attributed to a high potency, moderate side effects and the lack of bacterial resistance formation [12]. In the present investigation, two commercially available CHX solutions, Eludril and Curasept were chosen for integration into microfluidic system. Controlled release devices, for a prolonged treatment have already been developed and clinically tested within polymer based systems and with different effects [12], and mainly for the use in periodontal disease treatment. However, the use of CHX based solutions is not limited to the periodontal pockets treatment, since the local delivery of antiseptic agents to hard dental tissues and oral mucosa has a lot of indications, comprising dental plaque accumulation prevention, both bacterial and fungal infections, oral ulcers and various types of stomatitis. In addition, during several past decades, the researchers and clinicians search for a therapeutic option employing the device to be placed in the oral cavity, with the possibility of adherence to hard dental tissues, intraoral appliance or oral mucosa, with the aim of treating surgical wounds, as well as wounds that are caused by mechanical, physical or chemical trauma, and other types of oral ulcerations [13], which is for the most part important in the therapy of children experiencing oral and dental trauma, or persons with disabilities, whose non-acceptance behavior makes problematic to put on dressings or local medications.

The expansion of microfluidic setups for salivary diagnostics, controlled drug delivery, possibility for incorporation into intraoral appliances offers significant advantages such as minimal risk of infectivity with no emotional and physical pain together with mechanization, combination, ability for multiple and simultaneous biomarker analysis. This approach offers opportunity for rapid testing using small samples amounts and requires minimal training for final user. Despite the fact that the significant academic interest in microfluidics has been observed, together with the increased interest in salivary diagnostics and intraoral route of drug delivery, the commercial applications have not progressed at a similar rate.

The majority of the materials currently used in microfluidic research and experimental setups, such as polydimethylsiloxane (PDMS) has not translated over to production well due to matters with manufacturability and scaling. In contrast to that, the lack of research data with respect to other, alternative materials that can be used for microfluidic chip fabrication, such as glass and thermoplastic polymers has been observed, and this is recognized as the major obstacle for rapid transfer of these technologies from experimental laboratories to industry and finally, to everyday clinical practice. On top of that, salivary theranostics carries its own limits, criteria and prerequisites that must be met before actual clinical application. That is the reason why the PVC chips with simple design were fabricated and tested against the commonly used antibacterial agent in the present investigation. There is evident size match between microfluidics and salivary constituents, investigated metabolites and diagnostic analites. Active drug formulation particles sizes are also in the micrometer scale range. This overlap in dimensions will certainly facilitate application of microfluidic setups in salivary theranostics, and justify the need for incorporation of these appliances within intraoral devices.The present study defined the criteria for several basic experimental parameters when it comes to behavior of two similar, but not identical solutions within the microfluidic systems, revealing the fact that every different specimen requires different experimental parameters. This suggests that future applications require specific chip designs, controlled canals dimension, adequate pressure and sophisticated analytical and control mechanism.

V. CONCLUSIONS

The obtained data indicate that controlled drug delivery for routine use in dental clinical practice utilizing microfluidic setups require additional preclinical confirmation, calibration of all relevant parameters and the improvement of merge of existing medical and engineering technologies.

Performances of Microfluidic Mixing Regulated using Active Pressure Controller

Jovana Jevremov, Ivana Podunavac, Jovana Lazarević, Sanja Kojić, *Student Member, IEEE*, Vasa Radonić, *Member, IEEE,* and Goran Stojanović*, Member, IEEE*

***Abstract*— Microfluidics studies show how fluid dynamic changes at the microscale level. Interest in microfluidic technologies has been driven by associated developments in bio-related fields such as cell biology, genomics, drug delivery, high-throughput screening and diagnostics, as well as a recognized need to perform fast and efficient experiments on small-sample volumes. Fluid behaviour in the microfluidic channel depends on channel geometry, fluids inside the channels, used material for chip fabrication, chip complexity, presence of external force (passive or active) and many other factors. Rapid and uniform mixing are fundamental principles on which effective design and development of micro-mixer relies on. In this paper COMSOL Multiphysics simulation software was used to investigate the flow characteristics within Y shaped microfluidic channel model for different pressure signals (sin, ramp, step), their periods (1 and 1.5 s) and amplitudes (10 mbar, 50 mbar and 100 mbar). Results were compared with experimentally gained data obtained using commercial flow control system. The results confirm that the best mixing performance was achieved with step signal shape, on shorter periods, and with the higher pressure.**

***Index Terms*—microfluidics, fluids, active mixer, biomedicine, COMSOL Multiphysics.**

I. Introduction

Microfluidics represents cutting-edge combination of science and technology, which roots date back to the 1950s, when the microfluidic was used for the realization of inject printer head. It is based on control and manipulation of fluids at a microliter scale. Thanks to related advantages such as reduced sample volume, scalability, laminar flow (therefore predictable fluid behaviour), short time analysis and low-cost fabrication, microfluidics is becoming one of the fastest growing area of science [1]. These major advances made possible for microfluidics to be incorporated and applied in other fields such as tissue engineering, biosensors, medical diagnostics, ecology monitoring, etc. The "organ-on-a-chip" technology, which represents cellularized constructs integrated in microfluidics platform, faithfully imitates physiological, and pathological conditions of complex tissues, thus revolutionizing existing approaches to drug screening and toxicology studies [2]. More than often, this remarkable studies are followed with extensive and thorough computerized simulations in order to verify and test in vitro models [3]. The computational analysis and simulations are also performed alongside microfluidic experiment, in order to get more reliable insight in chip performance [4].

Jovana Jevremov, Jovana Lazarević, Sanja Kojić and Goran Stojanović are with the Faculty of Technical Sciences, University of Novi Sad, Trg Dositeja Obradovića 6, 21000 Novi Sad, Serbia (e-mails: sanjakojic@uns.ac.rs, sgoran@uns.ac.rs).

Ivana Podunavac and Vasa Radonić are with the BioSense Institute, University of Novi Sad, Dr Zorana Đinđića 1a, 21000 Novi Sad, Serbia (e-mail: vasarad@biosense.rs).

A microfluidic chip consists of set of micro-channels etched or moulded into different material (glass, silicon, ceramics, or polymers) and fabricated using different fabrication technologies such as photolithography, soft-lithography, PDMS (polydimethylsiloxane), LTCC (Low Temperature Co-fired Ceramics), laser micromachining or xurography [5-7]. The selection of the appropriate materials and technologies depend on the concrete application, chip complexity, applied detection principle, operating temperature, biocompatibility and many other factors.

The new generation of microfluidic chips are composed of network of micro-channels, chambers, and reagent storages connected together in order to achieve the desired features (mix, pump, sort, or somehow otherwise process the fluid) and can be integrated with other components such as micro-pumps, valves, electronics or optics. This system of micro-channels and components realized inside the microfluidic chip can be connected to the outside by inputs and outputs pierced through the chip that serves as an interface between the macro- and micro-world [8]. In that manner, different fluids can be injected and removed from the microfluidic chip through tubing, syringe adapters or even simple holes in the chip with external active systems (pressure controller, syringe or peristaltic pump) or with passive hydrostatic pressure.

New microfluidic platforms appear every day as a toolbox for the development of new testing kits and solutions, most commonly in combination with other technology such as PCB (Printed Circuit Board), LTCC, cellulose paper, glass, etc. The complexity of the chips and features of the systems depend on the application-specific requirements that can vary from very simple devices to complex lab-on-chip platforms [1]. The special attention in paid on the development of novel materials for chip fabrication and development of low-cost, disposable microfluidic chip for rapid in-field testing.

The aim of this study was to investigate mixing performance of low-cost microfluidic chip controlled with external active system. The standard Y geometry shaped microfluidic channel was used in order to test effects of different pressures and their nature (signal shapes and period) on percentage of the fluids mixing. Results obtained in COMSOL Multiphysics modelling software are compared with experimentally obtained results. In this paper, we use a novel hybrid technology concept that can be easily used for the rapid fabrication of low-cost microfluidic chips [5]. The proposed fabrication process combines Polyvinyl Chloride (PVC) foils and green tapes, and relies on the cost-effective xurography technique and laser micromachining process. The experimental results confirm that the best mixing performance was achieved with step signal. Potential biomedical applications in area of drug delivery and personal treatment are further discussed.

II. Materials and Methods

A. Materials

For the fabrication of the proposed microfluidic chips PVC foil—A4 hot lamination foil (MBL® 80MIC, Serbia) with the thickness of 80 µm was used. The middle chip layer has been realized using Ceram Tape GC (CERAMTEC GmbH®, Germany) and Heraeus CT800 (Heraeus Electronics LTCC Materials, Germany) green tapes.

Distillate water was the selected fluid. Water and water based food dye colorant (Aroma 1990®, Belgrade, Serbia) were mixed with ratio 5:1. All experiments were recorded with Digital Microscope.

B. Equipment

Plotter cutter (CE6000-60 PLUS®, Graphtec America, Inc., Irvine, CA, USA) with the 45° cutting blade (CB09U) and the cutting mat (12" Silhouette Cameo Cutting Mat, Sacramento, USA) were used for carving inlets, outlets and edges of PVC layers for microfluidic chips. Ceram Tapes GC and Heraeus CT800 tapes were cut out with laser (Rofin-Sinar Power Line D-100, Germany). Bondage between PVC and green tapes are performed through lamination with A4 card laminator (FG320, Minoan Binding Laminating, Serbia).

Profiler Huwitz Panasis with bioimaging software for 3D profile of microfluidic channels was used for profiler analysis and measurement of the channel width.

Microfluidic flow control system ElveflowOB1 [9] was used to set different pressures, periods of relaxation and shapes of pressure signal. In this experiment, three signal shapes were used: sine, ramp and step. Pressures were set to pressure amplitudes of 10 mbar, 50 mbar, and 100 mbar, while periods of pumping were set to 1 s and 1.5 s.

C. Methods

COMSOL Multiphysics® software was used for initial simulations of microfluidic active mixers and testing of their performances. Experimental testing has been performed on the fabricated chips using microfluidic set-up that consists of ElveflowOB1 microfluidic flow control system, PTFE tubing, fittings, holder, connections and digital microscope. Mixing efficiency in the channel was detected optically using digital camera, and mixing rates were determined using image processing algorithm developed in Matlab.

III. Chip Fabrication

The proposed microfluidic chip consists of three layers, as shown in Fig. 1. Top and bottom layers were realized using PVC foils, while the green tape was used for the middle layer. Fabrication of the chip was realized through of several steps. In the first step, laser cutting of the middle chip layer in the green tape, as for standard preparation of layers for LTCC technology was performed. Exact laser parameters used for microfluidic chip fabrication were: current 28 mA, frequency 10 kHz, and cutting speed of 15 mm/s. Plotter cutting of PVC layers, as for standard xurography technique, was used for cutting the inlets and outlet of the microfluidic channels. In the final step, lamination of the cut layers as for standard xurography technique (laminated first: Layer 1 and 2, and then Layer 3) has been accomplished at the temperature of 130 °C. Fig. 1b shows photographs of the fabricated Y-mixer microfluidic chip. In all designed chips, the width of the microfluidic channels has been set to 200

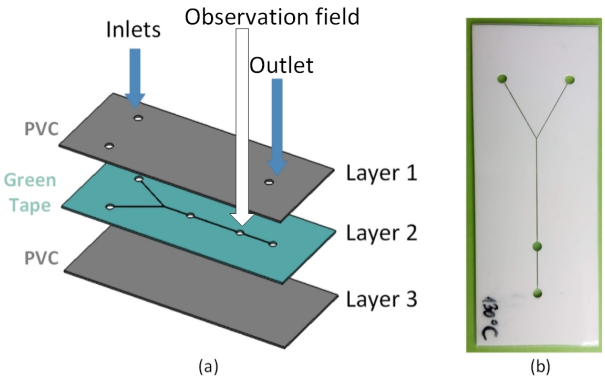

Fig. 1. Microfluidic chips fabricated using proposed hybrid technology (a) 3D model of the microfluidic chip, (b) Fabricated chip with Y-mixer.

µm, while the inlet and outlet holes, and observation field have been manufactured with the diameter of 2 mm. The total length of the microfluidics Y-mixer is chip is 50 mm.

In the process of the fabrication, dimensions slightly changes due to imperfection of laser cutting and lamination processes. Therefore, we fabricated 10 microfluidic chips, five using Ceram Tape GS and five using Hereaus CT800 as a middle layer. Profiler Huwitz Panasis was used for the characterization of the microfluidic channel widths. The width of the channel was measured at eight different points. Fig. 2 shows the measured channel and standard deviation of the channel width. It can be seen that the measured width of channels realized in Ceram Tape GC is smaller than predefined value, while relatively good agreement is obtained for Hereaus CT800 tape. The variation of the channel width in the worst case was below 15%. For experimental testing we used the chip with width of 150 µm and with a minimal deviation of 5% (chip marked as #1GC).

IV. COMSOL Multiphysics Simulations

COMSOL Multiphysics® software was used for simulation and testing of the proposed microfluidic mixer. COMSOL Multiphysics® software uses finite element method for numerical solving of different equations dictated by physical laws. In microfluidic simulations, fundamental equation used for the description of fluid motion in micro channels is Navier-Stokes equation [10]. Multiphysics simulation software was used to investigate the flow characteristics within Y shaped channel for different input pressure signals (sin, ramp, step), their periods (1 and 1.5 s) and amplitudes (10 mbar, 50 mbar and 100 mbar). Three different signal shapes were used for inlet pressure in simulations: sine, step and ramp. In Fig. 3 used signal shapes with period of 1 s are shown.

For visualization of the mixing process, different colours of fluids were used, representing the concentration of fluids. The concentration of one liquid was set to 500 mol/m^3 and concentration of the other one was set to zero. Fig. 4 represents the part of the micro channel in two specific cases.

Fig. 4a shows simulation results for constant pressure flows of 50 mbar at both inlets, while Fig. 4b shows simulation results for sine shaped pressure signals at both inlets. It can be seen that liquids mix only in their contact region, which is the property of laminar flow. Fig. 4b represents mixing of liquids with sine shaped pressure signal on both inlets with amplitude of 50 mbar. Mixing in this case covers almost the whole channel and it can be seen that mixing of liquids is significantly better.

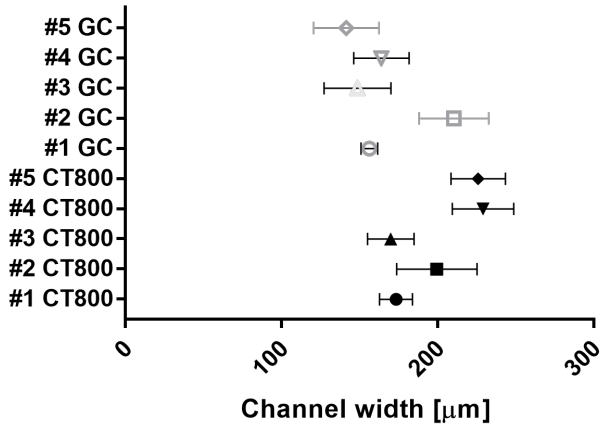

Fig. 2 The measured channel width and its standard deviation for 10 fabricated chips.

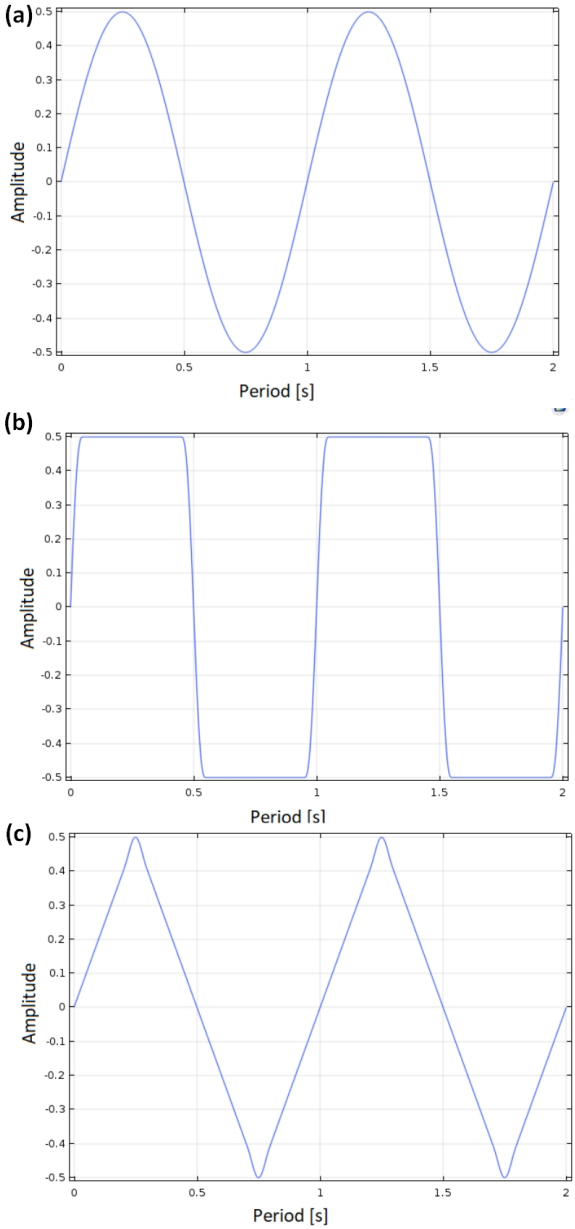

Fig. 3. Pressure signal at inlet of the chip: (a) Sine, (b) step, and (c) ramp.

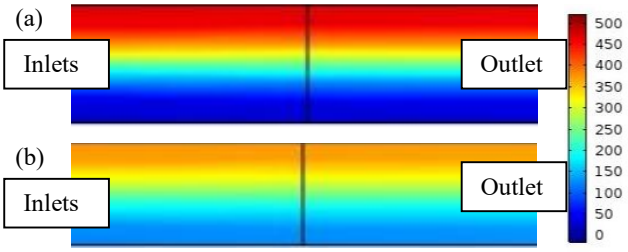

Fig. 4. Mixing of liquid for: (a) Constant pressure flows at inlets of mixer, and (b) Sine shaped pressure signal at inlets.

Fig. 5 shows the average value of concentration along the observation zone for the different signal shapes and pressures during 10 s. Results presented in Fig. 5 are simulation results with 1 s signal period. As it was expected, the better mixing of two fluids can be achieved for higher pressure values. Therefore, for 100 mbar pressure, mixing is achieved after 2 s, for 50 mbar after 4 s and for 10 mbar 10 s is not enough to achieve proper mixing of two fluids. Fig. 5 also shows that step signal gives the best mixing results in term of response time and mixing concentration.

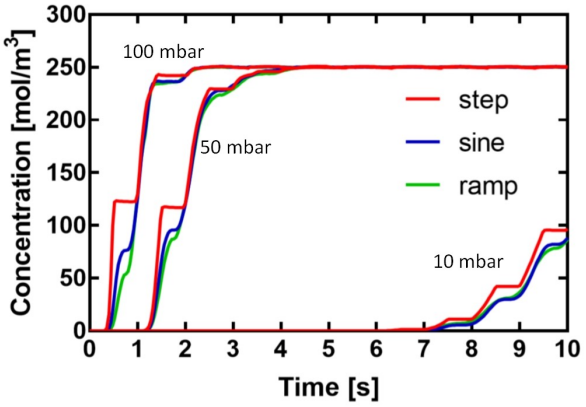

Fig. 5. Average value of concentration along the observation zone. Simulation results for step, sine and ramp signal shapes at pressures of 10, 50 and 100 mbar.

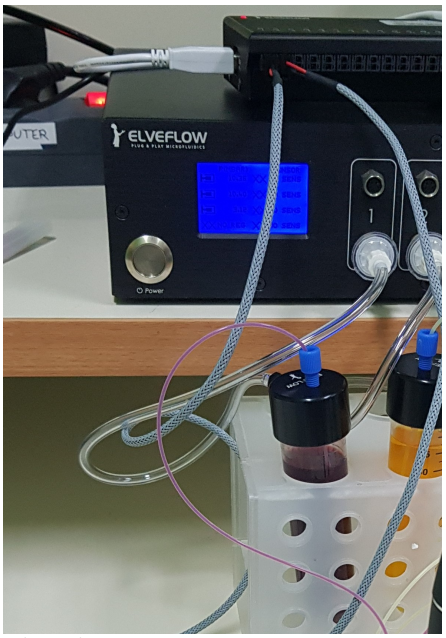

Fig. 6. Experimental set-up

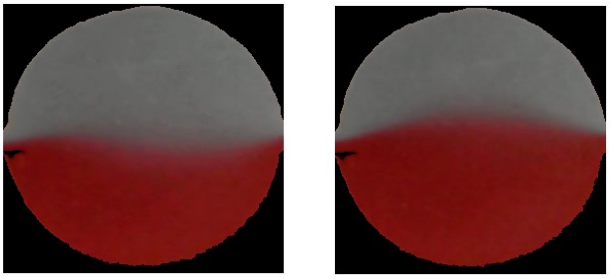
V. Experimental Results

In order to verify simulation results, experimental testing has been performed on the fabricated chips. Set-up for conducting the experiment, shown in Fig. 6, consists of microfluidic flow control system ElveflowOB1, PTFE tubing, fittings, holder, connections and digital microscope.

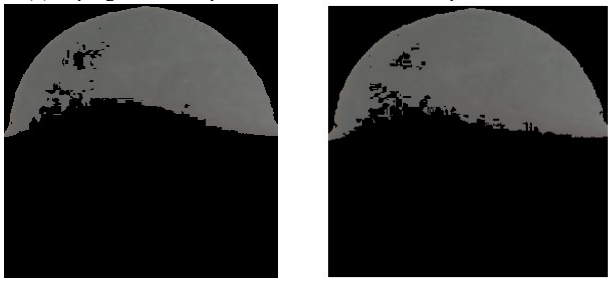
Mixing in the channel was detected visually using digital camera and mixing rates were determined in Matlab. For every flow pressure signal, amplitude, and period, 12 independent photographs during one period of signal were recorded. Photographs had high resolution of 3648 x 2736 dpi. Two examples of the recorded photos are shown in Fig 7. All pictures are further processed in Matlab in order to determine mixing efficiency.

Matlab software was used to isolate the observation field, and isolate the pure red and green color in the image, Fig. 8. Because of the equal flows at both inlets we assume that there is the equal amount of non-mixed red and yellow liquid. In the following step R, G and B components were determined in order to isolate pixels in the observation field, Fig. 9. Based on that for non-isolating, i.e. non-mixed liquids, pixels were classified and counted. The code is written to count the total number of pixels of the observation field, to take away the number of pure yellow/red, and to calculate the mixing efficiency. These results are presented as heat maps for the different amplitude and periods, after first period of signal. In Fig 9. heatmap of results is shown in percentage for different pressure, amplitude and period recorded after period of first impulse. As it was expected, better mixing is performed on shorter periods of pulsation, and higher pressures.



(a) (b)

Fig. 7. Photographs of the observation field after stimulation with: (a) sin, and (b) step signal with amplitude of 50 mbar within the period of 1 s.



(a) (b)

Fig.8. Isolated pixels of unmixed fluid based on 3 colour channels.

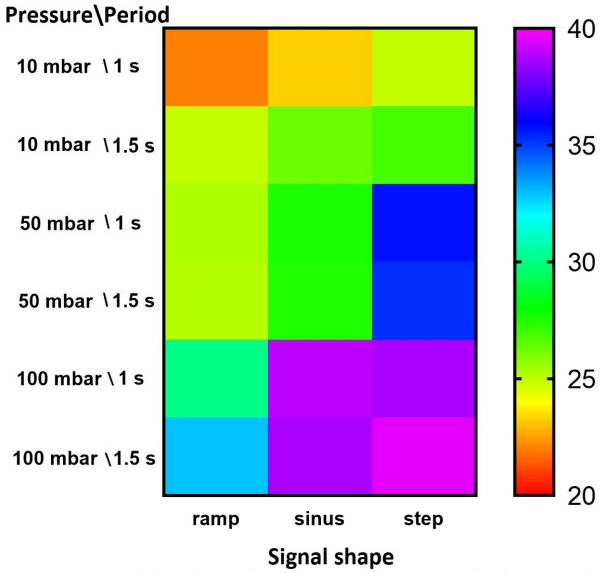


Fig. 9. Results of the mixing for different pressures, amplitude and period recorded after period of the first impulse.

The best mixing occurs for the stimulation with the step signal shape, because of the nature of signal itself, although mixing with sine and ramp signals give almost the same results. With the change of the shape of the signals and their period at the inlets of the microfludic chips the efficiency of the mixing can be increased for more than 30%.

VI. Conclusion

In this paper, we use novel technology concept for rapid fabrication of robust microfluidic mixer. The proposed fabrication process combines PVC foils and green tapes, and relies on the cost-effective xurographic technique and laser micromachining process. The comprehensive study of mixing performances on Y-shape microfluidic channel have been performed. Characteristics of mixing performances of Y shaped channel for different pressure signals (sin, ramp, step), their periods and amplitudes have been investigated using simulation and experimentally verified. Obtained results shows that the shape of signal at the inlets of active mixer, their amplitude and period can influence the mixing performances and can improve mixing efficiency.

The impact of the signal shape is demonstrated on a Y-mixer, but the same effect can also be applied to complex fluid mixing systems. Therefore, the proposed concept can be implemented in complex microfluidic mixing systems for applications in all types of lab-on-chip analysis where rapid mixing of two or more liquids is required.

Increase of the Energy Efficiency of an Urban Type Wind Turbine in a Smart Energy Building

Christos Mademlis, *Senior Member, IEEE*

***Abstract*—This paper presents an efficiency increase control strategy for an urban type wind turbine in a nearly zero energy building (nZEB). The efficiency increase is attained by employing the flux-weakening control technique for the electrical generator and the maximum power point tracking control for the wind turbine. Thus, maximum power harvesting from the whole wind energy conversion system (WECS) is achieved and additionally expansion of the exploitable wind speed region towards the lower-speed range is accomplished.**

Specifically, the developed control technique has been based on previous research work of the author and it is properly adjusted so as, it can be utilized as generic method for any urban type wind turbine for smart energy buildings. Therefore, the developed control method can narrow the advantage of the permanent magnet synchronous generator with respect to the energy efficiency and therefore, a low cost and high efficiency wind generation system can be provided. The usability of the developed wind system is highly important, since the urban type wind turbines have not been widely spread as a renewable energy source in nZEBs, due to the higher cost compared to the photovoltaic systems. It should be noted that, although the proposed control system has been developed with a squirrel cage induction generator (SCIG), due to the advantage of the low cost; it can be applied to a permanent magnet synchronous generator, as well.

In the developed control method, a Minimum Electric Loss (MEL) controller is introduced in order to minimize the generator electric loss and a Maximum Power Point Tracking (MPPT) controller is used in order to maximize the wind turbine output power. Common input to the two optimal controllers is only the generator speed, while the measurement of the wind speed is not required. The two controllers determine the optimal *d*- and *q*-axis stator current components of the SCIG through optimal conditions and therefore, fast dynamic response of the WECS is accomplished. An experimental procedure is proposed to determine the MEL and MPPT controller parameters. Therefore, neither the knowledge of SCIG loss model nor the characteristic curves of the wind turbine are required. The effectiveness and the operational improvements of the suggested optimal control scheme have been verified experimentally.

***Index Terms*— Nearly zero energy building, wind power generation, optimal control, power generation, generators, variable speed drives.**

I. Introduction

NOWADAYS, the wind power industry is growing very fast and the modern wind turbines are efficient, reliable and produce power at reasonable cost [1]. Utilizing a squirrel cage induction generator (SCIG) as a mean to convert the mechanical energy captured by the wind turbine to electrical energy has a series of advantages, making it an attractive option for small and medium size WECS [2]. A SCIG has low manufacturing cost with robust construction compared to a permanent magnet synchronous generator. Also, it requires little maintenance compared to a wound rotor synchronous generator and a doubly fed induction generator.

On the other hand, buildings are the largest energy consuming sector in the world [3]. They are accountable for the one-third of the global energy consumption and consequently highly responsible for the increase of the carbon emission. Thus, several technologies have been developed to increase the efficiency and sustainability of the buildings and also, various policy measures have been adopted to support investments in RES and cultivate residents' consciousness in energy saving [4].

According to the Energy Performance of Buildings Directive (EPBD, 2010/31/EC), the definition of the nZEB is a building with very high energy performance where the required energy is covered by renewable energy sources (RES) produced onsite or nearby [5]. The RES in a nZEB can be any type, although more common are the photovoltaics and the wind turbines [6]. The research efforts for cost reduction of transforming an existing building to nZEB are towards the directions of reducing the construction cost of the renewable energy sources (RES) and on seeking cost-effective solutions for the constructional interventions [7], [8]. Key elements for the above techniques are the improvement of the quality and the cost reduction of the materials and devices, as well as the onsite study of the building needs in order to provide the best in case solutions for constructional interventions that can reduce the energy losses of a building.

However, considerable reduction of the cost for transforming a conventional building to nZEB can be attained by reducing the power capacity of the required RES, increasing the exploitation of the ESS and minimizing the complementary electric energy that is to be absorbed by the grid in order to fully cover the energy needs of a nZEB. These can be realized by increasing the efficiency of the RES, improving the energy management of the building microgrid by properly cooperating and highly exploiting the ESS and also, increasing the efficiency of the building's devices. Therefore, although the energy needs of a building in the level of use and comfort of the residents remain the same, the power and energy capacity requirements of the RES and ESS can be reduced (that result to the CAPEX reduction), as well as the energy consumption in the building can be confined (that results to lower OPEX). Moreover, constructional conversions of high cost and low energy saving result can be avoided, since the same level of

C. Mademlis is Professor with the Faculty of Electrical and Computer Engineering, Aristotle University of Thessaloniki, GR-54 124, Thessaloniki, Greece (e-mail: mademlis@auth.gr).

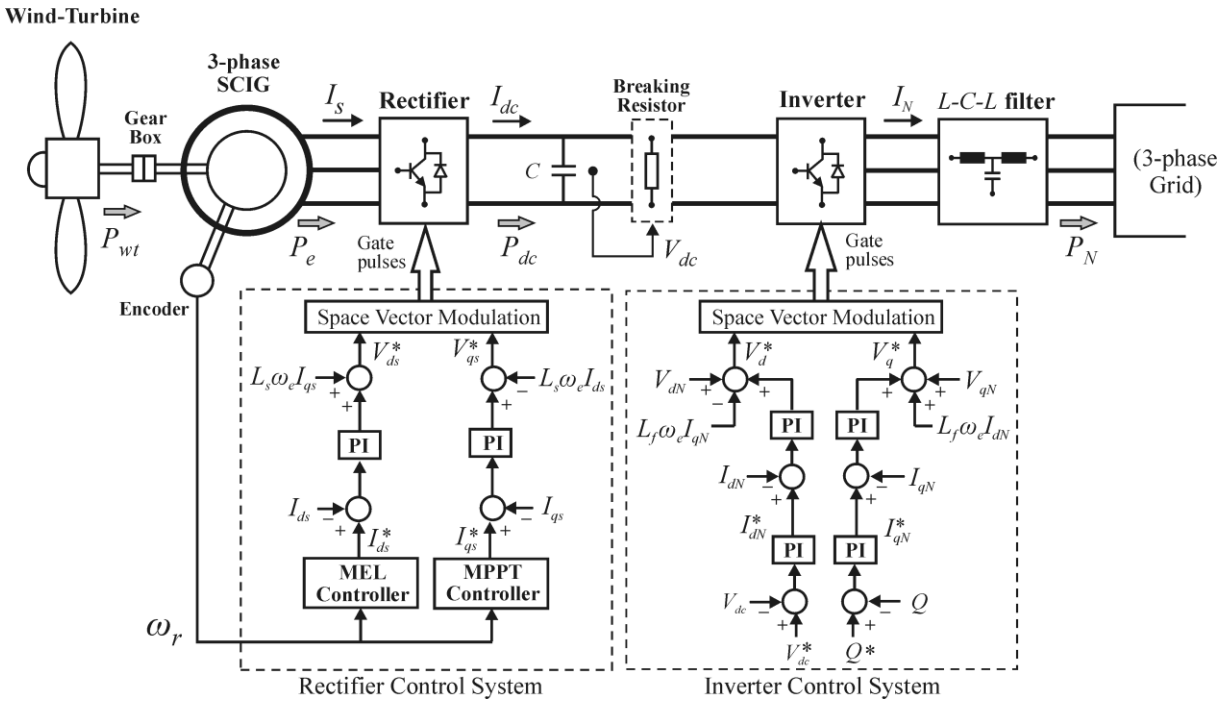

Fig. 1. Structure of the optimally controlled WECS with a 3-phase squirrel cage induction generator (SCIG).

energy autonomy and reliability in a nZEB can be achieved with lower installation cost.

The RES that is mainly utilized in a nZEB consists of photovoltaic and small wind turbines of urban type. In this paper, the efficiency increase in a RES is referred to the wind system, since this exhibits more margins for efficiency improvement.

Efficiency of a WECS is of great importance to provide maximum power harvesting from the incident wind. Variable speed capability of a wind turbine enables operation at its maximum aerodynamic efficiency and also, provides minimum torque perturbation in the drive train. Apart from the tip speed ratio control that requires an anemometer to measure the wind speed, several MPPT control schemes have been reported in the technical literature which are mainly based on optimal torque control [9], search control [10], fuzzy-logic control [11] and neural networks control methods [12]. Also, a fast tracking control algorithm has been presented in [13], an adaptive fuzzy-logic based scheme has been proposed in [14] and an MPPT controller with adaptive compensation control has been proposed in [15]. Finally, an MPPT algorithm for WECS with doubly fed induction generator, which takes advantage of the rotor inertia power has been presented in [16].

Additionally to MPPT control, the efficiency of the whole WECS can be improved by increasing the efficiency of the electric generator. This can be achieved through the appropriate control of the generator flux-linkage by regulating the d-axis stator current. A fuzzy-logic control method has been presented in [17] and search control techniques have been proposed in [18] and [19]; however, the WECS response is very slow and cannot follow the fast changes of the wind. A WECS control scheme of combined SCIG minimum ohmic loss controller with either a search or a fuzzy-logic MPPT controller has been presented in [20]. Model based optimal efficiency control methods for SCIG have been proposed in [21] and [22]; however, in [21] the variation of iron loss with frequency was disregarded and in [22] the accurate wind speed measurement is required. An optimized capacitance design for the dc-link of a back-to-back converter for wind turbine power generation was presented in [23]. A loss minimization method (considering copper and iron losses) for an induction generator that can be used for a stand-alone system for battery charging was presented in [24]. Finally, a model based optimally controlled method for interior PM synchronous generator in combination with an MPPT algorithm has been presented in [25].

From the above, it is concluded that there is a need for a cost-effective optimal efficiency control strategy for WECS with SCIG that has fast dynamic response and can be easily implemented. This control system can be applied to high as well as low power wind turbines, since it can be easily implemented and does not require any hardware modifications, but only replacement of the existing firmware of the WECS. The latter advantage is very important, since by not affecting the cost of the energy conversion system, the developed control technique can be adopted by any low power wind turbine. Therefore, the developed control method can contribute to narrowing the advantage of the counterpart permanent magnet synchronous generator against the SCIG, with respect to the energy efficiency of the wind system and thus, a low cost and high efficiency wind system can be provided that can be used for any smart energy building.

The developed control system for WECS with SCIG has been based on the methodology proposed by the author in the

[26] and [27], and it is properly adapted in order to by applied, as a generic control method, for any urban type wind turbine for smart energy buildings. The developed control method, minimizes the electric loss of the SCIG and maximizes the mechanical power extraction by the wind turbine and therefore, provides maximum efficiency of the whole WECS.

It should be noted that all electric loss of the SCIG has been considered. Specifically, two controllers have been introduced for the *d*- and *q*-axis stator current components, and the optimal efficiency is attained by properly controlling the above current components by means of optimal conditions. Therefore, both increase of the efficiency as well as fast dynamic performance of the WECS can be achieved. In particular, the MEL controller regulates the *d*-axis stator current in order to minimize the SCIG's loss and the MPPT controller adjusts the q-axis stator current in order to maximize the aerodynamic power in the wind turbine. Common input to the two optimal controllers is only the generator rotor speed.

An experimental procedure is proposed in order to determine the controller parameters and therefore, the proposed control scheme can be easily implemented because neither the loss model of the SCIG nor the characteristics of the wind turbine are required. Moreover, the wind speed information is not required and hence, the implementation of the suggested control system is cost-effective.

The effectiveness of the developed control technique WECS has been validated experimentally in a laboratory emulator of a wind system. Selective experimental results are provided in order to validate the theoretical considerations and demonstrate the operational improvements of the proposed control scheme.

II. WECS CONFIGURATION

Fig. 1 illustrates the block diagram of the optimally controlled WECS. The wind turbine is coupled to the shaft of a SCIG through a gear box that is inserted in order to adapt the low rotational speed of the wind turbine to the high speed of the generator. The SCIG is connected to the power grid through two back-to-back converters. For the rectifier, the field oriented control technique with two control loops is utilized. The inner PI control loop regulates the *d* and *q* axis current components for providing the respective *d* and *q* axis voltages through space vector modulation. The outer control loop contains the MEL controller that determines the optimal I_{ds} current so as the electric loss of the generator is minimized and the MPPT controller that determines the optimal I_{qs} current so as the mechanical power, that is provided from the wind turbine to the electric generator, is maximized. Common input to the MEL and MPPT controllers is the generator rotor speed ω_r.

For the line-side inverter, the voltage oriented control is employed by applying a double loop control system, as well. An inner PI control loop that regulates the *d* and *q* axis current components for providing the respective *d* and *q* axis voltages through space vector modulation and an outer PI control loop for the decoupled control of the active and reactive power

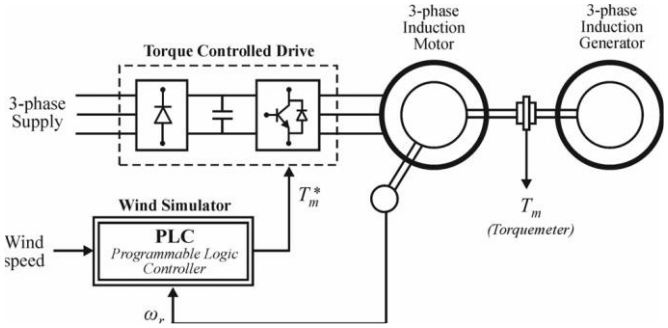

Fig. 2. Structure of the WECS emulator.

provided to the grid by controlling the I_{dN} and I_{qN} grid current components, respectively. In particular, the one PI controller of the outer loop is utilized to keep the *dc*-link voltage constant and thus, to control the active power. The other PI controller is used to regulate the line-side power factor and thus, to provide the demanded reactive power to the grid.

III. WIND TURBINE CHARACTERISTICS AND SCIG LOSS MODEL

The power captured by a wind turbine is given by

$$P_{wt} = \frac{1}{2}\rho\pi R^2 C_p u^3 \tag{1}$$

where ρ is the air density, R is the radius of the blades, C_p is the wind-turbine power coefficient and u is the wind speed. For each blade pitch angle β, the value of the tip-speed ratio λ_{opt} is constant for all MPPs and the optimum wind turbine shaft speed $\omega_{wt_{opt}}$ at a wind speed u is calculated by

$$\omega_{wt_{opt}} = \frac{\lambda_{opt} u}{R} \tag{2}$$

In this paper, a wind turbine emulator is used for the laboratory tests, implemented by an inverter fed induction motor, as per [28], [34] and the test WECS is illustrated in Fig. 2. A programmable logic controller (PLC) obtains wind speed values and, by using turbine characteristics and induction motor speed, calculates the torque value of the wind turbine. This is the reference value to the torque-controlled drive that forces the three-phase induction motor to act like a real wind turbine to the energy conversion system.

The relation of C_p versus λ of a three-blade horizontal axis wind turbine for various blade pitch angles β is illustrated in Fig. 3. The curves have been obtained by using the following equation that is commonly used in wind turbine simulators [12], [36]

$$C_p(\lambda,\beta) = 0.5176\left(\frac{116}{\lambda_i} - 0.4\beta - 5\right)e^{-\frac{5}{\lambda_i}} + 0.0068\lambda \tag{3}$$

with

$$\frac{1}{\lambda_i} = \frac{1}{\lambda + 0.08\beta} - \frac{0.035}{\beta^3 + 1} \tag{4}$$

A three-blade horizontal axis wind turbine with radius of 3.5 m is emulated at the system. Fig. 3 illustrates the steady state power-speed characteristics (solid curves) for a blade pitch angle of 0 degrees ($\beta = 0^0$). The maximum power point curve (dashed line) is attained at each wind speed with $C_p = 0.46$. Since a gear box is used, the wind turbine speed ω_{wt} and torque $T_{wt} = P_{wt} / \omega_{wt}$ are converted to the generator level on the basis of the gear ratio n as follows: $\omega_r = n\omega_{wt}$ and $T_r = T_{wt}/n$.

In field-oriented control on SCIG, decoupled control of d- and q-axis stator current components is provided by aligning the rotor flux linkage ψ_r to the d-axis ($\psi_{dr} = \psi_r$ while $\psi_{qr} = 0$). Therefore, the d- and q-axis rotor current components are given by [29]

$$I_{dr} = \frac{\psi_r}{L_r} - \frac{L_m}{L_r} I_{ds} \tag{5}$$

and

$$I_{qr} = -\frac{L_m}{L_r} I_{qs} \tag{6}$$

In Laplace transformation, the rotor flux linkage is given by

$$\psi_r = \frac{L_m}{(L_r / R_r)s + 1} I_{ds} \tag{7}$$

From (7), it is concluded that at steady state the rotor flux-linkage is given by

$$\psi_r = L_m I_{ds} \tag{8}$$

and consequently, from (5) results

$$I_{dr} = 0 \tag{9}$$

The d- and q-axis air-gap flux-linkage components are given as follows

$$\psi_{dm} = L_m (I_{ds} + I_{dr}) \tag{10}$$

$$\psi_{qm} = L_m (I_{qs} + I_{qr}) \tag{11}$$

and using (6) and (9) yields

$$\psi_{dm} = L_m I_{ds} \tag{12}$$

$$\psi_{qm} = I_{qs} (L_m - \frac{L_m^2}{L_r}) \tag{13}$$

The SCIG electric power loss is given in terms of d- and q-axis current components as follows [29]-[31]

$$P_{loss} = 3R_s (I_{ds}^2 + I_{qs}^2) + 3R_r (I_{dr}^2 + I_{qr}^2) + c_{Fe}\omega_e^2 \psi_m^2 + c_{str}\omega_e^2 (I_{dr}^2 + I_{qr}^2) \tag{14}$$

where c_{Fe} and c_{str} are the iron and stray loss coefficients, respectively. The mechanical and harmonic losses are not included in the above SCIG loss equation (14) because they are not controlled by the proposed method. However, harmonic loss is indirectly controlled and it is reduced through flux weakening. From (6), (9), (12) and (13) yields

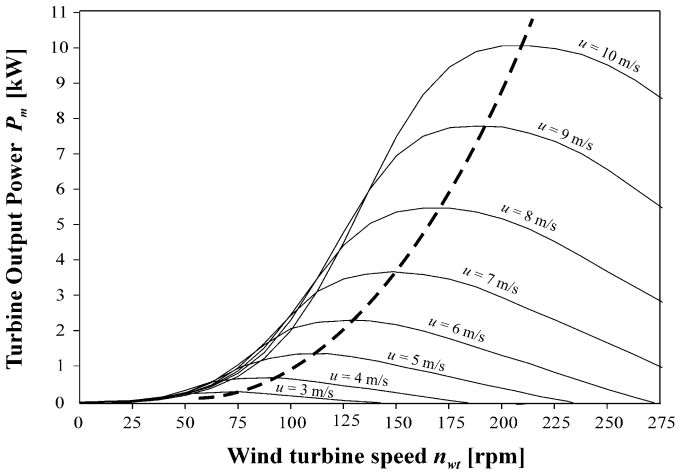

Fig. 3. Power-speed characteristics of a three-blade horizontal axis wind turbine, for various wind speeds and blade pitch angle at 0 degrees ($\beta = 0^0$).

$$P_{loss} = aI_{ds}^2 + bI_{qs}^2 \tag{15}$$

where

$$a = 3R_s + c_{Fe}\omega_e^2 L_m^2 \tag{16}$$

and

$$b = \left[3R_s + 3R_r \frac{L_m^2}{L_r^2} \right] + \left[c_{Fe}(L_m - \frac{L_m^2}{L_r})^2 + c_{str} \frac{L_m^2}{L_r^2} \right] \omega_e^2 \tag{17}$$

Due to decoupled control of the d- and q-axis stator currents, the electromagnetic torque expression is given by

$$T_e = \frac{3}{2} p \frac{L_m^2}{L_r} I_{qs} I_{ds} \tag{18}$$

IV. WECS Optimal Efficiency Conditions

The control objectives of a WECS include the following: a) electric loss minimization of the induction generator, b) maximum power extraction of the wind turbine, c) fast dynamic performance and d) cost-effective implementation of the control scheme.

The MEL controller regulates the flux-linkage through the I_{ds} current in order to minimize the electric loss of the SCIG. The MPPT controller adjusts the rotor speed of the SCIG through the I_{qs} current in order to maximize the wind turbine mechanical power. Both controllers operate simultaneously, so as optimal efficiency of the whole WECS is achieved.

Fast dynamic performance is achieved because the optimal I_{ds} and I_{qs} currents are determined through optimal conditions. Also, cost-effective implementation is provided because wind

speed measurement is not required and only the SCIG rotor speed is needed.

WECS operation is studied in two separate control modes. Specifically, SCIG loss minimization is investigated for constant electromagnetic torque T_e and speed ω_e operation while MPPT operation is examined for constant I_{ds} current operation.

A. MEL Controller

The electric loss minimization condition at steady state (T_e and ω_e constant), with respect to I_{ds} is given by

$$\left.\frac{\partial P_{loss}}{\partial I_{ds}}\right|_{\omega_e=\text{const.}} = 0 \tag{19}$$

Using (15), condition (19) is satisfied when

$$aI_{ds} + bI_{qs}\frac{\partial I_{qs}}{\partial I_{ds}} = 0 \tag{20}$$

Since the electromagnetic torque is constant with respect to I_{ds} current

$$\left.\frac{\partial T_e}{\partial I_{ds}}\right|_{\omega_e=\text{const.}} = 0 \tag{21}$$

and using (18) results

$$\frac{\partial I_{qs}}{\partial I_{ds}} = -\frac{I_{qs}}{I_{ds}} \tag{22}$$

Substituting (22) into (20), and using (16) and (17), the MEL condition is given by

$$I_{ds_{opt}} = \left|I_{qs}\right| G_d \sqrt{\frac{1+T_a^2\omega_e^2}{1+T_b^2\omega_e^2}} \tag{23}$$

where

$$G_d = \sqrt{1+\frac{R_r L_m^2}{R_s L_r^2}} \tag{24}$$

$$T_a = L_m \sqrt{\frac{c_{Fe}(L_r - L_m)^2 + c_{str}}{3(R_s L_r^2 + R_r L_m^2)}} \tag{25}$$

and

$$T_b = L_m \sqrt{\frac{c_{Fe}}{3R_s}} \tag{26}$$

In (23), the absolute value of I_{qs} current is used because the I_{qs} current is negative in the generator operation.

Condition (23) means that I_{ds} current should be supplied according to a torque demand (i.e. according to I_{qs} current). As speed increases, the iron loss increases. Therefore, iron loss can be reduced by reducing the field current through the factor $T_b\omega_e^2$, at the denominator of (23). If speed increases beyond a certain value, further reduction of field current would increase stray loss and iron loss due to leakage inductance. Such an effect can be avoided by keeping the field current I_{ds} constant through the factor $T_a\omega_e^2$ at the nominator of (23).

B. MPPT Controller

When maximum power harvesting from the incident wind is accomplished by the wind turbine, the maximum power coefficient $C_{p_{opt}}$ is achieved. Therefore, from (1) and (2), the maximum wind turbine torque for a given wind speed is given by

$$T_{wt_{opt}} = \frac{\rho\pi R^5}{2n^3\lambda_{opt}^3} C_{p_{opt}} \omega_{r_{opt}}^2 \tag{27}$$

The net mechanical torque, that results from $T_{wt_{opt}}$ after the subtraction of the mechanical loss, is equal to the SCIG electromagnetic torque and thus,

$$T_{e_{opt}} = T_{wt_{opt}} - T_{ml} \tag{28}$$

where T_{ml} is the mechanical loss torque at the speed-up side of the wind turbine due to gear box, bearings etc. Since the mechanical loss power is proportional to the third power of rotational speed [33], from (27), (28) and by using (2) yields

$$T_{e_{opt}} = \left[\frac{\rho\pi R^5}{2n^3\lambda_{opt}^3} C_{p_{opt}} - c_m\right] \omega_{r_{opt}}^2 \tag{29}$$

where c_m is the mechanical loss coefficient. Therefore, from (18) and (29), it is concluded that the MPP condition is given by

$$I_{qs_{opt}} = G_q \frac{\omega_{r_{opt}}^2}{I_{ds}} \tag{30}$$

where

$$G_q = L_r \frac{\rho\pi R^5 C_{p_{opt}} - 2c_m n^3 \lambda_{opt}^3}{3pL_m^2 n^3 \lambda_{opt}^3} \tag{31}$$

C. WECS Optimal Control

In order to achieve maximum efficiency of the whole WECS, both MEL and MPP conditions of (23) and (30), respectively, should be active simultaneously. Therefore, by combining (23) and (30), the optimal conditions that determine the *d*- and *q*-axis components of the SCIG stator current are given by

$$I_{ds_{opt}} = \omega_r \sqrt{G_d G_q} \left[\frac{1+T_a^2\omega_e^2}{1+T_b^2\omega_e^2}\right]^{1/4} \tag{32}$$

and

$$\left|I_{qs_{opt}}\right| = \omega_r \sqrt{\frac{G_q}{G_d}} \left[\frac{1+T_b^2\omega_e^2}{1+T_a^2\omega_e^2}\right]^{1/4} \quad (33)$$

V. Implementation of the Optimal Efficiency Control Scheme

The parameters of MEL and MPP conditions of (32) and (33), respectively can be determined experimentally by the following procedure.

Specifically, the MEL controller parameters can be adjusted with off-line laboratory experiments, as follows:

1) A wind turbine emulator is employed that it provides steady mechanical torque to the SCIG equal to 15% of its nominal value. The WESC output power to the grid is measured.
2) The SCIG rotates at low speed (about 10% - 15% of its nominal value) and in this case condition (23) becomes

$$I_{ds_{opt}} \approx \left|I_{qs}\right| G_d \quad (34)$$

The gain G_d is adjusted so that the maximum power to the grid is achieved.

3) The SCIG speed is increased to 40%-60% of its nominal value and under this case, condition (23) becomes

$$I_{ds_{opt}} \approx \left|I_{qs}\right| G_d \sqrt{\frac{1}{1+T_b^2\omega_e^2}} \quad (35)$$

The parameter T_b is adjusted so that the maximum power to the grid is attained.

4) The speed is increased to its nominal value and the parameter T_a is adjusted so that the maximum power to the grid is attained.
5) Steps 2 up to 4 are repeated until the desired accuracy is obtained.

An adaptive neuro-fuzzy logic-based control method can be adopted for the experimental identification of the MPPT controller parameter G_q at the real wind turbine, as that presented in [32]. Specifically, the SCIG is operated with the MEL controller as determined from condition (23) and for any instant wind speed, the MPPT is achieved by adjusting the I_{qs} current through the adaptive neuro-fuzzy logic control method. Due to degradation that may occur owing to aging of the mechanical system of the wind turbine, the above experimental procedure should be periodically repeated.

The L_m and L_r vary due to saturation while R_s and R_r vary due to temperature; hence, they may affect the WECS optimal controller gains and parameters. Specifically, gain G_q is proportional to the term (L_r/L_m^2), the value of which increases with saturation. As SCIG speed ω_r increases, saturation increases due to I_{ds} increase and consequently, gain G_q should be an increasing function of ω_r speed, as given by

$$G_q = G_{q1} + G_{q2}\omega_r \quad (36)$$

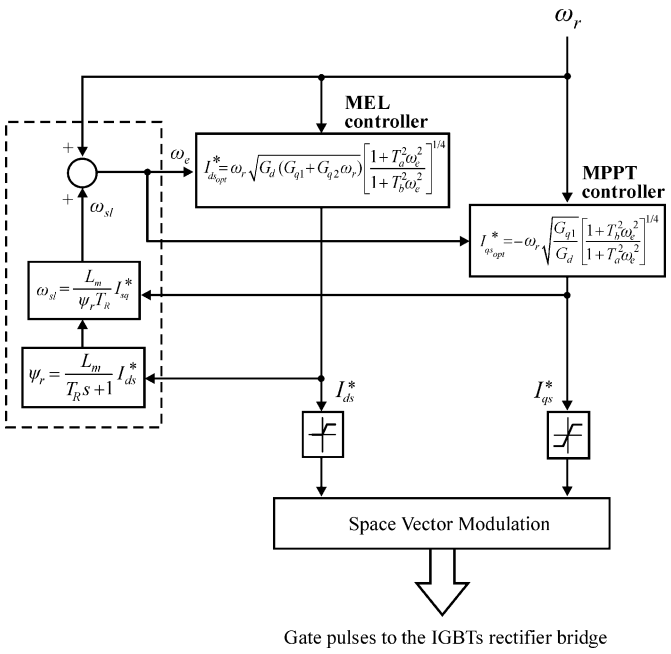

Fig. 4. Control algorithm for the rectifier converter of the optimal efficiency WECS.

By applying the aforementioned adaptive neuro-fuzzy logic based technique and recording the G_q and ω_r values at various wind conditions, the coefficients G_{q1} and G_{q2} of expression (36) are determined.

The gain G_d remains unaffected by saturation and temperature variations because a resistance and a magnetic inductance are both in nominator and denominator of (24) and therefore, their variation is neutralized. The parameters T_a and T_b are affected by temperature variation. However, since they vary in both nominator and denominator of (32) and (33), the variation of I_{ds} and I_{qs} with temperature is narrow. For similar reasons, T_a is unaffected by saturation. Contrarily, T_b varies with saturation and specifically it reduces as SCIG speed increase, because of I_{ds} increase. However, the variation of T_b with saturation is partially compensated by the increase of G_q, as given in (36).

From the above analysis and specifically from (32) and (36), it is concluded that the MEL condition is given by

$$I_{ds_{opt}} = \omega_r \sqrt{G_d (G_{q1} + G_{q2}\omega_r)} \left[\frac{1+T_a^2\omega_e^2}{1+T_b^2\omega_e^2}\right]^{1/4} \quad (37)$$

In condition (33), G_q increases with saturation whereas T_b reduces with saturation. Therefore, the variation of I_{qs} with saturation is narrow and consequently the MPP condition (33) is given as follows

$$\left|I_{qs_{opt}}\right| = \omega_r \sqrt{\frac{G_{q1}}{G_d}} \left[\frac{1+T_b^2\omega_e^2}{1+T_a^2\omega_e^2}\right]^{1/4} \quad (38)$$

Fig. 4 illustrates the block diagram of the proposed control algorithm for the rectifier of the optimal efficiency WECS.

TABLE I
3-PHASE, 10-kW, INDUCTION MACHINE AND OPTIMAL CONTROLLER PARAMETERS

V_s= 380 V (rms)	I_s= 21 A (rms)	
f_e= 50 Hz	$2p$= 4 (number of poles)	
R_s= 0.7 Ω	R_r= 1 Ω	
L_m= 0.2 H	L_{ls}= 0.01 H	L_{lr}= 0.01 H
G_d= 1.558	G_{q1}= 2.23·10^{-2}	G_{q2}= 2.9·10^{-4}
T_a= 2.51·10^{-3}	T_b= 1.82·10^{-2}	

The MEL controller determines the I_{ds} current through condition (37) and the MPPT controller determines the I_{qs} current through condition (38). Common input to the two controllers is only the generator rotor speed, while the measurement of the wind speed is not required. The stator frequency ω_e is obtained from the calculation of the slip frequency ω_{sl}. The MEL controller parameters are determined with off-line laboratory experiments and the MPPT controller parameters are determined with on-line experiments during the WECS operation.

It should be noted that the adaptive neuro-fuzzy logic technique is used only for the experimental identification of the MPPT controller parameters, because the MPPT controller is implemented through the condition (38).

VI. PROPER ADAPTATION OF THE DEVELOPED OPTIMAL EFFICIENCY CONTROL METHOD TO URBAN TYPE WIND TURBINES

In order to properly adjust the developed optimal efficiency control method to the specific needs of an urban type WECS, the following procedure should be followed:

a) The experimental procedure of the Section V (steps 1-5) should be carried out, to determine the parameters of the two optimal controllers MEL and MPPT for the loss minimization of the SCIG and the maximum energy extraction by the wind turbine.
b) The adaptive neuro-fuzzy logic control procedure should be carried out to experimentally identify the MPPT controller parameter G_q.
c) The calibration procedure for the G_q parameter should be conducted, as determined by condition of (36).
d) Then, the optimal controllers MEL and MPPT are established by the conditions (37) and (38), respectively, and the optimal values of the I_d and I_q stator current components are online determined.

It is worth noting that in case of a vertical type wind turbine, there is need for yaw control. Contrarily, in the case of a horizontal axis wind turbine, the nacelle of the turbine should be properly controlled in order to correctly oriented to the direction of the wind. For the latter case, the improved active yaw control technique can be employed, in which the wind turbine is aligned to the wind direction through the error between the rotor speed determined by the optimal tip speed ratio and the real wind speed commanded by the maximum power point tracking control, as per [35].

As in the optimal efficiency control method, the aforementioned yaw control is cost effective since only changes in the yaw control software are required and the highly expensive remote sensing instruments based on laser and hypersonic technologies can be avoided. Therefore, the yaw control method of [35] is affordable for low power wind systems. Moreover, it is highly accurate, since the yaw misalignment is

(b)

Fig. 8. WECS performance when only the MPPT controller is active. The wind speed is constant at 5 m/s and the I_{ds} current is equal to the nominal value.

indirectly determined by the rotor speed error of the turbine and thus, it does not suffer from inaccuracies that are caused by the vortices in the wake of the flow downstream of the wind turbine, for the case that the wind direction is directly measured by a sensor installed at the rear end of the nacelle.

VII. Experimental Results

The parameters of the SCIG and the WECS optimal controllers are given in Table I. The gear ratio of the gear box is n=5.2. A gear box of ratio 1/5.2 is used in the wind-turbine emulator system. A capacitor of 2mF and a braking resistor of 85Ohm are used at the *dc*-link. The *LCL* filter between the inverter and the grid is composed of two series inductances of 1.8mH each and a capacitor of 15μF.

Two dSPACE DS1104 controller boards are used for the implementation of the rectifier and the inverter control schemes. The rectifier controller board houses the MPPT and the MEL controllers. The sampling periods of both MEL and MPPT controllers are 5ms. The inverter controller board houses a PI controller for regulating the I_{qN} current that maintains constant the *dc*-link voltage at 600V and a PI controller for regulating the I_{dN} current that controls the reactive power injected to the grid. Both PI controllers on the inverter side run at sampling periods of 5ms. For the experiments, a power factor of unity is considered and therefore, the inverter only injects active power into the grid. Thus, the inverter output power factor is slightly capacitive to compensate the filter reactive power.

The existence of exact values of I_{ds} and I_{qs} stator currents that provide SCIG minimum electric loss and maximum power of the wind turbine, for each wind speed, are experimentally verified in Fig. 5. Specifically, Fig. 5 (a) illustrates the variation of SCIG loss versus I_{ds} stator current, for various wind speeds. In this case, the I_{ds} current is manually regulated, and the generator speed corresponds to maximum power of the wind turbine (MPPT controller is active). As can be seen, for each wind speed, there is one specific value of I_{ds} current at which SCIG loss is minimized (all points noted by asterisk). Fig. 5 (b) illustrates the variation of wind turbine output power P_{wt} versus I_{qs} stator current of the SCIG, for various wind speeds. In this case, the I_{ds} current is equal to the nominal value. As can be seen, for each wind speed, there is one specific value of I_{qs} current at which wind turbine output power is maximized (all points noted by asterisk).

Fig. 6 validates the improvement of the optimal controlled WECS in the produced electrical power versus wind speed, for power factor equal to unity at the point of common cou-

pling to the grid. The diagrams extended up to wind speed of 7.5 m/s because this region covers the most probable mean and average wind speeds [33]. Specifically, Fig. 6 compares the produced electrical power to the grid accomplished when both MEL and MPPT controllers operate, against that produced when only MPPT controller is active and the generator operates with nominal flux-linkage.

It can be seen in Fig. 6 that, the increase of the produced electrical power is higher at low wind speeds, since at this region the load power is low and therefore considerable reduction of generator loss can be accomplished by reducing the generator flux-linkage. Additionally, the exploitable wind speed region is expanded towards the lower range. Specifically, with the optimal control (both MEL and MPPT controllers in operation) the WECS starts to provide electrical power to the grid from a wind speed of 3.0 m/s, whereas with the conventional control (only MPPT in operation and generator under nominal flux-linkage) electrical power production is attained only above 3.5 m/s wind speed.

Figs. 7 and 8 examine the separate response of the MEL and the MPPT controllers. Specifically, Fig. 7 illustrates the WECS performance for wind speed 3.5 m/s and $\beta = 0^0$, when only the MEL controller is active. The generator reference speed is $n_r^* = 411\,\text{rpm}$ (or 411/5.2=79 rpm of the wind turbine) that corresponds to the optimal value of the MPPT controller. As can be seen, the MEL controller is very fast and finds the minimum SCIG loss operating point in less than 0.5 s. Due to the MEL control, additional electric power of 230 W can be provided to the grid and thus, the efficiency of the WECS is increased.

Fig. 8 illustrates the WECS performance for wind speed 5 m/s and $\beta = 0^0$, when only the MPPT controller is active. The I_{ds} current is equal to the nominal value. The generator initially rotates at a random speed value of 306 rpm (or 306/5.2=58.8 rpm of the wind turbine) and when the MPPT controller is activated, the generator reaches very fast the optimal speed of 620 rpm (or 620/5.2=119.2 rpm of the wind turbine) that corresponds to the maximum C_p coefficient of 0.46.

Fig. 9 illustrates the WECS response to an abrupt change of the wind speed from 3.5 to 5 m/s, when both MEL and MPPT controllers are in operation and $\beta = 0^0$. The wind speed values have been chosen on purpose, in order to verify the effectiveness of the proposed optimal controlled WECS in wind speed step changes. It can be seen that the proposed MEL and MPPT controllers can find very fast the optimal operating point at which minimum SCIG loss and maximum

power of the wind turbine are accomplished and thus, maximum efficiency of the whole WECS is achieved.

Fig. 10 verify the effectiveness of the proposed optimal efficiency WECS in real wind speed conditions. The wind speed ranges from 3m/s up to 6.6 m/s and therefore the WECS output power ranges from 50W up to 2270W. This large range can be justified by the large range in the wind speed variation of 3.3 m/s during the measured period of 120s (see the wind turbine power-wind speed characteristics of Fig. 3). Note that, Fig. 3 illustrates wind turbine power curves while Fig. 10 gives the WECS output power P_N (the active power P_N is the mechanical output power of the wind turbine subtracting the losses on the turbine, the generator and the converters).

The system operates with power factor equal to unity at the point of common coupling to the grid. It can be seen that, the two optimal controllers (MEL and MPPT) can follow the wind speed variations and they well cooperate in providing both minimum electric losses of the induction generator (through MEL controller) and maximum power harvesting of the wind turbine (through MPPT controller). This is achieved because the simultaneously MPPT and MEL operation is accomplished through conditions that can define the optimal operating point for each given wind speed.

VIII. Conclusions

In this paper, an optimal efficiency control strategy for WECS with SCIGs was presented. The developed control system provides minimum electric loss of the SCIG and maximum power harvesting of the wind turbine. Additionally, expansion of the exploitable wind speed region towards the lower speeds is achieved. The generator is connected to the power grid by means of two back-to-back PWM converters, both employing the space vector control technique.

The developed control technique has been based on previous research work of the author and it is properly adjusted so as, it can be utilized as generic method for any urban type wind tur-bine for smart energy buildings. Two optimal controllers have been introduced. The MEL controller adjusts the SCIG *d*-axis stator current according to torque conditions and accomplishes minimum electric loss of the SCIG. The MPPT controller regulates the SCIG *q*-axis stator current according to wind speed conditions and maximizes the wind turbine output power. The optimal *d*- and *q*-axis stator currents are online determined through optimal conditions. Therefore, fast dynamic response of the WECS is accomplished.

An experimental procedure is adopted for determining the parameters of the WECS optimal controllers. Also, the implementation of the suggested control scheme is cost-effective because common input to the two optimal controllers is only the SCIG rotor speed, while the wind speed measurement is not required. Selective experimental results on a WECS with emulated wind turbine have been presented in order to validate the resulting improvements of the proposed control scheme.

Propagation of Electromechanical Waves in Conventional Power Grids

Ruzica Cvetanovic, Filip Cvejic and Slobodan N. Vukosavic, *Senior member, IEEE*

***Abstract*—The paper reinstates the impact of distributed generation, consumption and accumulation on the dynamic response and transient stability of the electric power system. Modern power systems consist of distributed loads and power generation with both conventional synchronous generators and grid-side inverters. In comparison to the discrete model, the continuum model, discussed here, offers the opportunity to gain insight into the spatial aspects of transient stability and therefore has the potential to play a role of great importance in stabilizing the modern, distributed power system. In the paper, the phenomenon of electromechanical power waves in a string of conventional synchronous generators is considered and studied. Disturbance waves propagate considerably slower than electromagnetic waves and exhibit multiple reflections at the points of inhomogeneity. There are cases where the interference of direct, indirect and reflected waves can drive the system to instability. The paper considers the practical implementation of the simplified form of the previously proposed wave-quenching control law which is based on local measurements. The requirements point out that the practical implementation of the wave-quenching control law strongly relies on power electronic devices.**

***Index Terms*—Distributed power generation, Impedance matching, Power system dynamics, Power system stability.**

I. Introduction

The wave nature of the electromechanical disturbances in power systems was first considered almost 50 years ago [1], but it is only in the past decade that the research in this field has gained considerable attention. Previous work in this area comprises several different aspects: derivation of the continuum model [2], verification of the analytical model by the observations in actual power systems [3], control strategies for suppressing disturbances [4], [5], practical aspects for the implementation of the proposed control strategies [6]. Most recently, the continuum model was for the first time applied to networked inverters where basic modeling and control techniques of the electronic power waves were presented [7].

The modern power system involves distributed power generation as well as distributed loads, both controlled by power electronic converters. The discrete model described in [8], which assumes centralized representation of the loads and power generation and relies on the nodal description of the components and interconnections, is of no use anymore.

The main shortcoming of this model is its inability to take into account spatial aspects of the disturbance propagation. The correct modeling of the modern power system includes representation of both loads and sources as spatially distributed quantities. Moreover, the dynamics of the grid-side converters is completely different from the one of the traditional synchronous generators, as power electronic devices exhibit considerably faster transient phenomena [9]. Thus, in order to describe and work towards stabilizing the transient behavior of the modern inverter-rich power system, an alternative approach must be applied.

This paper provides recapitulation of the previous research in the study of electromechanical waves using systematic, methodical approach. Our main tool is the derived model for a one dimensional power system consisting only of conventional synchronous generators, which treats system to be continuum. According to the swing equation of the synchronous machine, this approach results in the power system being described by the second order differential equation. This equation corresponds in the form to the wave equation, thereby alluding to the wave nature of the disturbance propagation. In order to suppress multiple reflections at points of inhomogeneity, control strategies based on the impedance matching principle are proposed as in [5]. Practical implementation of the aforementioned wave-quenching compensation law implies digital control of the power at certain points of the grid and relies only on local, readily available measurements. Conclusions drawn from the continuum model are verified by the means of computer simulations of the discrete system. It is important to note that similar concepts can be applied to the string of inverters [9], as well as to the more realistic case of the two dimensional grid containing both grid-side inverters and traditional synchronous generators.

II. Wave Propagation on a String of Conventional Synchronous Generators

In order to gain better understanding of the general concept, we will introduce some approximations so that the use of complex mathematical tools is avoided. It can be shown that the principles derived for the simple model also hold true in the more realistic case [2]. The developments brought up in this section are largely based on those published in [1-5] and [7-9] and represent their summary.

A. Derivation of one dimensional wave equation

The wave equation will be derived following the procedure provided in [2], for a one dimensional power system comprising only traditional synchronous generators (Fig. 1) which are considered to be equidistant and interconnected with transmission lines of the same parameters (G [p.u] and B [p.u]) and lengths (Δ [m]). In each node there is a generator, with the inertia constant H [s] and damping D [s], providing variable power (P_m [p.u]) at the constant voltage (E [p.u]), thereby assuming uniform voltage magnitude along the string. The load is represented as the constant power sink (P_l [p.u]).

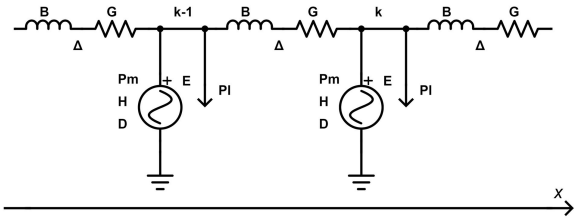

Fig. 1. A string of conventional synchronous generators.

Net power at each node is denoted as difference between generation and load ($P_g = P_m - P_1$). For the purpose of the following analysis we consider fluctuations of the frequency around the nominal value ω_s [rad/s] to be small enough, so that the small-signal stability analysis could be applied as in [4]. According to the swing equation and power balance equation for the k-th node, deviation of the k-th generator's mechanical angle δ_k [rad] is defined by:

$$\begin{aligned}\frac{2H}{\omega_s}\frac{\partial^2\delta_k}{\partial t^2} &= P_g - D\frac{\partial\delta_k}{\partial t}\\ &-E^2\left(B\left(\sin\left(\delta_k-\delta_{k+1}\right)-\sin\left(\delta_{k-1}-\delta_k\right)\right)\right)\\ &+E^2\left(G\left(\cos\left(\delta_k-\delta_{k+1}\right)+\cos\left(\delta_{k-1}-\delta_k\right)-2\right)\right)\end{aligned} \quad (1)$$

If we, as in [4], introduce per unit length parameters of the generators ($h=H/\Delta$ [s/m], $d=D/\Delta$ [s/m], $p_g=P_g/\Delta$ [p.u/m]) and transmission lines ($b=B\cdot\Delta$ [p.u·m], g=[p.u·m]), (1) results in:

$$\begin{aligned}\frac{2h}{\omega_s}\frac{\partial^2\delta_k}{\partial t^2} &= p_g - d\frac{\partial\delta_k}{\partial t}\\ &-\frac{E^2}{\Delta^2}\left(b\left(\sin\left(\delta_k-\delta_{k+1}\right)-\sin\left(\delta_{k-1}-\delta_k\right)\right)\right)\\ &+\frac{E^2}{\Delta^2}\left(g\left(\cos\left(\delta_k-\delta_{k+1}\right)+\cos\left(\delta_{k-1}-\delta_k\right)-2\right)\right)\end{aligned} \quad (2)$$

Focusing on the case with d=0 and g=0, for the small angular variations, equation (2) is well approximated with:

$$\frac{2h}{\omega_s}\frac{\partial^2\delta_k}{\partial t^2} = p_g - \frac{E^2\cdot b}{\Delta^2}\left(2\delta_k-\delta_{k-1}-\delta_{k+1}\right) \quad (3)$$

By taking the limit $\Delta\to 0$ of (3) and considering the definition of the spatial derivative of the rotor angle:

$$\lim_{\Delta\to 0}\frac{\delta_{k+1}-2\delta_k+\delta_{k-1}}{\Delta^2} = \frac{\partial^2\delta}{\partial x^2} \quad (4)$$

We arrive at the second order linear differential equation known as the wave equation [4]:

$$\frac{2\cdot h}{\omega_s}\cdot\frac{\partial^2\delta}{\partial t^2} = p_g + E^2\cdot b\cdot\frac{\partial^2\delta}{\partial x^2} \quad (5)$$

Notice that in the more realistic case of the two dimensional grid with distributed generator ($h(x,y)$ and $d(x,y)$) and transmission line parameters ($b(x,y)$ and $g(x,y)$), with the large angular disturbances where the approximation $sin(x)=x$ is not valid, an analogous derivation can be made. In this case derivation results in a second-order nonlinear partial differential equation [2].

Let $P(x,t)$ and $\omega(x,t)$ denote the deviation (from their nominal values) of the power flow and angular frequency in the direction of increasing x at the point x and the instant t. By taking the limit $\Delta\to 0$ of the power flow between discrete nodes, power flow in the continuum model is determined by:

$$P(x,t) = -E^2\cdot b\cdot\frac{\partial\delta}{\partial x} \quad (6)$$

Differentiation of (6) and substitution of the appropriate variables into (5) results in the following set of equations [5]:

$$\frac{\partial P}{\partial t} = -E^2\cdot b\cdot\frac{\partial\omega}{\partial x} \quad (7)$$

$$\frac{2\cdot h}{\omega_s}\cdot\frac{\partial\omega}{\partial t} = p_g - \frac{\partial P}{\partial x} \quad (8)$$

It is important to note that the acquired set of equations resembles the *Telegraph equations* which describe electromagnetic transient behavior on the transmission lines.

B. Traveling waves and their properties

The general solution of the derived wave equation (5) assumes the following form [2]:

(2)

$$\delta(x,t) = \delta\left(x-\frac{t}{v}\right)+\delta\left(x+\frac{t}{v}\right) \quad (9)$$

Where v is the velocity of the electromechanical waves defined by:

$$v = \sqrt{\frac{\omega_s\cdot b\cdot E^2}{2h}} \quad (10)$$

Hence, when the sudden disturbance occurs at some point of the considered string (due to the random fluctuations in the loads and generation levels), it propagates from that point along the string in the form of a traveling wave of power, frequency and angle. Note that the velocity of these waves depends on the per unit length values of the generator´s inertia constant h and transmission line susceptance b. The functional dependency is such that in the case when the generators are more densely packed (Δ decreases) or they are more capable of storing kinetic energy (H increases), the electromechanical waves propagate more slowly. Analogously, when the transmission lines are more prone to oppose power flow (b decreases), the speed of electromechanical waves decreases.

In order to acquire deeper understanding of the physics of the problem, it is useful to make a rough estimation of the electromechanical wave's propagation speed. Consider the previously analyzed string of generators assuming nominal line voltage to be 220kV (50Hz), with the base power of 100MVA (resulting in the base impedance of 484 Ω) and transmission line reactance of 0.4 Ω/km. Let voltage be equal to its nominal value (E=1p.u). The distance between each two generator is considered to be $\Delta = 120km$ and each generators' inertia constant H=10s (with respect to the given base power). The substitution of all of the above in (10) results in the velocity of approximately 1500km/s. Authors in [5] and [6] state that the values of the velocities observed in the real power systems by the use of synchrophasor measurements and Wide Area Measurement System ranges from 500km/s to 1000km/s. The deviation of the estimated value from the observed range is due to the fact that the real power system is a two dimensional grid with inhomogeneous distribution of inertia constants and transmission line parameters. In addition to this, real power systems contain centralized (as well as distributed) generation and load, which have an impact on the properties of the electromechanical waves [6]. However, the order of magnitude of our rough estimation is in accordance with the observed range.

As the wave propagates along the string, the ratio between the forward travelling waves of frequency $\omega^+$and of power flow P^+ stays constant [4]. This enables us to define a characteristic impedance through the procedure given in [4]:

$$Z_0 = \frac{\omega^+}{P^+} = \sqrt{\frac{\omega_s}{2h}\frac{1}{E^2 \cdot b}} \tag{11}$$

Note that, taking into account that (7) and (8) are analogus to the *Telegraph equations*, Z_0 [rad/sW] is analogus to the ohmic impedance defined as a ratio between voltage and current waves in electromagnetic waves. It will be demonstrated in the subsequent sections that the characteristic impedance plays a crucial role in determining a compensation law used to enhance power system transient stability [5].

III. Multiple Reflections at Points of Inhomogeneity

When the forward travelling (incident) wave reaches the point of inhomogeneity of the grid, it splits into two components: the reflected and transmitted waves (absorption is neglected here). The ratio between those two components depends on the boundary condition at the point of inhomogeneity that needs to be satisfied. Unless we act in a proper manner that would diminish the negative effects of the reflections or preferably completely prevent them from happening, multiple reflections of the electromechanical waves can cause the severe problems and endanger the stability of the power system. Without the lack of generality, in the proceeding analysis we will examine the end of the string as an example of the aforementioned inhomogeneity. Waves exhibit similar behavior in all of the other cases (the change in the transmission lines' or generators' parameters, DC/AC interconnections, etc). Developments brought up in this section are largely based on those published in [1-5] and [7-9] and represent their summary.

A. Problem description

In order to quantify and mathematically describe reflections at the point of inhomogeneity, the reflection coefficient of the frequency wave R is introduced, defined as the ratio between magnitude of the reflected (ω^-) and incident (ω^+) frequency wave [4]. Note that an analogous definition can be made for the power wave. If we assume that it is possible to terminate a string in such a way that the ratio between the frequency variation at the end of the string $(\hat{\omega}_{end})$ and the power flow variation at the end of the string $(\hat{P}_{end})$ is held in constant proportion, we can express the impedance that terminates the string as:

$$Z = \frac{\hat{\omega}_{end}}{\hat{P}_{end}} = \frac{\omega^+ + \omega^-}{P^+ + P^-} \tag{12}$$

Where P^+ and P^- respectively denotes incident and reflected power flow waves [4]. According to (11), (12), and the fact that $\frac{\omega^+}{P^+} = -\frac{\omega^-}{P^-}$, the definition of the reflection coefficient introduced above results in:

$$R = \frac{\omega^-}{\omega^\mp} = \frac{Z - Z_0}{Z + Z_0} \tag{13}$$

We will discuss two extremes, as far as string endings go: an infinite bus ($Z = 0$) and an open end ($Z \to \infty$). In the first case, the frequency variation at the end of the string is equal to zero, meaning that the incident and reflected waves of the frequency must cancel out at the end of the string ($R = -1$). In the case of an open end, the power flow at the end of the string is equal to zero, meaning that incident and reflected waves of the power flow at the end of the string must cancel out ($R = 1$). In this case the reflected wave resembles the incident wave. Thus, after the reflection the wave that travels along the string in the opposite direction may have the magnitude that is twice the magnitude of the incident wave (total reflection occurs). As the frequency wave represents variations of the rotors' angular velocities from their nominal values, this leads to the unwanted acceleration of certain

generators and can potentially trigger the loss of synchronism. Therefore, from the transient stability aspect, the case of an open end is considered to be the most important one to examine.

B. Problem solution

Conventional frequency control strategies consist of the primary (Governor/Droop control), secondary (Automatic Generation Control) and tertiary (Economic dispatch) frequency control. This concept stems from the discrete model which was traditionally used to examine power system stability of the centralized power system comprising only classical synchronous generators and AC transmission lines. Conventional control strategies preserve grid from losing its synchronism with a certain stability margin. However, when this margin is reached the system becomes unstable.

The preceding analysis points to the underlying physics behind the stability issue. Namely, disturbances travel as electromechanical waves and reflect at nodes of inhomogeneity. These reflections could accumulate to the point where the stability margin is exceeded, even though conventional control algorithms are designed such that this is a rare occurrence. The chances of this happening are considerably increasing with the escalating distribution of generation and load which is present in modern power system. In addition to this, the modern power system is mixed, meaning that it contains both conventional synchronous generators and renewable energy sources connected to the grid through power electronic devices. In such an inverter-rich power system electronic power waves also exist [7]. They are considerably faster than the electromechanical waves, thus making the stabilization process based on the conventional control strategies even more difficult. Moreover, modern power systems comprise both DC and AC transmission lines which increases the number of points of inhomogeneity. Thus, in order to ensure the conditions for the modern power system to function normally, it makes sense to develop an alternative way of stabilizing the system which would consider wave nature of the disturbances.

In the subsequent analysis an open ended string is considered, as this case was previously shown to be the worst one in terms of transient stability. Following (13) one can infer that if the string was terminated with the impedance that is equal to its characteristic impedance:

$$Z = \frac{\hat{\omega}_{end}}{\hat{P}_{end}} = Z_0 \tag{14}$$

The reflection coefficient of the frequency wave would be equal to zero [4]. This means that the reflections would be eliminated provided that the ratio between frequency and power flow deviations at the end of the string is held constant. Thus, (14) is the control objective we strive towards.

In order to determine the appropriate control action that would enable the implementation of the desired compensation law, let us focus on the swing equation for the last node [4]:

$$\frac{2 \cdot H}{\omega_s} \cdot \frac{\partial \hat{\omega}_{end}}{\partial t} = P_g + P_{end} \tag{15}$$

Where P_{end} represents the total power flow of the last node and is equal to the sum of the steady state power flow $\bar{P}_{end}$ and its deviation due to transients ($P_{end} = \bar{P}_{end} + \hat{P}_{end}$). Analogously, P_g represents the total net power of the last node and is equal to the sum of the steady state net power $\bar{P}_g$ and its variation due to transients ($P_g = \bar{P}_g + \hat{P}_g$). The steady state power balance for the last node results in $\bar{P}_{end} = -\bar{P}_g$.

The following analysis considers $\hat{P}_g$ as the control variable [5]. If we, according to (14), express $\hat{P}_{end}$ as a function of $\hat{\omega}_{end}$ and Z_0, and along with the statements given above, substitute it in (15), we arrive at the required control action:

$$\hat{P}_g = \frac{2 \cdot H \cdot Z_0}{\omega_s} \cdot \frac{\partial \hat{P}_{end}}{\partial t} - \hat{P}_{end} \tag{16}$$

However, this control action requires having information of the first time derivative of the variable $\hat{P}_{end}$, which turns out to be a problem because this quantity cannot be easily measured. Alternatively, this information can be obtained from (8) but it would require non-local measurements which we want to avoid, due to potential delays in communication and difficulties in information exchange. Our aim is to derive wave-quenching control action that would rely only on local measurements which are already available from the Phasor Measurement Units. With regard to the considerations explained above, the following compensation law is proposed:

$$\hat{P}_g = -\frac{\hat{\omega}_{end}}{Z_0} \tag{17}$$

Which provides an approximate tracking of the desired control objective and is a simplified version of the controller proposed in [5]. Even though it does not enable us to instantaneously achieve the impedance matching objective, it successfully suppresses reflections as it will be demonstrated in the next section by the means of computer simulations. The proposed wave-quenching compensator acts in the following way: if the frequency deviation at the end of the string is positive, compensator takes power from the grid that is proportional to this deviation; if the frequency deviation is negative it injects power in the grid that is proportional to this deviation. In both situations, the proportionality constant is equal to the inverse of the string's characteristic impedance.

The proposed compensation law implies digital control of the power at the end of the grid, or in the general case, wherever there exists a risk of reflections occurring. It is important to note that it relies only on local, readily available measurements.

IV. Simulation Results

In order to examine the validity of the derived continuum model, a string comprising a total of 64 synchronous generators is modeled and simulated in MATLAB. The model is implemented as a linked list of blocks of generators [2]. The number of the elements in the list was chosen such that it is large enough to illustrate the phenomena of interest, but small enough to keep simulation demands at a reasonable level. Each of the 64 blocks is formed with respect to (1), by introducing per unit time according to the following base time constant:

$$T_b = \sqrt{\frac{2 \cdot H}{\omega_s}} \tag{18}$$

This yields the equation that describes generator dynamics in our Simulink model:

$$\begin{aligned} \frac{\partial^2 \delta_k}{\partial T^2} &= P_g - D\frac{\partial \delta_k}{\partial T} \\ &-E^2\left(B\left(\sin\left(\delta_k - \delta_{k+1}\right) - \sin\left(\delta_{k-1} - \delta_k\right)\right)\right) \\ &+E^2\left(G\left(\cos\left(\delta_k - \delta_{k+1}\right) + \cos\left(\delta_{k-1} - \delta_k\right) - 2\right)\right) \end{aligned} \tag{19}$$

Where T is per unit time ($T=t/T_b$). Note that the swing equation for the last node (15), used for derivation of the desired compensation law, could be derived from (19) simply by neglecting D, substituting $T=t/T_b$ into (19) and expressing the sum of the second and third term on the right side of (19) as P_{end}.

In comparison to the model of the generator we used for analytical derivation of the wave equation, for the purpose of simulation, there is no need to neglect transmission line conductance and generator damping, nor to linearize the swing equation in terms of applying the approximation $sin(x)=x$. Note that in simulation tests only the generator's electromechanical dynamics is considered (exciter and turbine dynamics are neglected).

The disturbance is considered to be a sudden increase in the 7th generator's net power which is modeled as a power pulse with both magnitude and duration of 1p.u. The parameters of the generators and transmission lines used in the simulations correspond to the ones used to estimate the velocity of electromechanical waves: $\Delta = 120km,\ B = 10p.u,\ G = 1p.u,\ E = 1\,p.u,\ D = 0.01\,p.u,\ \omega_s = 2 \cdot \pi \cdot 50\ rad/s,\ H = 10s$. The base time is therefore 225ms. It is also assumed that the net power of each node is equal to zero ($P_g = 0$).

Simulation results shown in Fig. 2 represent the change of the rotor mechanical angle at the connection points of corresponding generators in the case of an open ended string of generators [5]. The waveforms are intentionally scale-shifted in the vertical direction, so that the properties of the travelling electromechanical wave could be discussed.

It takes roughly $22T_b$=4.95s for the wave to reach the end of the string. With the string length of 120·64=7680km, the speed of the electromechanical waves is found to be 1552km/s. Note that such a long string is unrealistic for the Serbian power system, but can be apllied to North American power system. Speed estimation given above is in agreement with the estimation based on (10). Thus, the validity of the derived continuum model is verified. After the wave reaches the end of the string, it gets reflected and travels back thereby threating the system to lose stability. The reflection process is repeated whenever a wave reaches an open end. In Fig. 2, multiple reflections are clearly noticeable.

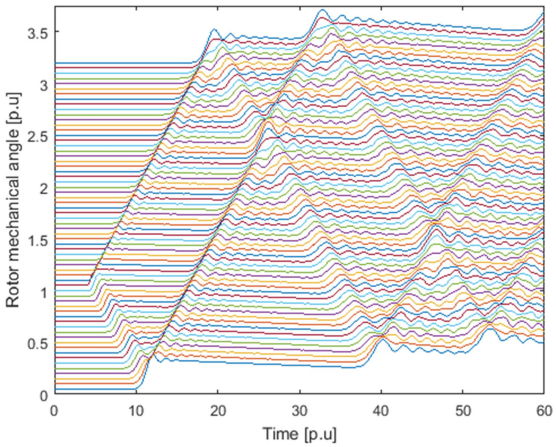

Fig. 2. Disturbance propagation in an open-ended string of synchronous generators without wave-quenching compensator.

The simulation results given in Fig. 3 are obtained by adding the wave-quenching compensator. The compensation law based on (17) is applied at the right end of the string. The reflection at the right end of the string is successfully suppressed even though an approximate compensation law is implemented [4]. It is important to note that the compensation law works extremely well although it was tested on the nonlinear model with both generator damping and transmission line conductance assuming non-zero values. Thus, results given in Fig. 3 attest to the robust nature of the proposed compensation law [5].

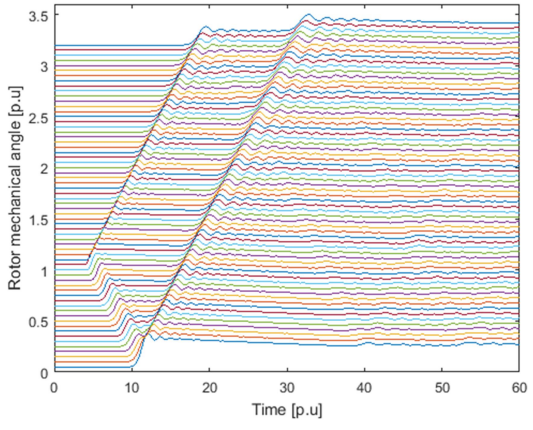

Fig. 3. Disturbance propagation in an open-ended string of synchronous generators with wave-quenching compensation.

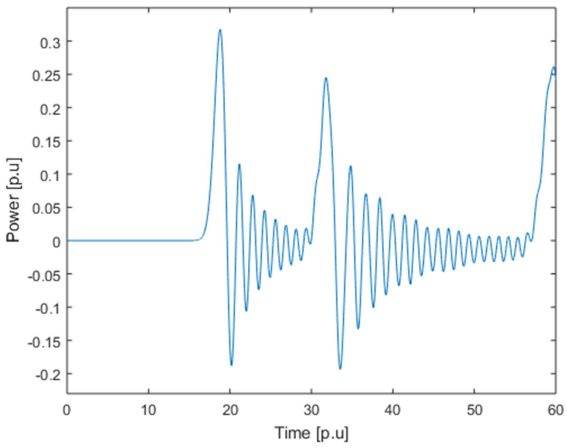

Fig. 4. The power drawn from the wave-quenching compensator at the end of the string, obtained simultaneously with the results plotted in Fig. 3.

The wave-quenching compensator has to supply the transient power pulses illustrated in Fig. 4. Note that the rate of change of the power during this transient is considerably larger than what a conventional synchronous generator is capable of. The limiting factor is the physical nature of exciter and turbine regulation. Thus, a practical implementation of this wave-quenching compensator would require a power electronics device and a local form of energy storage. Batteries are not fast enough for this application. Capacitors do not have enough capacity to store the required amount of energy. Therefore supercapacitors are found to be an adequate solution for the local form of energy storage. The above mentioned power electronics devices are mostly designed as modular multilevel converter topologies (MMC) because they have to operate at high voltages. Instead of a single switch, several H-Bridge cells are connected in series to form a chain [9]. The converter consists of six of these chains in a three-phase inverter configuration (Fig. 5).

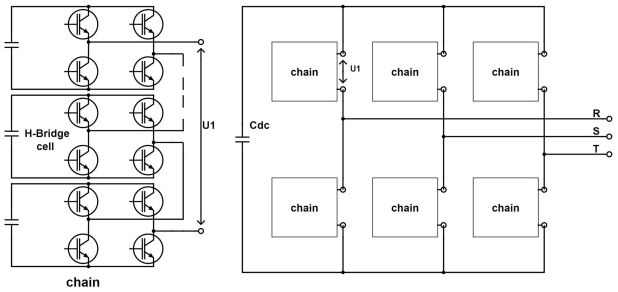

Fig. 5. Modular multilevel converter topology.

V. Conclusions

The main issues addressed in this paper are techniques for modelling and stabilizing power systems with spatially distributed sources and loads. A one dimensional string of conventional synchronous generators is considered, and it is determined that the electromechanical power waves exist. In order to examine validity of the derived continuum model and verify the conclusions drawn from such a model, computer simulations of the discrete system are implemented. It is noticed that, at the points of inhomogeneity, multiple reflections take place. They endanger power system stability, and therefore must be suppressed. A simplified version of the previously proposed wave-quenching compensation law, which is based only on local, readily available measurements is discussed and tested by the means of computer simulations.

Due to the fast transient response of power and the large amount of energy that the wave-quenching compensator has to supply during these transients, the practical implementation of the proposed control law implies the use of power electronics devices for the actuators and supercapacitors for the energy storage. Taking into account the voltage level at which those actuators have to operate, it is most likely that they would be realized as modular multilevel converters.

Further studies on the wave nature of the disturbance propagation in the power system include: a more detailed description of the conventional power system, simulations of distributed feedback control strategies, the implementation of the continuum modelling techniques on networked inverters as well as on a mixed grid, containing both traditional synchronous generators and grid-side inverters.

A Fault-Tolerant DC UPS System Based on a Battery Charger with an Automatic Load Transfer Function

Vladimir Dj. Vukić

***Abstract*—A direct current uninterruptible power supply (DC UPS) system, designed for operation in a hydro power plant, is presented in this paper. Standard DC power supply configurations for large power plants consist of two AC/DC converters with accompanying storage batteries. To improve the system's reliability, an active fault tolerant control system (FCTS) was utilised. Aside from the two primary AC/DC converters, a third device was implemented with the same nominal characteristics, albeit with some additional advanced functions. This secondary AC/DC converter has two high-power contactors on its output, enabling it to operate (either manually or automatically) in parallel with one of the primary rectifiers. In order to achieve the high reliability of this facility, a serial communication was not established between battery chargers. Instead, a procedure for the turnout detection of a remote battery charger was utilised, based only on data from the auxiliary contacts of its main switch and the input contactor. Based on these logic conditions, an algorithm for the automatic load transfer was devised for implementation in cases when some of the inoperative primary battery chargers would automatically be replaced by a secondary AC/DC converter operating in a "hot reserve".**

***Index Terms*—AC/DC converter, Fault-tolerant control system (FTCS), Uninterruptible power supply (UPS), Algorithm.**

I. Introduction

IN previous years, the area of static uninterruptible power supply systems (UPS) demonstrated intensive technical progress [1]-[2], especially due to a reduction in power converters' weight and size [3]. Furthermore, there were increased demands for highly reliable power converters [4]-[5]. One way to improve the reliability of power supply is to implement fault-tolerant control systems (FTCS) capable of continually operating after a failure has occurred. Some authors divide these systems into passive (PFTCS) and active fault-tolerant control systems (AFTCS) [6]. Usually, passive FTCS (PFTCS) means ordinary redundant systems, such as modular power converters in N+1 configurations (with at least one spare module), enabling the power converter to continue its operations with nominal load even in the case of module failures. Therefore, modular construction with reserve modules is a frequent topology for modern power converters in industrial UPS systems. Nonetheless, often PFTCS are not even considered to be true fault-tolerant systems, since it is not possible to isolate the failure or continue device operations with modified characteristics [6]. Therefore, if a customer has high demands for the secure operation of their power plant, among the first requests would be highly reliable UPS devices, particularly in the case of DC voltage. Accordingly, the implementation of redundant batteries and active fault-tolerant AC/DC converters would be strongly justified.

Another important issue is to realise a simple and reliable state diagnostic of a primary ("master") battery charger. If such a diagnostic relies on a serial communication, it would depend on the regular operation of a battery charger control unit. Nevertheless, in the case of a battery charger control unit fault, or the loss of its power supply voltage, a serial communication would simultaneously fail. Consequently, it would be preferable to develop some mode of diagnostics that could solely rely on a secondary ("slave") battery charger, not depending on the correctness of a primary charger operation. Nonetheless, such a method, with few available signals, should be capable of reliably detecting the state of the monitored device, avoiding both false alarms and oversight of real faults.

In this paper, an active fault-tolerant DC UPS system was presented, implemented in the "Djerdap 2" hydro power plant. A detailed description was given of a method for fault diagnostics in primary battery chargers, as well as a utilised automatic transfer function.

II. Battery Chargers

A. DRI-PT Series of Thyristor AC/DC Converters

Owing to the implemented design, based on a programmable logic controller (PLC) and a touch-sensitive human machine interface (HMI), this specific kind of AC/DC converter distinguishes itself among other thyristor rectifiers, made in the second half of the previous decade. The devices of the DRI-PT series are rectifiers developed in the "Nikola Tesla" Electrical Engineering Institute, designed to be implemented as battery chargers in UPS systems [7]-[9]. Seven thyristor rectifiers were produced in three lots (based on mutually significantly different designs) and commissioned in three hydro power plants (HPP) in Serbia: "Djerdap 2" [7], "Bajina Bašta" [8] and "Djerdap 1" [9].

All of these three types of AC/DC converters had different circuit topologies to achieve fault-tolerant operations. The original devices (DRI 220-70PT) were configured to operate

Vladimir Dj. Vukić is with University of Belgrade, Electrical Engineering Institute "Nikola Tesla", Koste Glavinića 8a, PO Box 139, 11000 Belgrade, Serbia (e-mail: vvukic@ieent.org).

as two battery chargers with accompanying storage batteries, keeping a third battery charger, without its own battery, in a "hot reserve" [7].

The second system, comprised of two rectifiers DRI 48-50PT, was commissioned in the "Bajina Bašta" HPP [8]. This was preferably PFTCS, with a single battery charger and redundant DC load power supply. The thyristor rectifier was expanded with 100% redundant DC/DC converters in its output stage, supplying critical loads with a nominal voltage of 48 V for numerous possible variations in battery voltage (between 36 V and 75 V) [8].

The third system was the most complex of all, forming a conjoint facility of two AC/DC converters (DRI 220-160PTD) and a DC distribution board with two mutually independent busbar systems, designed for "Djerdap 1" HPP [9]. The DRI 220-160PTD line-frequency phase-controlled rectifiers have a two-channel control system, a primary from a PLC microprocessor unit, and a secondary from an analogue PI controller, activating in cases of PLC failure [9].

B. Construction of DRI 220-70PT AC/DC Converters

DRI 220-70PT Rectifiers (Fig. 1) are line-frequency self-commutated power converters, with a thyristor half-bridge serving as an actuator, designed for nominal output parameters of 220 V and 70 A. These AC/DC converters were foreseen for use in lead-acid or nickel-cadmium storage battery charging, as well as the power supply of a critical DC load (either with or without a connected storage battery) in an additional facility of the "Djerdap 2" HPP (situated on the border between Serbia and Romania, on the river Danube). There are "master" (DRI 220-70PTM) and "slave" (DRI 220-70PTS) varieties of these AC/DC converters, with the "slave" type being somewhat more complex (see Fig. 2). Three DRI 220-70PT rectifiers, together with two lead-acid storage batteries, represent the UPS system for a load operating with 220 V DC safety voltage in the power plant (presented in Fig. 3).

Fig. 1. DRI 220-70PTM1 (left), DRI 220-70PTS (in the middle) and DRI 220-70PTM2 (right) AC/DC converters in an additional facility of the "Djerdap 2" HPP.

The control unit is primarily based on the "Omron" CJ1-series PLC. Analogue circuits and drivers, specific to the line-frequency self-commutated rectifiers, were separately consolidated on the "DIGISP 06" motherboard. Occupying the role of the human-machine interface (HMI) was the "Omron" NS5 touch panel, replacing all the push-buttons, instruments and switches (except the main switch) on the AC/DC converter's cabinet front door. Above the HMI, the 20-diode LED panel was mounted.

Fig. 2. Interior appearance of the DRI 220-70PTM1 (left) and DRI 220-70PTS (right) AC/DC converters. Note the two output contactors in the upper back field of the "slave" device.

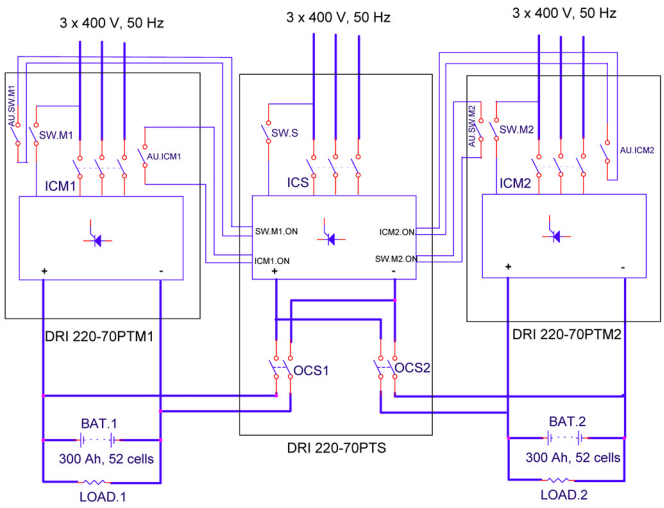

Fig. 3. Simplified schematic circuit diagram of the DC UPS system installed in the "Djerdap 2" HPP. While every battery charger has its input contactor (IC), the output contactors (OCS1 and OCS2) are only part of the DRI 220-70PTS "slave" battery charger. Note the auxiliary contacts of the main switches (AU.SW.M1 and AU.SW.M2) and input contactors (AU.ICM1 and AU.ICM2) of two "master" rectifiers.

When an input contactor is turned off, the power circuit of a battery charger is isolated from the mains grid voltage. As soon as the main switch (on the front door of a battery charger cabinet; see Fig. 1) is turned on, the input contactor activates, connecting a power circuit to the mains grid voltage (3 x 400 V, 50 Hz). Nonetheless, the battery charger is only turned

on after the activation of the virtual "START" taster on an HMI panel.

At an HMI panel, user can make wide variations of the preset parameters, such as the modes of operation, references of output voltage and current, thresholds of overvoltage and undervoltage protections, load transfer options, as well as parameters of PI controllers. A variation of the reference voltage is a particularly important function in the case when one or more battery cells were short-circuited. Rectifier may charge the battery with the reference voltage even if some of battery cells are missing, but this shouldn't be performed for a long time. In such a case, referent voltages in all modes of the battery charging operation (float, boost and equalizing charge) should be reduced, in order to prevent the battery damage due to the operation with excessive voltage. Thus, for all the battery chargers, it is important to operate with the same number of battery cells. The secondary battery charger can have only one set of reference voltages, for the one exact number of the storage battery cells. Therefore, in order to permanently keep active the automatic load transfer function of the secondary battery charger, both storage batteries should have the same number of the short-circuited cells. Nonetheless, it should be noted that the short-circuiting of the storage battery cells is an improvisation that should be avoided if not necessary, and that the spare battery cell should be mounted as soon as possible after the perceived failure of a storage battery string.

In order to enable autonomous operation of all battery chargers of the "DRI-PT" series, they do not have measurement data on the output current of other rectifiers in the same facility. Thus, these rectifiers do not have a possibility for equal current sharing during the parallel operation. Usually, for the same values of the reference voltages, the DRI 220-70PT battery chargers should perform some division of the total load current. Nonetheless, there is no chance for overload of any of the parallel operating rectifiers. In the worst case, if the total output current is too high, one battery charger would reach the current limit, while the other would take the remaining load. All the battery chargers were dimensioned to operate with the nominal load current for the entire operational life, that is, at least, twenty years.

DRI 220-70PT rectifiers have multiple monitoring and test functions implemented, such as a battery presence check and the service mode of operation. There are also several fault detection procedures, either for failure of the complete power devices (rectifiers or storage batteries) or just parts of a battery charger. The former procedures are primarily related to the secondary device DRI 220-70PTS to detect fault (or its cessation) of either of the primary devices. The letter procedures are related to all AC/DC converters, since there is a need to detect either unacceptable operation states or failures that affect the device's operation but can be tolerated (earth fault, low output voltage, etc.).

There are five internal states ("hard faults") that cause immediate the shutdown of the DRI-PT battery chargers: high voltage, overload, mains voltage fault, high output voltage ripple and drive pulse loss (or the total thyristor bridge failure – described in the following section). If a shutdown happens (excluding cases of mains voltage fault), thirty seconds later an automatic restart begins and the rectifier enters the soft-start phase, gradually increasing the output voltage. If the cause of failure ceases to exist, after another 30 seconds the soft-start phase is over and the device reaches the preset nominal output voltage. If the cause of failure is still present, rectifier protection will react and the device would again be turned off. There is a programmed procedure for three automatic restarts: if after the third attempt the rectifier protection reacts intermittently, the automatic restart procedure is discontinued and the input mains contactor is turned off, leaving an inoperative AC/DC converter without mains voltage power supply.

III. Detection of Faults

A. Internal Detection of a Thyristor Bridge Fault

If the failure of some of the actuator's elements occurs (such as particular thyristor or ultrarapid fuse), an AC/DC converter may continue its operation, though with degradation of its characteristics. However, in order to achieve the "graceful degradation" and timely reduction of its output characteristics, fault-tolerant devices need reliable procedures even to detect minor failures.

The most common practice for fuse failure detection means the use of auxiliary contacts to provide an independent logical signal for any one of the blown fuses. On the other hand, this simple method cannot be implemented in cases of thyristor failure, let alone for every power semiconductor in a thyristor bridge.

On DRI 220-70PT rectifiers, auxiliary contacts for the detection of failures in a thyristor bridge were not used. As was first implemented in the "DRI" series of thyristor rectifiers [10], in the "DRI-PT" series the detection of the second mains voltage harmonic was utilised as an indicator of a (partial) thyristor power converter failure, or, alternatively, "a thyristor bridge asymmetry" [10].

If some of the actuator element faults occur (such as particular thyristor or fuse), a battery charger may continue its operation. Nevertheless, it is not impossible for a battery charger to remain in operation with a completely dysfunctional power semiconductor actuator. There may be many reasons for such a failure, from a heavy incident in the surrounding environment, but also seemingly trivial incidents, such as the loss of drive pulses on the power semiconductor switches (even by simply pulling out an appropriate connector from a printed circuit board). In the latter case, a battery charger control unit may continue its operations, and, due to the presence of a storage battery at the output terminals of an AC/DC converter, consequently be unable to detect such a fault for a long time. Thus, a new protection function was developed for the series of DRI-PT rectifiers, designed to detect drive pulse loss on a thyristor bridge.

This protection function operates in the following way: if the output voltage declines for more than 10 V, in comparison with a voltage reference, and if the output current in a battery is lower than 2 A continuously for a period of twenty seconds,

then a battery charger is inoperative and a signalisation of the drive pulses loss activates. Activation of this protective function leads to an automatic battery charger turn-off, with the triple automatic restart procedure simultaneously beginning.

B. Detection of Faults Occurring at External AC/DC Converters

A simplified diagram of the UPS facility, comprised of three battery chargers from the DRI-PT series, is presented in Fig. 3. If a "hard fault" (described in section *II.B*) occurs on some of the primary devices (DRI 220-70PTM1 or DRI 220-70PTM2), it is necessary for the secondary device to detect it. To begin the normal operations of an AC/DC converter, it is, at first, necessary to turn on the main switch. The normal rectifier operation means that when the main switch is turned on, the input mains contactor is also turned on. However, if the automatic triple restart procedure fails and the input contactor subsequently turns off, this is a sign of a hard fault of a battery charger. This simple condition is used for a primary device fault diagnostic from the secondary rectifier. Therefore, the turnout detection of an external battery charger is accomplished in the following way: if the mains contactor is off and the main switch is on, then the conclusion may be drawn that the remote rectifier is inoperative. This simple procedure enables the fault detection of a primary rectifier even if it suffers a central processing unit failure or power supply loss, without the need for the establishment of a serial communication between AC/DC converters. It also disables inadequate automatic load transfer activation, such as in the case when one of the primary battery chargers is turned off, *i.e.,* not operating, whilst without the simultaneous "hard fault" signalisation.

The auxiliary contacts of a main switch and the input contactor of both primary devices (DRI 220-70PTM1 and DRI 220-70PTM2) were wired to the secondary device (DRI 220-70PTS). The local power supply voltage of 24 V DC, from the secondary rectifier DRI 220-70PTS, was used as the command voltage for the aforementioned auxiliary contacts in primary devices, enabling the safe monitoring of these logical conditions by the secondary device. This was also a method of precise fault detection in either of the two primary rectifiers, enabling only the activation of the proper output contactor of the secondary battery charger. Additionally, if the logical condition of the primary device fault ceased to exist, this is a signal to turn off the output contactor and put the secondary rectifier into the idle mode again.

IV. Automatic Load Transfer

A. Description of the Load Transfer Function

The DRI 220-70PTS thyristor rectifier, as opposed to its accompanying DRI 220-70PTM device, has an implemented load transfer function (both manual and automatic). During normal operations, two primary devices, DRI 220-70PTM, charge their storage batteries and the supply load connected to their DC current distribution boards. The load is connected to some of the two 220-V DC-Busbar systems, each supported with a separate battery and AC/DC converter. On the other hand, the secondary DRI 220-70PTS device operates in idle mode, regulating the output voltage and monitoring the operation of primary battery chargers.

In the appropriate menu of an HMI display, a user may select either a manual or automatic load transfer. Before the option of a manual load transfer is activated, a user has to select, by pressing virtual tasters on an HMI panel, the secondary device connection either to the first (DRI 220-70PTM1) or the second (DRI 220-70PTM2) of the primary AC/DC converters. Thus, the activation of a manual load transfer leads to the immediate connection of a secondary battery charger to one of the selected primary devices. Connection is established using one of two output contactors in rectifier DRI 220-70PTS. Rectifier DRI 220-70PTS therefore operates in parallel with one of the selected DRI 220-70PTM devices. If a virtual switch for a manual load transfer is turned off, the secondary DRI 220-70PTS rectifier disconnects from its primary rectifier and returns to the idle mode of operation.

More importantly, there is also the possibility of users choosing the automatic load transfer function. If the automatic load transfer function is active, the secondary device monitors the operation of the two primary battery chargers. If either of the primary devices endures a "hard fault" and the automatic triple restart fails, the mains input connector is automatically turned off. In such a case, the DRI 220-70PTS rectifier automatically connects (through one of its two output contactors) to the output of the failed device after the selected time delay (from one to ten minutes) expires. In the meantime, DC load is supported only by the storage battery.

In the manual mode of the load transfer, the secondary rectifier may operate with the inoperative device's battery and load if necessary, until the manual command is given to an output contactor to turn off. If the secondary battery charger operates with an active option of the automatic load transfer, a failed primary rectifier, after the repair, resumes operations, whilst the secondary device automatically disconnects from a load and a battery, after the expiration of the preset time delay.

B. An Algorithm for the Automatic Load Transfer

An algorithm for the automatic load transfer, implemented in the DRI 220-70PTS battery charger, was realised as a software function, performed by the central processing unit of a PLC. A simplified algorithm of the implemented automatic load transfer function is presented in Fig. 4.

In order to implement the automatic load transfer, several logical conditions have to be fulfilled, with the appropriate values of the corresponding software flags. At first, the "slave" battery charger, DRI 220-70PTS, has to be in a stationary state, when the phases of initialisation (F.Start = 1; Fig. 4) and "soft start" (F.Soft.Start = 0) are over. Further, no detection of any "hard fault" is allowed (F.Hard.Fault = 0), and a flag for the automatic load transfer should be active

(F.Auto.L.Trans = 1; Fig. 4). In the next step, there is a need to detect the main switches of both the remote "master" battery chargers (SW.M1.ON = 1 or SW.M2.ON = 1) powering on. Finally, it is necessary to detect the inactive state of the input contactors of two "master" AC/DC converters (IC.M1.ON = 0 or IC.M2.ON = 0). This way, when all the specified logical conditions are fulfilled, a counting sequence commences, which may last from one to ten minutes (presented in Fig. 4 utilising RC circuits). When the preset time delay is over, the "slave" device turns on the appropriate output contactor, either for connection to the output terminals of the DRI 220-70PTM1 battery charger (using the output contactor OCS.1) or the second rectifier, DRI 220-70PTM2 (utilising the output contactor OCS.2). As may be seen from Fig. 4, both output contactors must not be turned on at the same time. Finally, if any of the necessary logical conditions are no longer being fulfilled, after a new countdown sequence the active output contactor is turned off, and the "slave" battery charger again goes back into idle mode.

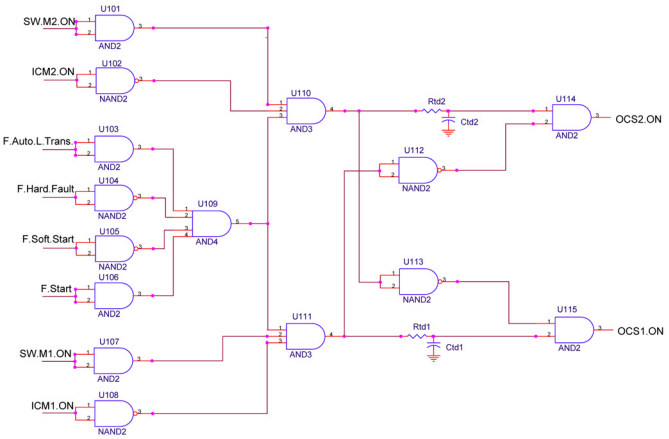

Fig. 4. Logical conditions for the execution of the automatic load transfer, utilised on the "slave" battery charger DRI 220-70PTS. A simplified algorithm was presented in the form of a Boolean (switching) circuit, utilising AND and NAND elements. Time delays were presented with RC circuits.

V. Conclusion

For implementation in the DC UPS system of an HPP, a fault-tolerant facility was developed, comprised of three AC/DC converters. In order to enable the quick replacement of a potentially failed rectifier, a load-transfer procedure (automatic or manual) was utilised in one of these three battery chargers.

In the automatic mode of operation, two primary ("master") AC/DC converters are charging the accompanying storage batteries and DC load, while the secondary ("slave") device operates in idle mode, simultaneously monitoring the state of the two primary devices. If a hard fault of either of the primary devices was detected, the secondary device would, after the preset delay time, connect to the failed rectifier output contacts, supplying the accompanying battery and load. If the primary device comes back into operation, the secondary AC/DC converter would, after the same predefined delay time, disconnect from its output contacts and return to the idle mode of operating.

In order to enable the implementation of the automatic load transfer, it was necessary to utilise a simple procedure for the on-line monitoring of two primary battery chargers without the implementation of a serial communication. Such a procedure was realised utilising only two auxiliary contacts on both of the monitored AC/DC converters, obtaining data on the state of the input switch and input contactor of each battery charger. The fault detection of the monitored battery charger is accomplished in the following way: if a mains contactor is off and a main switch is on, then the conclusion may be drawn that a remote AC/DC converter is inoperative.

In order to enable the fault detection of a primary battery charger even in the case of drive pulse loss on a thyristor bridge, a new protective function was developed. It operates in the following way: if the output voltage significantly decreases, whilst the output current in a battery is simultaneously negligible, then the conclusion may be drawn that the battery charger is inoperative and the signalisation of the drive pulses loss activates. The utilisation of the drive pulse loss protection function, together with other "hard faults" (overvoltage, overload, high output voltage ripple), enables the timely and reliable fault detection of the monitored battery charger.

The operation of the load transfer functions, both automatic and manual, was tested in all phases of the construction of the described facility, *i.e.*, during the phases of development, manufacture and commissioning of the DRI-PT series of battery chargers. Tests were successfully performed with a resistive load in a workshop, as well as with an accompanying DC load and lead-acid batteries in a "Djerdap 2" HPP.

The described technical solution is not restricted only to a field of thyristor power converters but may also be implemented in battery chargers based on high-frequency, switching power converters (PWM rectifiers).

Autogenerated Power Distribution Network Model

Lazar Prodanović, Darko Čapko, Aleksandar Erdeljan, *Faculty of Technical Sciences, Novi Sad*

***Abstract*—This research paper covers the development of a smart greedy algorithm, used for autogeneration of a test distribution network model, with predetermined parameters. Autogeneration is done using input data set, which is first clustered in order to reduce its size and thereby simplify the given task. Each cluster provides one representing object that is later used in the optimization algorithm. Proposed optimization algorithm chooses the objects needed to create a network model that is optimal in size and creates a resulting data set. The algorithm is tested with real life data set, extracted from an existing CIM-based distribution network model, and results in a new distribution network model created using the same specification.**

***Index Terms*—Distribution network data model, CIM, clustering, optimization algorithm.**

I. Introduction

Power systems [1] have changed dramatically in recent years, especially those parts that are used for delivering electricity to the customers. Distributed resources are being included (wind farms, photovoltaics, electrical vehicles, batteries, etc.) and the power industry tends to reduce power consumption and losses. By doing that, it challenges power utilities to achieve efficient control and management of the power network. In order to achieve that goal, various software solutions are being used, including sophisticated SCADA systems enhanced with DMS (Distribution Management System), OMS (Outage Management System), DERMS (Distributed Energy Resources Management System), collectively known as ADMS (Advanced Distribution Management System) [2].

These systems are based on models and simulations are being used before making any decisions, be it immediate applied control or planned operations. Size and complexity of these systems lead to big models and require substantial hardware resources for computations. Estimation of needed resources is not an easy task, especially when considering diverse model-dependent ADMS applications. As building a real model represents a long-term process, and resources need to be timely determined, it is desirable to carry out experiments on a similar test model. Therefore, this research proposes a parameterized data model autogenerator, as a fast way of creating those test models. Parameters are selected to represent the model size and they denote total numbers of certain data model elements, like power transformers, power lines, consumers, remotely controlled devices, etc.

Researches on this topic are almost nonexistent. Most test models are created manually, by hand picking model components, one by one. However, there are some simple autogenerator solutions that are based on the multiplication of a smaller model. In this case, the entire model is being multiplied, leading to a bigger model, with the same parameter ratio. As simple as this approach seems, that fixed parameter ratio presents a big problem. If the starting model does not have the desired parameter ratio, that desired ratio is unattainable.

The proposed solution includes setting model parameter values, regardless of the starting model parameter ratio. Multiplying parts/components of the existing model, instead of the entire model, represents the main idea behind this approach and provides greater flexibility when choosing the desired model configuration. Connectivity model is autogenerated, and topological model can be affected using switching devices' status. Aside from this, the attributes of certain components used in multiplication have to be modified, in order to get a valid model, with respect to the power calculations. Some attribute modifications can be done based on simple rules (defined by domain experts), but other require running advanced calculations (power flow, for example). The proposed solution is primarily oriented towards generating models for testing nonfunctional requirements (system attributes such as security, reliability, performance, maintainability and usability), and therefore, does not utilize advanced calculations. After being created, test models are imported into ADMS applications, allowing for all the applications' computations and operations to be run, without affecting consumers. In the background, systems' hardware resources are being monitored, and modifications are made if necessary. For example, hardware resources are added if the application runs slowly, or they can be removed for better cost efficiency if tests show that they are excessive.

Actual model data is usually considered confidential, thereby making its usage in development unworkable or at least limited. The proposed approach goes around these limitations, as it only needs one existing model in order to create countless test models. That existing model can be based on real-life data or it can be manually created, component by

Darko Čapko is with the Faculty of Technical Sciences, University of Novi Sad, Trg Dositeja Obradovića 6, 21000 Novi Sad, Serbia (e-mail: dcapko@uns.ac.rs).

Aleksandar Erdeljan is with the Faculty of Technical Sciences, University of Novi Sad, Trg Dositeja Obradovića 6, 21000 Novi Sad, Serbia (e-mail: ftn_erdeljan@uns.ac.rs).

component, while making sure it stays valid throughout the process. Standardized data models play a big role in this segment, as they are not origin-dependent. The proposed autogenerator uses models based on Common Information Model (CIM) [3][4], which is an abstract information model used for electrical network modeling and is built on a few basic technologies:

- Unified Modeling Language (UML),
- eXtensible Markup Language (XML) and
- Resource Description Framework (RDF).

RDF/XML [5] files are being used for storing the existing model data and the new test model is exported in the same form, after it is autogenerated.

II. Mathematical Task Description

The aim of the proposed algorithm is to determine a resulting set, consisted of CIM containers – in this case substations and feeders – that comes closest to fulfilling the predetermined distribution network configuration, i.e. total numbers of selected elements in the generated model should be as close as possible to the desired numbers of elements. Therefore, each container has a defining set of parameters, and only some of those parameters are considered when generating a new network model (considered parameters can be added, changed or removed, if needed). Parameters that are used in this research paper are:

1. Number of transformers,
2. Number of signals,
3. Number of SCADA points, and
4. Number of MV consumers (referred to as "consumers").

In other words, the goal of the autogenerator is to analyze the input data set, and pick a new set of substations and feeders out of it, so that the resulting set's total number of transformers, signals, SCADA points and consumers, comes as close as possible to the desired values, given for the new distribution network model.

Mathematical definition of this task can be formulated in the following way. For a given input set of *n* objects, where every object has *m* parameters, determine the set *S*, which consists of those objects, so that each parameter sum becomes as close as possible to the predetermined parameter value. Every object can appear multiple times in the set *S*. All parameter values are whole numbers.

The goal is to determine:

$$\min_{X_i} J = \min_{X_i} \sum_{j=1}^{m} \left(\frac{P_j - \sum_{i=1}^{n} X_i p_{ij}}{P_j} \right)^2 \qquad (1)$$

Where:

- p_{ij} represents *j*-th parameter value for the *i*-th object
- P_j represents predetermined *j*-th parameter value for set S
- X_i represents *i*-th object's number of occurrences in set S

A. Clustering input data

Typical data models consist of hundreds or even thousands of different containers and each container requires additional computational time, if included in the algorithm. Adding more container parameters to this problem increases the number of dimensions and makes it almost impossible to work with the given input data set. In order to improve the speed and the efficiency of the optimization algorithm, the input data set has to be reduced in some way. For this practical reason, k-means clustering [6][7] is performed on the input data. As data clustering represents a process of classifying objects into groups/clusters of similar objects, it is not reducing the input data set itself. However, as each cluster contains similar objects, it can be represented by a single object, without sacrificing diversity. Choosing a representing object is done by calculating every object's distance from its cluster's centroid/center, and choosing the closest one as that cluster's representative. This way, starting data set size is reduced to a desired number of clusters, which can be passed to the algorithm as an input argument.

Moreover, clustering can be used for eliminating the usage of untypical objects/containers in the generated data model. Cluster centroids are positioned as close as possible to all of its belonging containers – total Euclidean distance between the centroid and all of its containers tends to be as low as possible – which makes containers with abnormally high or abnormally low parameter values significantly less likely to be chosen as the cluster representatives.

Although there are clustering algorithms that are better suited for finding the cluster representatives, as well as eliminating the untypical data (k-medoid and c-medoid, for example), the k-means algorithm does almost the same job in considerably smaller time interval, making it ideal for fast optimization algorithms with a lot of input data.

III. System Workflow

The autogenerator consists of:

- Initial data model importer (RDF/XML parser),
- Clustering tool and,
- Optimization algorithm.

System workflow block diagram can be seen in Figure 1. Starting data set is extracted from an existing CIM-based model, given in the form of an RDF/XML file, using the RDF/XML parser, embedded into the autogenerator. Clustering tool then divides that data set into groups, and chooses a representative for each group, thereby creating a reduced data set, used in the optimization algorithm. Optimization algorithm, whose pseudo code is given in the next chapter, creates a new/resulting data set by choosing objects/containers from the reduced data set, while trying to satisfy the predefined network model parameters. When the resulting data set is created, it is exported into a new RDF/XML file, which defines the generated data model of network distribution.

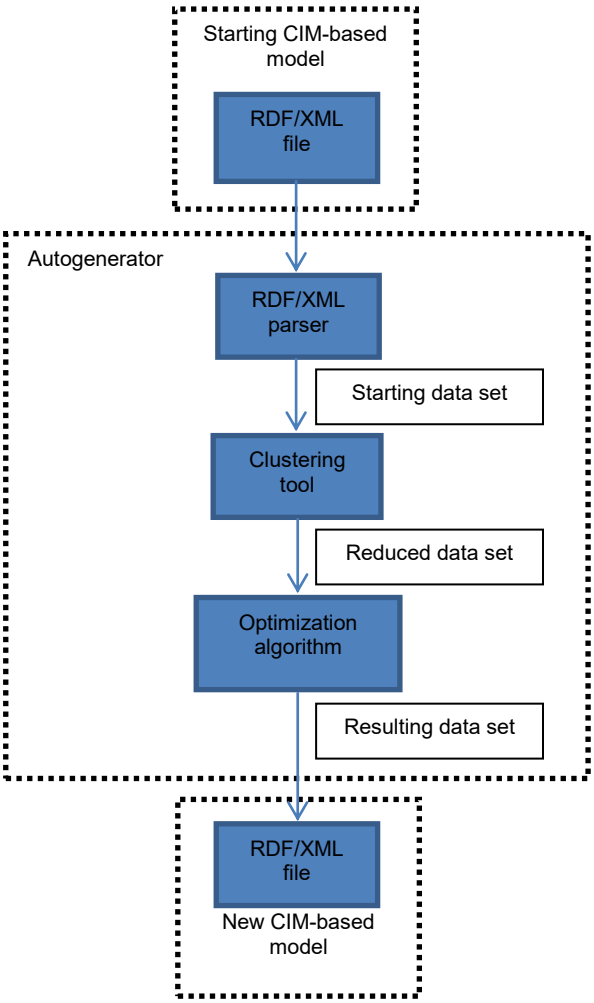

Figure 1 System workflow overview

IV. Implementation

This chapter describes the optimization algorithm, used for determining the optimal configuration of the data model. The algorithm works with a reduced data set, described in the previous chapters. It works as a greedy algorithm, meaning that it is making an optimal choice at each step, while trying to get to the best solution at the end. Greedy algorithms are effective at solving some kinds of problems, but tend to go astray while solving the other kinds, as they always choose the most beneficial element at the moment, instead of the one that makes the final solution better. However, the proposed algorithm is tweaked so it does not go for quantity over quality, and leads to better results in the end.

The other thing that distinguishes this greedy algorithm is the fact that it has multiple iterations. Each iteration produces a different solution, using different reduced data set, thanks to the clustering tool. Different data sets are created using a random number generator that allocates different starting clusters for each iteration. These starting clusters affect cluster centroids, which leads to different representatives at the end of each clusterization process. As there are more iterations and problem solutions at the end, the one that best satisfies the optimization criteria (1) is chosen.

Pseudo code for the proposed smart greedy algorithm:

```
1:  function SmartGreedyAlgorithm(data, needs, numIter, numCluster)
2:      for i = 1:numIter
3:          R = ExtractClusterRepresentatives(data, numCluster)
4:          newJ = CalculateJ(needs)
5:          previousJ = MAX_SE
6:          while newJ <= previousJ
7:              previousJ = newJ
8:              CalculateProfitMatrix(R)
9:              for e = R
10:                 CalculateAverageProfit(e)
11:                 CalculateDeviationForParameters(e)
12:             end for
13:             SelectElementWithMinDeviation(R)
14:             InsertSelectedElementInModel
15:             remainingNeeds = CalculateRemainingNeeds
16:             newJ = CalculateJ(remainingNeeds)
17:         end while
18:         SaveSelectedElements
19:         finalJ = CalculateJ(remainingNeeds)
20:     end for
21:     sol = FindMinFinalJ
22:     ExportSolutionToXML(sol)
23:     end function
```

Input arguments:

- data – starting data set
- needs – predetermined network model parameters
- numIter – assigned number of iterations
- numCluster – assigned number of clusters

Output:

- Resulting data set (line 21), exported into an XML file (line 22), later used by the GDA importer for creating a new distribution network model

A. *Profit matrix calculation*

Main steps of the proposed smart greedy algorithm can be seen in the form of pseudo code. However, profit matrix calculation (line 8) and the selection of the best fitting object (line 13) have to be described with more details.

Object's profit is determined by temporarily inserting that object into the resulting set, and recalculating system's relative errors for each parameter (line 8), in regard to current needs. Object is removed from the resulting set as soon as profit is calculated. In order to make the algorithm smarter, the current fitness of an object is no longer seen as the quantitatively biggest contribution to solving the optimization problem given with the equation (1). Instead, profit mean value is calculated for each object (line 10), thereby enabling the calculation of a deviation for each parameter (line 11). Object that has smallest deviation sum is chosen as the fittest (line 13). This means choosing the object that can even the current relative error levels, as much as possible. By choosing this type of objects, the algorithm tends to keep the predefined parameter/needs ratio until the end, resulting in a better solution, preferably with zero relative errors for all the parameters. After each selection, the fittest object is inserted into the resulting set (line 14), and system needs are

recalculated by subtracting object's parameter values from the current needs (line 15).

B. *Determining the final solution*

Each iteration in the algorithm runs until new *J* value, defined in the equation (1), becomes bigger than the previous *J* value (line 6). After that, the final solution is saved, together with its last *J* value.

When the assigned number of iterations passes, all the collected solutions are compared, and the one that best satisfies the equation (1) is chosen (line 21) and exported to the RDF/XML file (line 22), creating a new distribution network model in the process.

V. RESULTS

The algorithm was implemented and tested for creation of 8 data models each having different set of parameters. For each of those sets, algorithm was run several times, using different numbers of iterations and clusters as input arguments. Iteration numbers used were: 10, 100, 1000 and 2000. Cluster numbers used were: 5, 10, 20, and 50. Those values were chosen randomly (but limited by a size of the starting data set) and are analyzed in the following paragraphs. Table 1 shows results for each test's best combination of the assigned input arguments. Results are given in form ***set value / deviation***. For example, model #1 has 10001 transformers, 19995 signals, 750 SCADA points and 8000 consumers, but its set values were 10000, 20000, 750 and 8000. Each run used the same existing model data for creating the starting data set.

TABLE 1
TEST RESULTS

Set parameter values / final deviations	Number of transformers	Number of signals	Number of SCADA points	Number of consumers
Model #1	10000 / 1	20000 / -5	750 / 0	8000 / 0
Model #2	15000 / 46	20000 / 1	1000 / 1	8000 / 14
Model #3	5000 / 0	15000 / 0	750 / 0	5000 / 0
Model #4	10000 / 1621	10000 / -1169	750 / -10	5000 / -189
Model #5	5000 / -2	7500 / -73	500 / 0	8000 / -13
Model #6	10000 / 15	15000 / -56	1000 / 0	10000 / -16
Model #7	10000 / 0	20000 / -9	500 / 0	5000 / 2
Model #8	1000 / 353	1000 / -10	200 / -32	1000 / 0

Figure **2** shows a graphical view of the results for one of the tests, with all the possible combinations of input arguments.

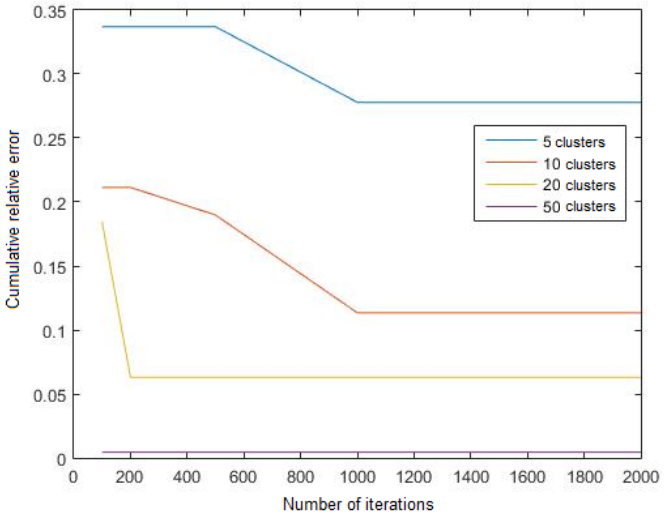

Figure 2 Graphical view of the results

As can be seen from the results provided in Table 1, the proposed algorithm usually provides acceptable results, where relative errors do not exceed 1%. It also points to the unrealistic parameters, as can be seen in tests 4 and 8. This happens when certain parameter values become too high or too low, leaving the clustering algorithm unable to find right representatives. For example, in model #4 test, the desired number of transformers matches the desired number of signals, which leads to big parameter deviations at the end, because there are no suitable containers in the existing model whose standard ratio is 1:2 for those parameters. This means that the starting data set or predefined network model parameters have to be changed, because desired values cannot be achieved using existing objects.

Figure **2** shows the relation between assigned number of iterations, assigned number of clusters and the relative error, that appears at the end. As can be seen, chances of finding an optimal solution decrease significantly if smaller values are taken for any of the input arguments. On the other hand, bigger values lead to a smaller error, which is logical, considering that there are more objects to choose from for a bigger cluster number, and more solutions to choose from at the end for a bigger iteration number. The thing that should be taken into account here is time. Bigger argument values lead to a bigger time consumption and, after some point, have a minor effect on the results. Increasing number of passes leads to a proportional increase in execution time, but increasing number of clusters affects execution time in exponential fashion. For example, changing number of clusters from 5 to 10 leads to a 20-25% increase in execution time, but changing it from 20 to 50 leads to a 20000-25000% increase. With that in mind, input arguments should be chosen carefully. Number of clusters should be 5-20% of the starting data set size, and number of iterations should reflect the desired precision/speed ratio, starting with a few hundred iterations for fast execution, and going all the way to tens of thousands for best precision. These numbers can vary depending on model size and personal precision/speed preferences.

VI. CONCLUSION

This paper describes the algorithm used for autogenerating distribution network test models, with predefined sets of parameters. Autogeneration is done by finding the optimal combination of containers (feeders and substations), extracted from an existing CIM-based data model. These test models are used for testing the nonfunctional requirements in the ADMS software development process.

By looking at the results, a few conclusions can be made:

- For the same number of clusters, the solution is always equal or better when using a bigger iteration number
- The solution is almost always better when the bigger cluster number is assigned
- The algorithm is pretty robust, and provides acceptable results, even for the unrealistic parameter ratio
- For typical network model specifications, relative errors do not exceed 1%

By increasing the iteration and cluster numbers, the execution time rises, so there has to be some compromise when assigning those values.

Current Sampling Techniques for Digitally Controlled Inverters

Filip Filipović, Milutin Petronijević, Nebojša Mitrović, Bojan Banković and Vojkan Kostić

***Abstract*—The purpose of this paper is to describe common problems that influence accurate current sampling in the case of power inverters. The current sampling is observed for nominal and low load of the inverter. Considered problems include dead time of power switches and small load time constant. Techniques considered for minimization of the influence of these problems are synchronized sampling method, multisampling method and antialiasing filter. The common algorithms for obtaining a single current value in the multisampling method are also considered. Effects of reviewed techniques on current sampling are examined in the case of one power inverter that supplies passive load in isolated grid. The results confirm the necessity of careful current sampling method consideration with respect to the application. Model of the inverter with all considered techniques for accurate current sampling is built using MATLAB/Simulink.**

***Index Terms*—Inverter, Current Sampling, Pulse Width Modulation, Synchronised Sampling, Multisampling, Antialiasing Filter**

I. Introduction

Today, control of inverters is realised using digital logic circuits (DSPs of FPGAs) [1]. Digital control showed several advantages over the analog in terms of smaller susceptibility to temperature variations and component aging, easier algorithm modification and lower bill of material. The downside would be inability to continuously monitor variables of interest, but rather in specific moments in time using the analog to digital converters (ADC). This reduction of continuous time to a discrete time signal is called sampling and some of the problems that can occur during this conversion process that deviate obtained signal from perfect reconstruction may include:

- Aliasing effect,
- Jitter,
- Noise,
- Quantisation and
- Other errors due to non-linear effects [2].

Inverters produce higher order harmonics at the switching frequency and its multiples. In order to minimise the influence of previously mentioned aliasing effect, sampling techniques such as single update pulse width modulation (PWM) [3], double update PWM [4] and multisampling PWM [5-7] are used. These sampling methods can put various technical requirements on the hardware used for sampling. For the single update PWM, only synchronization of PWM carrier signal with the ADC is required. On the other hand, for the multisampling method, more demanding hardware for ADC in terms of speed, along with the appropriate digital circuit for the manipulation of the obtained samples is required.

Digital current controller is the fastest control loop in the system for most inverters. Its accuracy determines the quality of the current waveforms injected into the grid [5]. Transport and sampling delays have a large impact on maximum possible performance of digital current controllers [7]. Any additional delay in sampling process would have a direct effect on current loop performance.

The purpose of this paper is to describe problems related to current sampling and the common ways of overcoming them. The main idea is to design alias-free sampling with as small effect on sampling delay as possible. In the second section, the single sampling and multisampling methods along with the antialiasing filter (AAF) will be considered. The details of test setup, AAF, along with the main results are presented in the third section. Based on the presented results, summary of the results and directions of future work is presented in the conclusion.

II. The Method

Prevention of aliasing is one of the key requirements for the accurate current sampling during inverter operation. The dominant part of inverter's current ripple located in the out-of-band region comes from the PWM. With the ideal sampling, we would be able to perfectly reconstruct all signals below the Nyquist frequency without attenuation and phase lag, while rejecting all signals above it. Commonly used techniques for the PWM ripple suppression in the sampled current include sampling and PWM synchronization, averaging over multiple samples and filtering of analog signal before digital conversion.

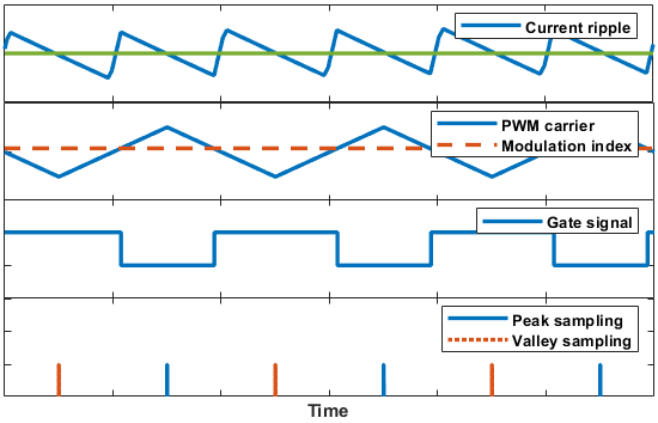

Fig. 1. Synchronized sampling with peak or valley of PWM carrier signal.

A. *Single Update PWM Method*

Since the current control algorithm has a typical closed loop bandwidth of several kHz, its controller cannot be designed without considering delays induced by appropriate low pass filters, if used [9]. Widely used technique today for current ripple suppression is sampling synchronization [10]. It uses the fact that in the ideal case no ripple is present in the sampled current if the sampling is done at the peak or valley of PWM carrier signal. Example of current sampling synchronized with the peak or valley of PWM carrier signal in three phase, three wire, two level voltage source inverter is shown in Fig. 1, for a current measured after L grid filter.

Zero current ripple coincides with peaks and valleys of the PWM carrier if series resistance through which current of interest passes is zero, supply voltage is constant and if there are no other delays in PWM generation. The effects of the PWM dead time and sufficiently large series resistance on the current sampling ripple can be observed in Fig. 2. Also, PWM voltage pulses along with an unneglectable parasitic capacitance can induce oscillations microseconds after the switching. If sampling occurs during that period, considerable sampling error can be induced. Synchronized sampling can be combined with AAF of much higher cutoff frequency than the one that would be needed if sampling without synchronization is done [9].

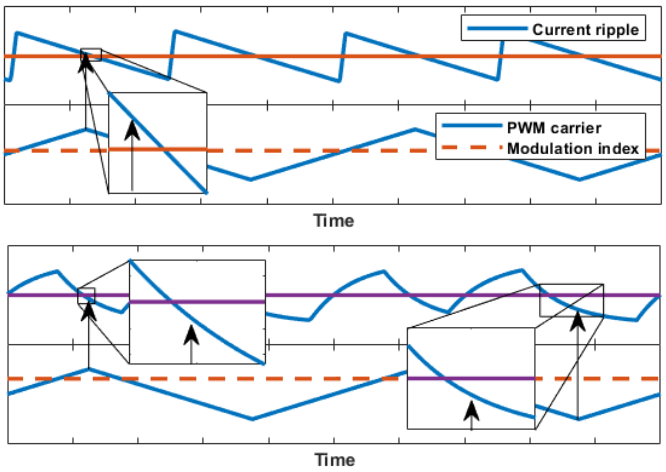

Fig. 2. Effects of dead time (top) and small time constant (bottom) on the sampled current ripple.

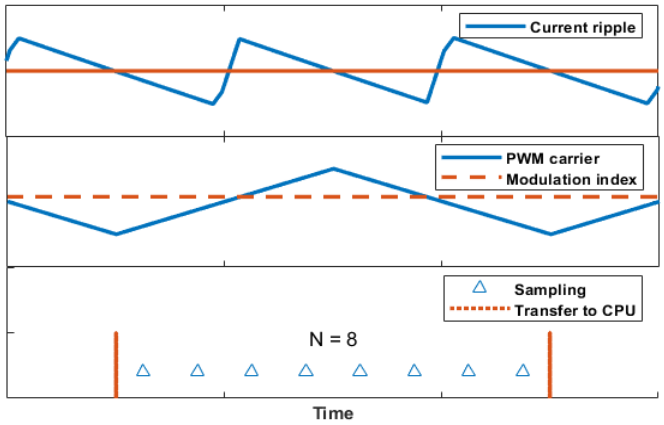

Fig. 3. Synchronized multisampling.

B. *Multisampling PWM Method*

Ever more attention recently is being given to the multisampling methods, due to the fact that it can be implemented in most of the modern hardware used for control. The process of synchronized multisampling can be seen in Fig 3. This method uses N equidistant current measurements between peaks or valleys of PWM carrier signal. N is called multisampling factor and recommendation for its proper selection can be found in [9].

For the triangular PWM carrier signal, single sampling method induces a pure delay phase lag. In the multisampling approach, there is a pure delay, that is a decreasing function of the N. Achieving high multisampling factor can be a hardware constraint. In one way, it can be achieved with timed CPU interrupts for sampling and synchronization with the PWM carrier, although it would result in relatively high CPU workload, even for today's DSPs. Arguably better way in terms of CPU workload is outsourcing of sampling command to direct memory access (DMA) controller. DMA would use timed interrupts to trigger ADC and store result in the dedicated array located in random access memory (RAM). Control algorithm executed on CPU would retrieve this array from RAM on PWM interrupt and based on the extraction algorithm, from N collected samples, it would calculate instance that would be used in control algorithm.

A possible solution for value extraction is usage of low pass filter or moving average filter (MAF). MAF is one of the most widely used filtering technique today, presents a linear phase finite impulse response (FIR) filter and can act as an ideal LPF if certain conditions are met [12]. Adjusting MAFs window length, switching harmonics can be eliminated since their frequency of occurrence is known, but that would induce a delay that is equal to single update PWM's sampling delay. This would eliminate any advantage of multisampling method in terms of phase boost [11]. Another filtering method that allows higher control bandwidth is presented in [13] and will be denoted here as a repetitive ripple estimation filter (RREF). The RREF behaves as an ideal low pass filter only on specific frequencies, while for all other frequencies it has no filtering effect. This implies that it would not be a good solution for sampling noise filtering. For value extraction, reduced version of RREF presented in [11] will be analysed here. Bode gain and phase plots of MAF and RREF are presented in Fig 4.

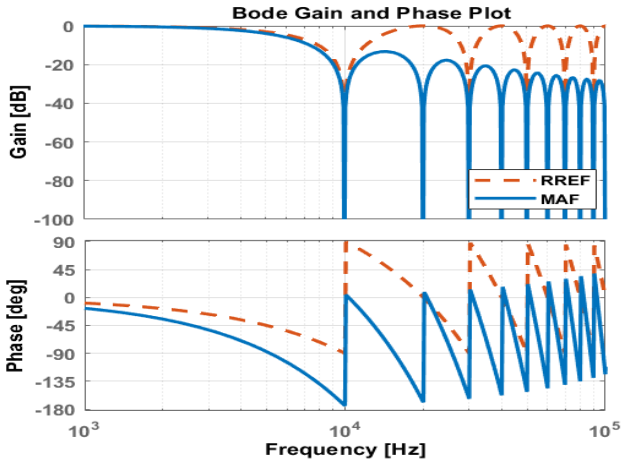

Fig. 4. Bode gain and phase plots of RREF and MAF.

C. Antialiasing Filter

The signal filters can be implemented in analog (prior to ADC) or in digital domain, with a number of differences between those two realizations. An analog filtering is more suitable for sampling speeds above 5 kHz, as it can eliminate high frequency noise before it reaches ADC and, in that way, reduce noise in the out-of-band region and alias signals. Also, with noise peaks removal, analog modulator saturation of the ADC can be avoided. Digital filters can remove noise after the conversion process and digital filters are programmable, thus allowing easier modifications [14].

In data-acquisition systems, analog low pass filters are commonly used for AAF implementation. With all real filters, various trade-offs have to be made, according to the desired application. Popular filter designs from [15] include:

- Butterworth – optimized for maximally flat gain in the pass-band. At the cutoff frequency, gain is -3 dB. Above the cutoff frequency, attenuation is -20 dB/decade/order. Transient response to pulse input shows moderate overshot and ringing.
- Bessel – optimized for maximally flat phase in the pass-band. At the cutoff frequency, gain is -3 dB. Above the cutoff frequency, attenuation is -20 dB/decade/order. Excellent response to pulse input, but slower roll-off.
- Chebyshev – designed with the desired ripple in the pass-band. Cutoff frequency is defined as the frequency at which the response falls below ripple band. Steepest roll-off, but pulse input shows highest overshoot and ringing.

Active filters can be made in a number of different architectures. Some provide better results in the case of stability, susceptibility to noise and the number of elements needed. Two most popular ones are:

- Sallen-Key – has unity gain in the pass band independent of component variation.
- Multiple Feedback (MFB) – has a superior high frequency response.

Transfer function of a second order low pass filter can be written as

$$F_{LPF}(p) = \frac{1}{\left(p\frac{1}{2\pi f_c FSF}\right)^2 + p\frac{1}{2\pi f_c QFSF} + 1} \quad (1)$$

where, p denotes Laplace complex variable, fc is crossover frequency, FSF is frequency scaling factor and Q is quality factor [15].

Low pass filters of the order higher than second can be obtained with a series connection of first and second order filters. Factors Q and FSF are selected following the recommendations from [15] (using provided table) in the way of uniform quality factor increase (lowest Q near the input, highest near the output).

III. Main Results

Testing of all previously mentioned sampling techniques was done on the model of the inverter supplying a passive load. The model is presented in Fig. 5 and it is build using MATLAB/Simulink R2018b using components located in Simulink library Simscape. Details of this setup are displayed in Table I. Algorithm that controls PWM of the inverter work in open loop mode with a 100 µs cycle time. It has a fixed reference frequency of 50 Hz and a fixed line to line reference voltage of 400 V. Dead time of the PWM is 1 µs and there is no dead time compensation in the control algorithm. Current sampling is modelled through 12-bit discretization. AAF is modelled in continuous time using transfer function.

Tested current sampling methods are:

- random sampling – sampling occurs at the speed of the control algorithm at the arbitrarily point on PWM carrier,
- single sampling – sampling occurs at the valley of the carrier,
- multisampling (MAF) – sampling occurs at the frequency of 320 kHz, AAF to be described is present and for the single value extraction MAF is used with a filtering window that corresponds to the frequency of 10 kHz,
- multisampling (RREF) - sampling occurs at the frequency of 320 kHz, AAF to be described is present and for the single value extraction RREF is used with a filtering window that corresponds to the frequency of 10 kHz.

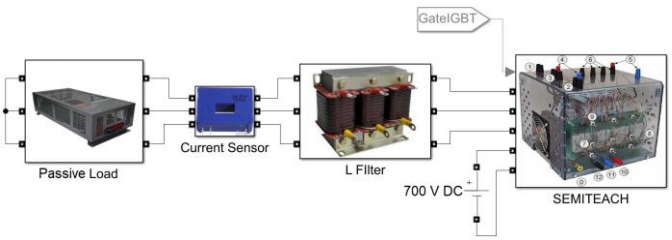

Fig. 5. Test setup used for simulation built in MATLAB/Simulink.

TABLE I
Simulated Setup Details

Inverter type	3 phase, 3 wire, 2-level voltage source inverter
Switching frequency	10 kHz
L filter inductance	6.4 mH
Current sensor	±10 A (±10 V)
ADC converter	12-bit (±10 V)
DC supply voltage	700 V

A. *Design of Antialiasing Filter*

AAF can be used in combination with any of the previously mentioned methods to reduce alias signals, although its implementation may require recalculation of current controller parameters in some cases. The AAF is designed for 12-bit ADC with a 320 kHz sampling frequency. According to the design consideration from [16], to use the full ADC dynamic range, any undesired out-of-band signal components have to be filtered to less than the ADC's Least Significant Bit (LSB) level. This implies that AAF with a gain of -72 dB at the frequency of 160 kHz would be desired. In the real case, there is a tradeoff between filter order, crossover frequency and the gain at the Nyquist frequency. Operational amplifiers with inappropriate characteristics can deteriorate performance of the filter. Using closed loop bandwidth and slew rate as additional design parameters [17], widely accessible LF356 [18] is used for practical filter implementation. For a current measurement system of the inverter, AAF is selected with the parameters provided in the Table II.

TABLE II
ANTIALIASING FILTER DETAILS

Type	Bessel
Architecture	MFB
Order	6^{th}
Crossover frequency	f_c = 30 kHz
First stage	Q = 0.5103 FSF = 1.606
Second stage	Q = 0.6112 FSF = 1.6913
Third stage	Q = 1.0234 FSF = 1.9071

Bode gain and phase plots of the filter are provided in Fig. 6. Schematic of the filter is presented in Fig. 7. In the schematic, the input (usually a buffer circuit and isolation amplifier) and the output (operational amplifier for signal range match and output impedance adjustment) stages are not shown.

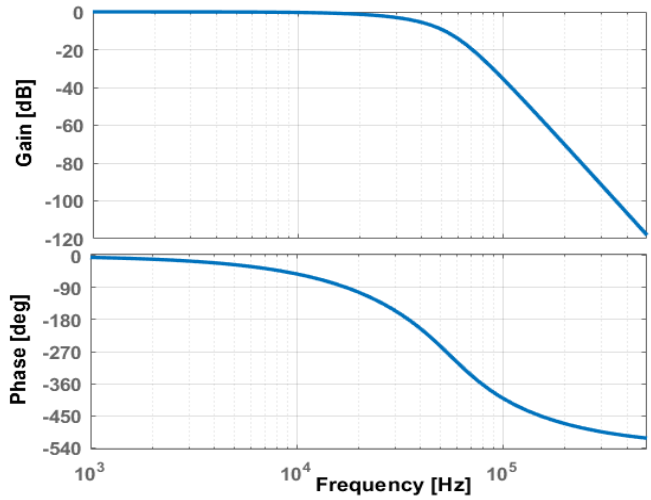

Fig. 6. Bode plots of analog antialiasing filter.

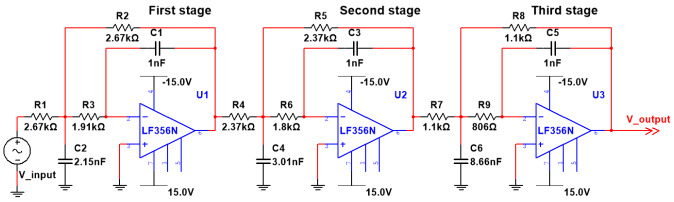

Fig. 7. Schematic of 6^{th} order LPF in MFB architecture with a 30 kHz cut off frequency.

B. *Rated Load Test*

For the first test, comparison of the selected algorithms during nominal load operation (phase resistance of 40 Ω) is chosen. In the Fig. 8. real current waveform is shown, along with the current obtained from sampling with each method. Lower part of the same figure presents Fourier transformation (FFT) of the real signal and each sampling method.

It can be observed that all sampling methods except random sampling during nominal load operation provide similar results. Multisampling (MAF) method provides the most similar result to the original. Random sampling in this case has a sampling phase that does not coincide with the peak or the valley of the PWM carrier and due to that, it has bigger deformation in original signal reconstruction. This can be observed from the FFT decomposition of this signal (larger deviation from the original value on some frequencies). For the multisampling (RREF) there is a problem with the fundamental harmonic estimation. It can be observed from the Fig. 4. that RREF behaves as an ideal low pass filter only for the odd multiples off first filtered frequency. For all other frequencies it has a small or negligible filtering effect. Since the AAF is designed for the crossover frequency of 30 kHz, switching current ripple at the twofold PWM frequency will be present in the sampled current with a negligible attenuation.

C. *Low Load Test*

Although nominal condition are the ones that power inverters are built for, in the case of renewable energy sources, nominal conditions are not so common in practice and nominal load results do not represent authentic situation most of the time. In the case of photovoltaic, typical power output ranges from twenty to fifty percent of the rated power [19]. If the inverter is located in the isolated grid supplying a small number of consumers, load can also vary substantially. Results from the low load operation are presented in Fig. 9. These results are obtained for a load phase resistance of 350 Ω, thus making this test a combination of small load and small load time constant.

From Fig. 9. substantial differences between the sampling methods can be seen even by waveform inspection. The same methods as for the previous test now show significantly different results among themselves. Random sampling method provides arguably worst results. FFT analysis shows substantial presence of even harmonics that results in asymmetry of the waveform. Somewhere better results show synchronized sampling method, although it suffers from the same problem of asymmetry. Synchronisation of the PWM carrier with the current sampling does not provide accurate results in the case of small load time constant.

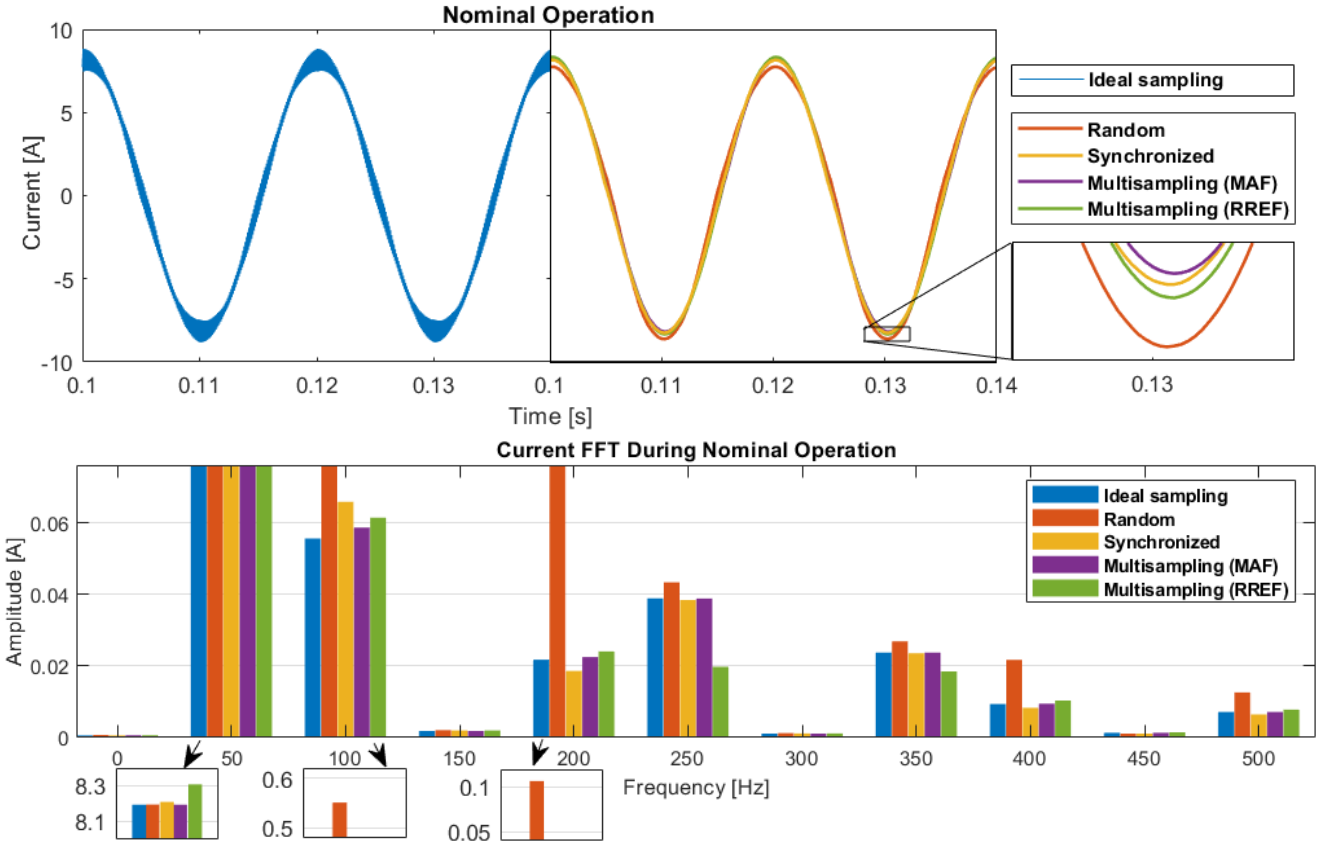

Fig. 8. Sampling of original current (upper) and FFT of it (bottom) for a nominal load operation.

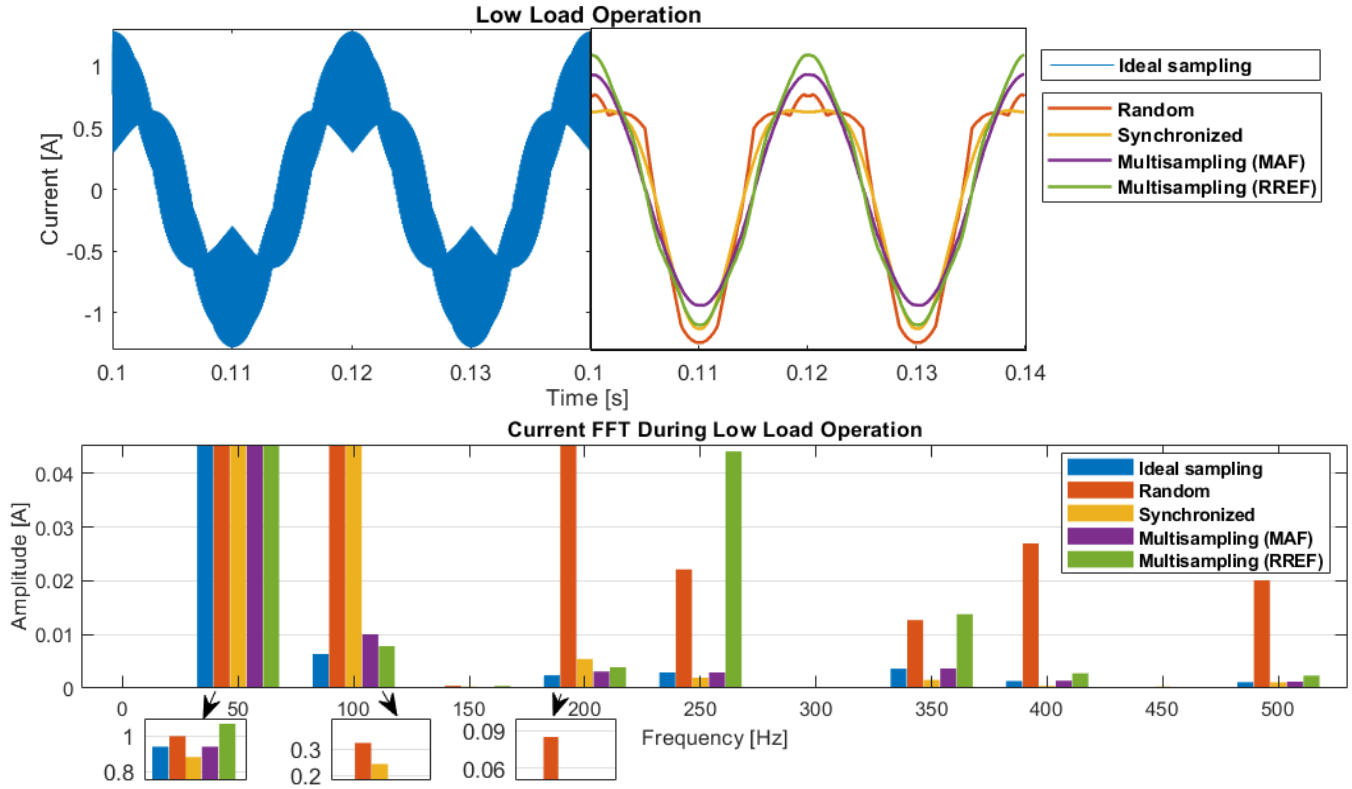

Fig. 9. Sampling of original current (upper) and FFT of it (bottom) for a low load operation.

Using multisampling methods, the influence of current ripple and small time constant on sampled current is reduced significantly. RREF extraction method provides information of higher fundamental harmonic and higher fifth harmonic compared to the real value. MAF extraction provides the most trustworthy results. Current sampled using multisampling technique and single value obtained using averaging method provides most consistent results at the cost of phase lag higher than in other tested method.

IV. Conclusion

The alias signals in sampled currents can induce substantial problems in control algorithms. For a high performance current controllers, selection of proper sampling and filtering method can have large impact on the controller bandwidth or control loop tracking capabilities.

Results comparison shows that random sampling should be avoided in all times if possible. With this method, the amount of out-of-band noise can vary with the variation of the point on the PWM carrier signal at which sampling occur.

Synchronized sampling provides consistent results for a relatively large time constant of the AC power line in respect to the sampling time. With an increase of active resistance present in the load accuracy of this method deteriorates.

Combination of AAF and multisampling with the averaging method provides the best results of all tested methods in terms of credible current waveform. The problem with the averaging method is substantial phase shift that is induced and that presents limiting factor in the case of high performance current controller implementation.

Usage of repetitive ripple estimation in combination with the AAF for a switching frequency harmonic elimination shows moderate results. It only manages to partially suppress occurrence of the PWM ripple in sampled currents. The main reason for the eventual usage of this filtering technique is a small phase lag, providing higher current control loop bandwidth.

AAFs can have limiting impact on the current control loop performance in terms of induced delay. Their design is a tradeoff between phase and gain flatness, filter order and phase delay and better response on higher frequencies or more stable gain with the component variation. For a high performance current controller design, current sampling requires careful planning.

In the future work, techniques for AAF phase lag compensation and more value extraction algorithms for multisampling techniques will be researched. This research will be done as an effort to improve the achievable bandwidth of current controller and the credibility of the sampled current.

Practical implementation of voltage dip, swell and interruption detection algorithm according to IEC 61000-4-30 standard

Lazar Sladojević, Miodrag Stojanović and Vladeta Milenković

***Abstract*—This paper describes a practical implementation of a part of IEC 61000 standard for Electromagnetic compatibility, part 4-30 which considers Power quality measurement methods for various power quality parameters. The developed algorithm implements real-time digital signal processing techniques for accurate detection and evaluation of the supplying voltage dips, swells and interruptions as key power quality parameters. Necessary prerequisites for this process such as frequency evaluation and hardware configuration are also briefly explained. The signal processing algorithm is written in Python programming language which is open-source and easy to use. Experimental results are evaluated to give some insights on practical problems that should be addressed in the future.**

***Index Terms*—Power Quality; Voltage Dip, Swell, Interruption; Digital Signal Processing; Python**

I. Introduction

Power Quality (PQ) is becoming an increasingly important problem in electrical power systems. The deviation of supplying voltage from the ideal sine wave in many areas is now evident more than ever. This is most obvious in areas with extensive usage of electronic devices, especially big computer centers and factories with large number of electronically controlled drives. These devices generate higher order harmonics which negatively impact the supplying power grid, generating unnecessary losses [1].

However, these are not the only problems in the electrical energy supply chain. Buyers of electrical energy expect suppliers to deliver voltage in a form of a clean sine wave with the rated magnitude and frequency. This is not an easy task, since the buyers are usually the ones that generate harmonics into the power grid [1].

However, there are some aspects that solely depend on the power suppliers. It is their responsibility to ensure reliability of the supplying power and to prevent power interruptions which could severely damage production in industrial facilities, normal functioning of important institutions or even human survivability in hospitals. It has been known for a long time that even the slightest variations in the supply voltage can represent a great deal of failures in various electrical devices [2]. Low reliability also affects residential loads such as common electrical household devices [3].

Besides technical, poor power quality can also produce negative economic effects. It can lead to unplanned interruptions in production lines, increased expenses for electrical energy due to increased losses, premature failure of equipment and therefore unforeseen capital investments etc. [4]. Therefore, it is very important to observe and detect all of these abnormal situations in order to find their root and be able to prevent them in the future.

There is a total of twelve power quality parameters defined in the IEC 61000-4-30 [5] standard that should be addressed, measured and evaluated. The standard defines measurement methods as well as measurement uncertainty and measurement range for each individual parameter, except for measurement of Flickers, Harmonics and Interharmonics, which are described in separate standards. Two classes of measurement equipment are recognized, class A and class S and the main difference between them is the demanded accuracy, with class A being more accurate than class S.

This paper will address the problem of real-time detection and evaluation of supplying voltage dips, swells and interruptions. A data acquisition platform has been developed and used in conjunction with fast ARM processor for the necessary calculations. The goal is to achieve real time detection and evaluation of these events and to present results of practical implementation of the methods proposed in standard.

II. Parameters Description

The IEC 61000-4-30 standard defines voltage dip as a "temporary reduction of the voltage magnitude at a point in the electrical system below a dip threshold" [5]. This threshold is usually a percentage of the rated voltage, but in the medium and high voltage systems a sliding voltage reference can be used too. The sliding voltage reference is one-minute averaged voltage magnitude preceding the dip or swell. In this paper, the threshold was simply a percentage of the rated voltage. This threshold is usually in range of 80 to 90 percent of the rated voltage.

Voltage swell is a "temporary increase of the voltage magnitude at a point in the electrical system above a swell threshold" [5]. This threshold is once again a percentage of the rated voltage or a sliding voltage reference. As in the case

Lazar Sladojević is with Faculty of Electronic Engineering, University of Niš, Aleksandra Medvedeva 14, 18000 Niš, Serbia (e-mail: lazar.sladojevic@elfak.rs).

Miodrag Stojanović is with Faculty of Electronic Engineering, University of Niš, Aleksandra Medvedeva 14, 18000 Niš, Serbia (e-mail: miodrag.stojanovic@elfak.ni.ac.rs).

Vladeta Milenković is with Faculty of Electronic Engineering, University of Niš, Aleksandra Medvedeva 14, 18000 Niš, Serbia (e-mail: vladeta.milenkovic@elfak.ni.ac.rs).

of dip, the first type of threshold was also used for swell detection. The threshold value is normally greater than 110 percent of the rated voltage.

Voltage interruption is "reduction of the voltage at a point in the electrical system below the interruption threshold" [5]. The standard defines that this threshold can only be a percentage of the rated voltage. This threshold is much lower than the dip threshold, and is usually in range of 5 to 10 percent of the rated voltage. Interruption can therefore be observed as a special case of voltage dip, but it should still be separated, at least by post processing.

The above definitions refer to single phase systems, but can also be applied to polyphase systems with some restrictions. For example, in a three-phase system, a voltage dip begins when the voltage magnitude of one phase drops bellow the dip threshold and ends when the magnitudes of all phases increase above the same threshold augmented by the dip hysteresis. Similarly, swell begins when voltage magnitude of one phase raises above the swell threshold and ends when magnitudes of all phases drop below the same threshold reduced by the swell hysteresis value. Unlike these two parameters, voltage interruption begins when magnitude of all three phases drop below the interruption threshold and ends when voltage of any of the phases exceeds interruption threshold plus the interruption hysteresis. This implies that any event can begin on one phase and end on another.

All hysteresis values are introduced to prevent a single event to be counted multiple times which can occur if the magnitude oscillates around the threshold value. Typical value for all hysteresis is 2 percent of the rated voltage [5].

III. Detection Method

The standard defines that the sliding Root Mean Square (RMS) value is used for events detection. RMS is equivalent to magnitude since there is a linear relationship between the two when the signals are simple sine waves. The RMS value is obtained over the window which is one full cycle long and slides half of cycle when updated. This means that the first RMS value will be obtained from the whole first cycle, second one will be calculated from the second half of first cycle and first half of second cycle, third value is calculated from the whole second cycle and so on. First RMS value for each channel should be synchronized with that phase first zero cross. For all three types of events, the event start is timestamped with the start of window whose RMS value initiated that event i.e. the first RMS value that crosses the corresponding threshold if the event is dip or swell or the last one if the event is interruption. Similarly, the event end is timestamped with the end of window whose RMS value ended that event i.e. the last RMS value that returned to normal operating limits including the event hysteresis if the event is dip or swell or the first one whose value is higher than the interruption threshold plus hysteresis if the event is interruption. The accuracy class A of the standard states that maximum error in event detection time can be one full cycle i.e. ±1/2 cycle before event and ±1/2 cycle after event.

The detection method described above implicitly requires three things: RMS value calculation, cycle duration calculation and periodic synchronization with the zero cross for each phase.

A. RMS values calculation

The RMS calculation is very straight-forward, for the sampled voltage signal of N samples, RMS value is simply obtained from (1):

$$U_{RMS} = \sqrt{\frac{\sum_{i=1}^{N} U_i^2}{N}} \tag{1}$$

In (1), U_i is the instantaneous value of sample with index i.

B. Cycle duration estimation

The necessary number of samples N is equal to number of samples in one full cycle. This number can be calculated from the frequency of signal, f and the sampling frequency f_s:

$$N = round\left(\frac{f_s}{f}\right). \tag{2}$$

There are number of frequency estimation methods, some of those are detailed in [6–9], but for this application a simple zero-crossing detection method will be used.

This method utilizes linear regression over the samples around the first and the last zero cross of a signal. Samples involved in the linear regression are the ones with values between the fixed upper and lower threshold. This way, a variable number of samples is used for each linear regression, because the signal always contains some noise. This noise can cause multiple zero crosses and non-equal number of positive and negative samples. Here, linear regression behaves as some sort of a filter, because it constructs the straight line which minimizes the sum of squared distances from all samples involved in regression,

$$\min \sum_{i=1}^{M} \left(U_i - \hat{U}_i\right)^2 = \min \sum_{i=1}^{M} \left(U_i - \left(a \cdot t_i + b\right)\right)^2 . \tag{3}$$

In (3), $\hat{U}_i$ is the projection of sample U_i on the regression line, M is number of samples involved in linear regression, a is the line slope coefficient, b is line intercept coefficient and t_i is time point at which the sample was taken.

The approach is fairly simple and computationally effective, both with processing time and memory requirements, but can give errors when applied to highly distorted signals. In that case, IEC 61000-4-30 standard recommends filtration of a signal before estimation of its frequency. However, primary goal of this paper is developing and evaluation of practical algorithm for detection of voltage dips, swells and interruptions, and for simplicity, that will be done on fairly clean, sine waveform signals. This assumption

is not always fulfilled in practice but processing of highly polluted signal would require a whole other paper, and will be subject of author's future work.

C. Periodic zero cross synchronization

The third requirement is periodic synchronization with each phase zero cross. The standard requires that the processed RMS value be calculated over the window which starts where that phase crosses zero and is one full cycle long. This window is moving half a cycle at each iteration. Therefore, only first zero cross is calculated and other windows' positions for RMS calculation can be estimated. During time however, a small frequency variation takes place in any electrical system and therefore the cycle duration varies slightly. If the synchronizations were not conducted periodically, error in window position would become too large to comply with standard. However, if the voltage interruption occurs, no frequency can be estimated from voltage signal and therefore window position can only be estimated from its last known position.

IV. Experimental Results

For experimental purposes, a data acquisition and processing platform has been developed. The platform contains 16-bit Analog to Digital (A/D) converter with the 25.6 kHz sampling frequency for data acquisition and ARM Cortex-A8 AM335X microprocessor [10] for digital processing of the gathered data. Platform is capable of sampling and processing of all three voltage channels simultaneously.

The algorithm itself was entirely written in Python programming language. Python was chosen because it is simple and open source programming language, yet very powerful when it comes to scientific computing. It runs on Linux operating system which is embedded in the platform.

The algorithm was developed to comply with class A measurement instrumentation from IEC 61000-4-30 standard. Sets of sampled data from each voltage channel arrive in packages of 25600 samples, which means they are sampled for one second before they are processed. This implies that the algorithm has to process the whole previous set of samples in time shorter than one second, before the new samples arrive. Therefore, the algorithm has to be highly optimized. Besides events detection, each second a new signal frequency is estimated and zero cross synchronization is conducted.

For test voltage generation, Omicron CMC 356 test set [11] was used. This test set is primarily intended for relay protection testing but it can as well serve for other purposes, such as this one. The algorithm has been tested on various cases of voltage dips, swells and interruptions. Some of the test cases are shown in Figs. 1 to 5. The rated Phase-to-Neutral voltage in all scenarios was 230 V_{rms}, with frequency of 50 Hz. All test cases contained a repeatable sequence of several signal states and those signals were recorded for 10 seconds. No synchronization between beginning of signal and beginning of recording existed, i.e. examined signal had been present for a random amount of time before the recording started.

Fig. 1 depicts the case of single-phase voltage dip occurring on phase A. The test signal is a repeated sequence of three states: one second rated voltage on all three phases, then 150 ms of rated voltage on phases B and C and 2/5 of rated voltage on phase A, and finally one more second of rated voltage on all phases. One of the several captured dips is shown in the figure, with black vertical lines representing dip start and end times. It is obvious that the dip beginning and end were captured at the right moments, where phase A voltage waveform crosses zero and its RMS values cross corresponding thresholds. Of course, no perfect zero cross can be detected due to quantization error, finite sampling rate and numerical errors in calculation, but the achieved precision was well above class A minimum. Real dip duration can be obtained from the figure by counting number of cycles from dip trigger point up to ending point. Since there are 9 full cycles, and each cycle is 20 ms long, total duration of dip was 180 ms. Calculated duration is obtained as a difference between end time and begin time and is equal to 180.35 ms. The absolute error is therefore 0.35 ms which is well below requested 20 ms.

Fig. 2 represents two phase voltage dip which begins on phase C and ends on phase B. The test signal consists of five states: one second of rated voltage on all phases, 100 ms of voltage dip on phase C, 100 ms of voltage dip on phases C and B, 100 ms of voltage dip only on phase B and finally one second of rated voltage on all phases. It can be seen that once again, dip begin and end times are estimated in the correct moments, when corresponding phases cross dip thresholds. At one point, voltage on phase C which initiated the dip returns to rated value, but there is still voltage dip on phase B, so no dip end is detected there. By counting full cycles and having in mind the phase difference between the voltage signals, real dip duration can be obtained. Since there are 16 plus 2/3 of the full cycle, real duration is 333.3333 ms, while the estimated duration is equal to 333.67 ms. The absolute difference is 0.3367 ms which is once again below the requested 20 ms.

Similar conclusions can be drawn from Figs. 3 and 4, where the only difference was that the event type is voltage swell. It can be observed that both single phase (Fig. 3) and two phase (Fig. 4) voltage swell are detected as precisely as two previous dips. The absolute differences between real and estimated duration of single phase and two-phase voltage swells are 0 and 0.067 ms, respectively. These errors are lower than those obtained during dip detection, but this is only due to fact that swells occurred near the beginning of one second buffer and dips occurred near the end of buffer. The zero error obtained in detection of single phase swell is a consequence of rounding the begin and end times to certain precision. Of course, such precision can never really be achieved in practice. Nevertheless, results are very good and satisfy the class A accuracy demands.

The special case is voltage interruption, presented in Fig. 5.

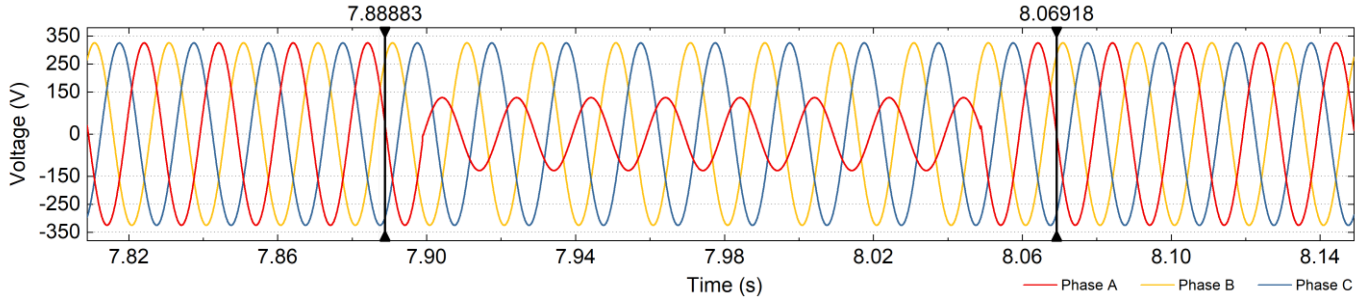

Fig. 1. Phase A voltage dip detection times

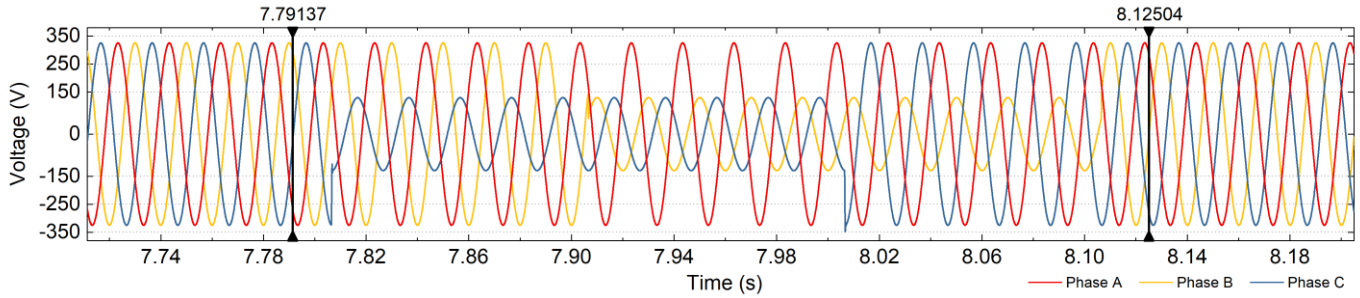

Fig. 2. Two phase voltage dip detection times

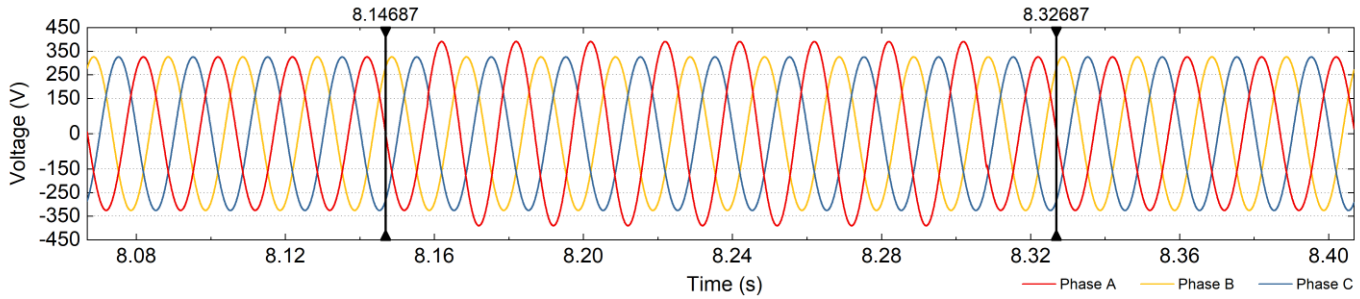

Fig. 3. Phase A voltage swell detection times

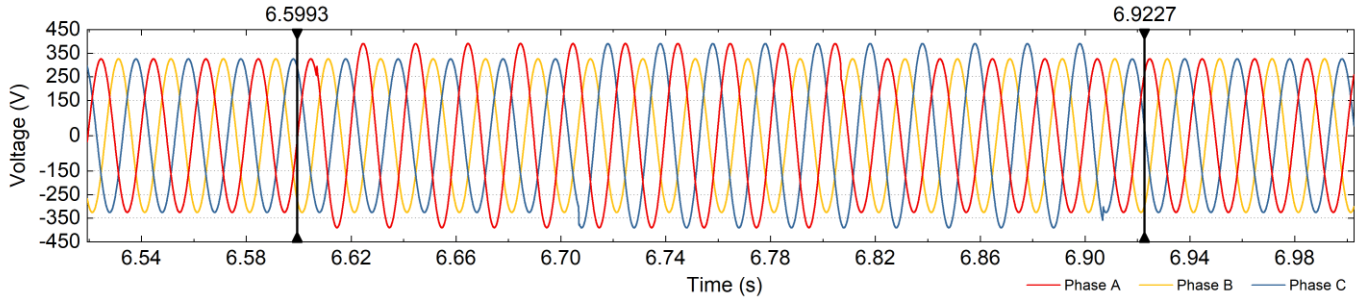

Fig. 4. Two phase voltage swell detection times

Voltage interruption begins when all three phases' voltage RMS values drop below the interruption threshold and ends when at least one raises above the threshold plus hysteresis value. Since all three phase voltages drop to zero at the same time, it is very difficult to estimate the real beginning of interruption. That would require interpolating all three sine waveforms and visually identifying their zero-cross times. However, it can be seen that interruption end was estimated precisely, because it was timestamped where phase B voltage first appears after the interruption. Of course, there have been voltage dips immediately before and after the interruption. These dips have also been detected, but their detection times

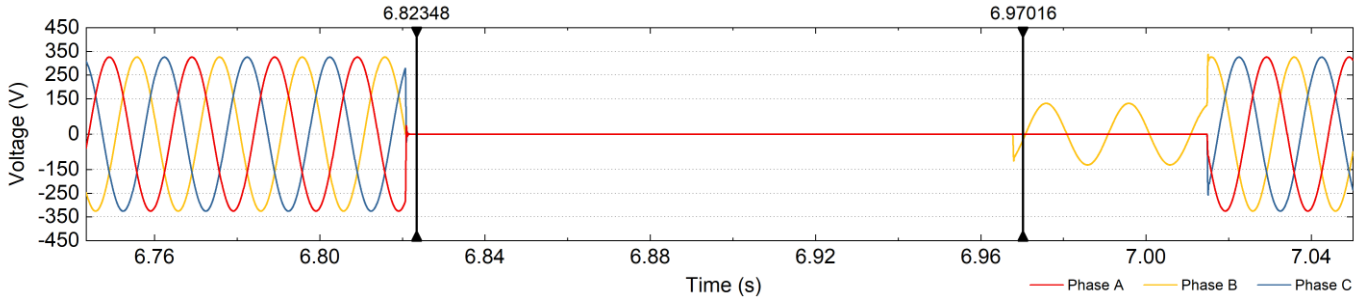

Fig. 5. Interruption detection times

are not shown in Fig. 5 for the sake of clarity. In fact, according to standard's event definitions, there are always a preceding and succeeding dips around interruption event.

The average time needed for processing of one second data buffer was also measured. The measurement results are shown in Table I.

TABLE I
DATA PROCESSING TIMES FOR DIFFERENT EVENT TYPES

Event type	**Average processing time for one buffer of data [s]**
Single phase dip	0.6719
Two phase dip	0.6647
Single phase swell	0.6710
Two phase swell	0.6700
Interruption	0.6605
Total average time	**0.6676**

From Table I it is obvious that all processing times are shorter than one second which is the time available for one buffer of samples to be processed before the new one arrives. This means that the algorithm is capable of conducting real-time events detection and evaluation.

V. CONCLUSION

In this paper a software algorithm for detection and evaluation of supply voltage dips, swells and interruptions was developed. The goal of algorithm was to achieve real time detection of aforementioned irregular events. Measurement methods and accuracy requirements are given in IEC 61000-4-30 standard and were only briefly discussed here. The overall main goal of this paper is not to propose new methods for events detection, but to evaluate practically obtained results with the methods already described in standard. For practical purposes, new data acquisition platform was developed and tested. Five typical cases of voltage dips, swells and interruptions were examined and experimental results are presented. It could be concluded that the proposed algorithm is capable of real-time dip, swell and interruption detection and evaluation with very high precision which complies with class A instrumentation from the standard. However, there are still some drawbacks for this algorithm. The main difficulty is estimation of frequency and zero crossing times for examined signals. In this paper only clean sinusoidal signals were examined, but in reality, these signals can contain a large amount of higher order harmonics which can make calculations either very unprecise or even impossible. Research in this field and improvement of the already developed algorithm will be subject to authors future studies.

I. INTRODUCTION

SKEWING of rotor slots (rotor bars) in a cage induction motor is well known method for attenuation of higher time harmonics in rotor bar currents due to the higher space harmonics in rotating magnetic flux density wave. Unfortunately, authors did not find the answer on question when and where this measure is firstly proposed and applied in commercially available induction motors.

As it is well known, three-phase stator windings produce rotating magnetomotive force (mmf) wave that beside the fundamental harmonic contain higher space harmonics of order $\nu=6k+1$, where $k=0,\pm1,\pm2...$ Fifth and seventh harmonic, phase belt harmonics, are consequence of the trapezoidal like mmf shape. Both of them could be significantly attenuated by appropriate shorting of stator winding coils. The most common solution is shortening of coil pitch for one sixth of the pole pitch. However, this measure has no impact on stator slot harmonics that are the most significant space harmonics in the rotating mmf wave from stator side, [1]. The order of these harmonics is $Q_S/p\pm1$, where Q_S is number of stator slots.

[4]Alberto Tessarolo, – Department of Engineering and Architecture, University of Trieste, Via Valerio 10, 34127 Trieste, Italy.

As any other of mmf space harmonics, through action across the assumed uniform air gap, relatively strong stator slot harmonics could induce higher time harmonics in rotor windings i.e. rotor bars. As a result, parasitic pulsation torques will be developed that have as a result higher vibrations of the machine, acoustic noise, higher losses and lower efficiency. In order to eliminate these high frequency components in rotor currents, skewing of rotor bars is commonly used. By this way stator slot harmonics in rotor currents could be significantly attenuated. On the other side, skewing of rotor bars has a small deteriorating effect on fundamental frequency emf induced in rotor bars i.e. weaker electromagnetic coupling of stator and rotor windings. Additionally, skewing of rotor bars as a side effect has appearance of inter-bar currents in cage rotors with uninsulated bars, [2]. Existence of these currents yields worse machine efficiency as well as appearance of axially directed forces on the rotor.

Quantitative measure of skewing of rotor bars is integral skew factor that is ratio of induced emf in skewed rotor bar and emf in straight rotor bar. In many electrical machine books skewing of rotor bars is not mentioned at all. In some of them skew factor is given in its final form, without explanation how this factor is obtained. In some books there exists derivation of skew factor that is based on vectorial summation of emfs along the rotor bar, [3]. Somewhere, skew factor is derived using the definition of winding pitch factor, [4].

Here, derivation of skew factor is given on clear and easy-to-follow physical explanation that is based on fundamental law of electromagnetic induction – flux cutting rule.

II. INTEGRAL SKEW FACTOR DERIVATION

Fig 1. shows frozen instant of time when one skewed rotor bar is beneath the maximum value of magnetic flux density wave from stator side. Without losing generality, it is assumed that magnetic flux density wave is stationary while rotor moves with constant tangential velocity v. For taking into account the most general case, magnetic flux density wave is described by its ν^{th} harmonic in $2p$ pole machine,

$$B(\theta)=B_m\cos(\nu p\theta) \tag{1}$$

where θ is a mechanical angle measured along the machine circumference. From the following proportion,

$$x : 2p\tau = \theta : 2\pi \tag{2}$$

where x is linear distance along the machine circumference and τ is the pole pitch, magnetic flux density could be written down as a function of x:

$$B(x) = B_m \cos\left(\frac{\nu\pi}{\tau}x\right) \tag{3}$$

From the flux cutting law, induced electromotive force (emf) along the infinitesimal length dl of skewed rotor bar is,

$$de_{skew} = d\mathbf{l}\cdot(\mathbf{v}\times\mathbf{B}) \tag{4}$$

i.e.

$$de_{skew} = vB_m \sin\alpha\cos\left(\frac{\nu\pi}{\tau}x\right)dl \tag{5}$$

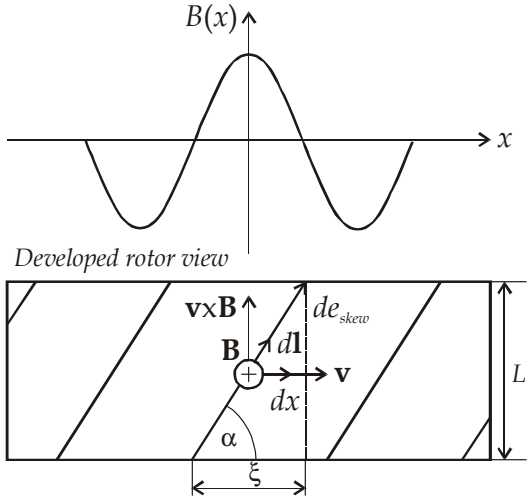

Fig 1. Induced emf in skewed rotor bar

The last expression is equivalent to:

$$de_{skew} = vB_m \tan\alpha\cos\left(\nu\frac{\pi}{\tau}x\right)dx \tag{6}$$

By integration of above expression between the limits x=–ξ/2 and x=ξ/2, all elementary induced emfs are taken into account:

$$e_{skew} = vB_m \tan\alpha \int_{-\xi/2}^{\xi/2} \cos\left(\nu\frac{\pi}{\tau}x\right)dx \tag{7}$$

$$e_{skew} = \frac{v\cdot B_m \tan\alpha}{\nu\pi/2\tau}\sin\left(\nu\frac{\pi}{\tau}\frac{\xi}{2}\right) \tag{8}$$

Finally, as $\tan\alpha = L/\xi$ (Fig 1):

$$e_{skew} = B_m Lv\frac{\sin\left(\frac{\nu\pi\xi}{2\tau}\right)}{\frac{\nu\pi\xi}{2\tau}} \tag{9}$$

As induced emf in straight rotor bar in observed instant of time is $e=B_mLv$, ratio of induced emf in skewed and straight bar is defined as integral skew factor, for ν^{th} harmonic:

$$k_{skew\_\nu} = \frac{\sin\left(\frac{\nu\pi\xi}{2\tau}\right)}{\frac{\nu\pi\xi}{2\tau}} \tag{10}$$

III. CHOOSING APPROPRIATE SKEW ANGLE

With a view to eliminate stator slot harmonic of order $\nu = Q_S/p - 1$, skew factor should be equal to zero for that harmonic, i.e.

$$\left(\frac{Q_s}{p} - 1\right)\frac{\pi\xi}{2\tau} = n\pi \tag{11}$$

where n is an integer. It means that the distance between the start and end point of rotor bar observed from the opposite rotor sides should be (Fig 1):

$$\xi = \frac{2n\tau}{\frac{Q_s}{p} - 1} = \frac{n\pi D}{Q_s - p} \tag{12}$$

For the smallest integer for which the above condition is satisfied, n=1, follows:

$$\xi = \frac{\pi D}{Q_s - p} \tag{13}$$

Similarly could be obtained from the cancellation conditions for second one stator slot harmonic, of order $\nu = Q_S/p + 1$:

$$\xi = \frac{\pi D}{Q_s + p} \tag{14}$$

In order for both the slot harmonics to be maximally attenuated in induced emf, wherein none of them does not eliminate completely, mean of two upper values should be chosen,

$$\xi = \frac{\pi D}{Q_s} = \tau_s \tag{15}$$

that is obviously equal to the stator slot pitch, τ_S, and additionally, does not depend on the number of pole pairs. Previous expression could be given in mechanical radians, so, desirable skew angle is:

$$\xi = \frac{2\pi}{Q_S} \tag{16}$$

By substitution of (15) into (10) skew factor for the ν^{th} harmonic is obtained for special case when skewing of rotor bars corresponds to the one stator slot pitch:

$$k_{skew\_\nu} = \frac{\sin\left(\frac{\nu p\pi}{Q_S}\right)}{\frac{\nu p\pi}{Q_S}} \tag{17}$$

This way, the induced emf in rotor bar due to the fundamental flux density wave in air gap is slightly deteriorated – skew factor for fundamental harmonic has value slightly less then one,

$$k_{skew\_1} = \frac{\sin\left(\frac{p\pi}{Q_S}\right)}{\frac{p\pi}{Q_S}} \tag{18}$$

while for both slot harmonics its value is close to zero:

$$k_{skew\_\nu=\frac{Q_S}{p}\pm 1} = \frac{\sin\left(\pi \pm \frac{\pi p}{Q_S}\right)}{\pi \pm \frac{\pi p}{Q_S}} = \frac{\mp \sin\left(\frac{\pi p}{Q_S}\right)}{\pi \pm \frac{\pi p}{Q_S}} \tag{19}$$

Fig 2. illustrates the effect of rotor bar skewing for one stator slot pitch. Along the skewed rotor bar emfs of opposite polarities are induced due to action of stator slot harmonic in flux density wave so the resultant emf in rotor bar approaches the zero value, as has already been shown analytically.

As an illustration, following case should be observed: four pole motor, p=2, with Q_S=48 stator slots. Skew factor for fundamental harmonic is,

$$k_{skew\_1} = \frac{\sin\left(\frac{2\pi}{48}\right)}{\frac{2\pi}{48}} = \frac{24\sin\left(\frac{\pi}{24}\right)}{\pi} = 0.9971$$

i.e. induced emf of basic frequency is smaller 0.3% due to the skewing of rotor bars. As skew factor for slot harmonics are,

$$k_{skew\_\nu=\left(\frac{Q_S}{p}\pm 1\right)} = k_{skew\_23,25} = \begin{cases} \frac{24\sin\left(\frac{23\pi}{24}\right)}{23\pi} = 0.0434 \\ \frac{24\sin\left(\frac{25\cdot\pi}{24}\right)}{25\cdot\pi} = -0.0399 \end{cases}$$

it is clear that induced emfs due to these harmonics are smaller by approximately 96%, what practically means that these emfs are almost completely eliminated in rotor bars.

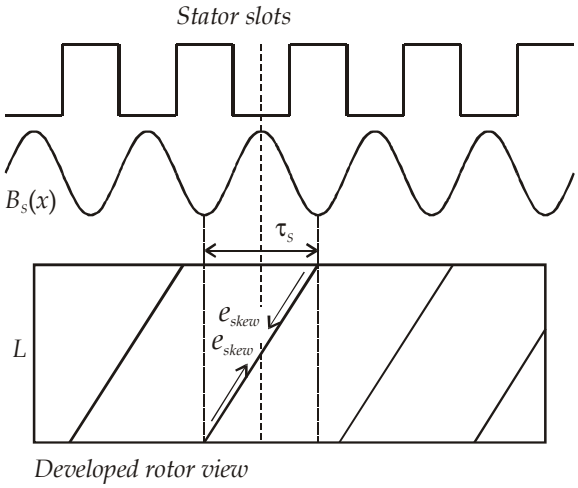

Fig 2. Skewing effect on induced emf in rotor bar for skewing angle of one stator slot pitch

By choosing higher value for n in (12), higher skewing angle will be obtained that is equal to integer multiple of stator slot pitch. The same effect regarding stator slot harmonics will be obtained but fundamental frequency emf in rotor bar will be significantly deteriorated and higher inter-bar currents will results as consequence of that choice. So, skew that achieves the effect of attenuation of stator slot harmonics with the small as a possible side effect is skew for one stator slot pitch.

IV. SKEWING EFFECT ON STATOR-ROTOR MUTUAL INDUCTANCE

In static induction motor model i.e. in standard equivalent single-phase circuit of induction motor skewing has an impact on value of magnetizing reactance [4]. Its value is smaller for integral skew factor in comparison with straight rotor bar case.

Skewing of rotor bars in induction motor numerical models is commonly taken into account by technique of slicing of rotor structure in n segments. In that case every of n segments are observed as segments with straight rotor bar. This technique is also commonly used for calculation of integral skew factor. In such cases it is desirable that number of slices

is as high as possible what on the other side leads to very time consuming software procedures.

A time and computationally effective approach is use of winding function approach as it is demonstrated in [5]. Number of slices could be as high as it has sense without any significant influence on execution time in numerical procedure. The main idea is in the definition of mutual inductance per length between stator phase windings and rotor loops. Rotor loop consists of two side by side rotor bars with corresponding end ring segments from both front sides of the rotor.

By using technique that is described in [5], following results for mutual inductance between stator phase winding and rotor loop is obtained for straight rotor bars, Fig 3, for motor whose details are given in Appendix. Together with mutual inductance dependence, derivative of that function with respect to mechanical angle is shown. Obviously, very intensive spikes in derivative of mutual inductance curve appear, which is resulting in spikes in developed electromagnetic torque versus time, [1].

Fig 4. gives the spectral content of mutual inductance curve from Fig 3. For better visibility of higher harmonics, fundamental harmonic (the second one) is reduced by five times.

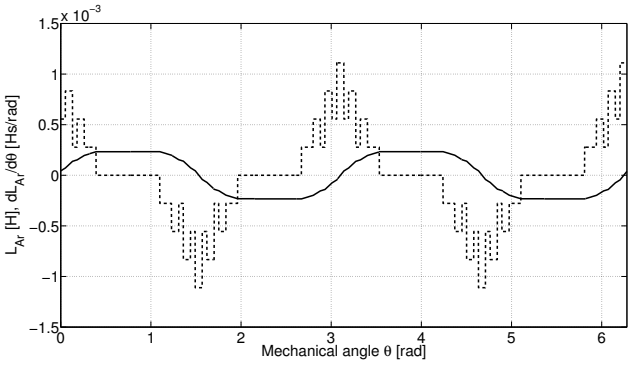

Fig 3. Mutual inductance between stator phase winding and rotor loop (solid line) and its derivative (dashed line) respect to the mechanical angle: straight rotor bars case

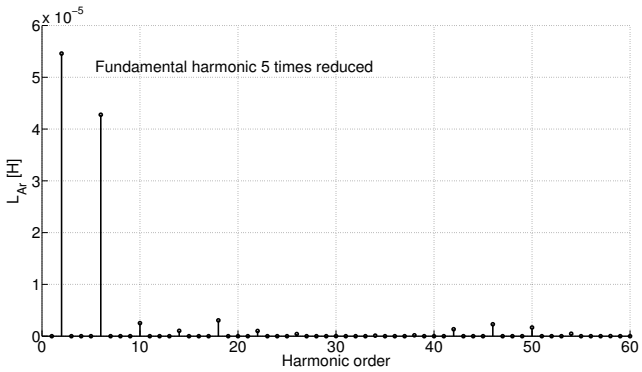

Fig 4. Spectral content of mutual inductance curve from previous figure. Amplitudes of harmonics of interest are: 1st: 0.273mH; 23rd: 2.3047μH; 25th: 1.673μH.

The case when rotor bars are skewed for one stator slot pitch is illustrated on Figs 5. and 6. Results are obtained by slicing of rotor structure axially in one hundred segments. Now, high spikes in derivative of mutual inductance disappear, Fig 5. that is additionally confirmed by spectral content of mutual inductance curve, Fig 6. By dividing the amplitudes of higher harmonics of interest by the amplitude of the main harmonic, following results could be obtained: for fundamental harmonic, 0.9971, for lower stator slot harmonic, 0.04577, for upper stator slot harmonic, 0.0431, which is in good correlation with already calculated integral skew factor for these harmonics.

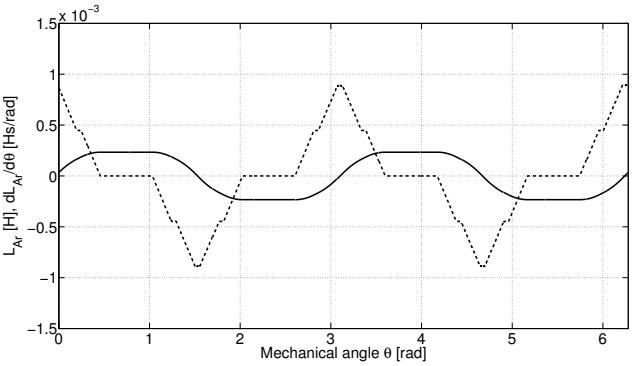

Fig 5. Mutual inductance between stator phase winding and rotor loop (solid line) and its derivative respect to the mechanical angle (dashed line): rotor bars skewed for one stator slot pitch

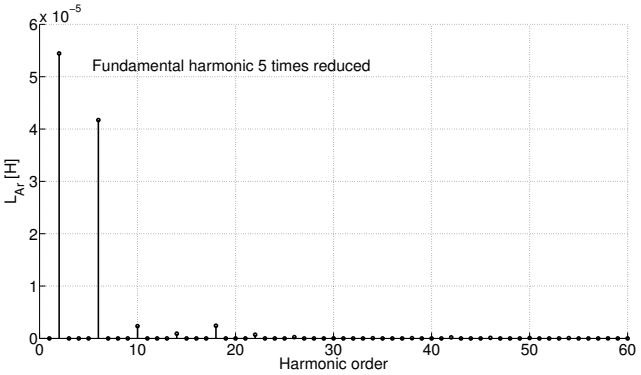

Fig 6. Spectral content of mutual inductance curve from previous figure. Amplitudes of harmonics of interest are: 1st: 0.2722mH; 23rd: 0.1055μH; 25th: 0.0721μH.

V. RESULTS FROM THE NUMERICAL MODEL

In order to illustrate the effect of skewing of rotor bars on pulsations in developed electromagnetic torque, Fig 7. gives results for two cases of rated loaded induction motor at steady state. As it is evident, significant attenuation of pulsations is a result of skewing of rotor bars.

As an additional feature of rotor bars skew is the elimination of so called cogging torque that appears as a consequence of improperly chosen number of stator slots and rotor bars. As one of drastic case of such choice is the same

number of stator slots and rotor bars, Q_S=Q_R. By using recently developed model, [6], developed electromagnetic torque and rotor speed in transient regime of starting of unloaded motor is given on Fig. 8.

As it is evident, motor with straight rotor bars can not start at all, while in case when rotor bars are skewed for one stator slot pitch motor can start without problem.

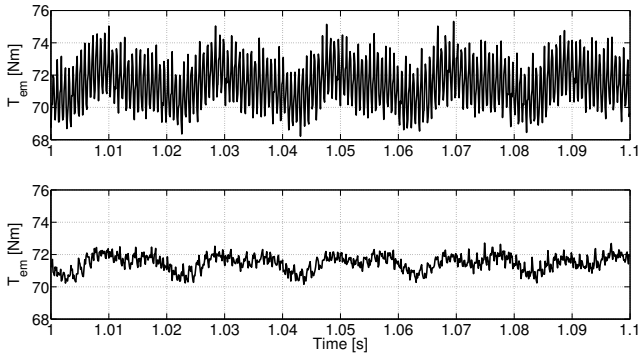

Fig 7. Developed electromagnetic torque in steady state condition: straight rotor bars case, above, and rotor bars skewed for one stator slot pitch, bellow.

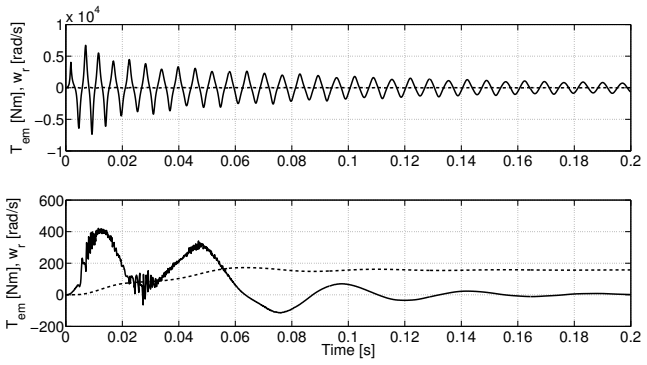

Fig 8. Electromagnetic torque (solid line) and rotor speed (dashed line) during the no-load speed up of the motor with Q_S=Q_R=48. Motor with straight rotor bars is unable to start, above, and motor with skewed rotor bars can start without problem, below.

VI. Conclusions

An alternative way of integral skew factor derivation that provides a deep insight into electromagnetic processes in machine and clearly demonstrates the basic idea behind the skewing of rotor bars in cage induction motors is presented in this paper. Detailed analysis of impact of skewing of rotor bars on elimination of stator slot harmonics in rotor bar currents is conducted. Additionally, by using the multiple coupled circuit model of cage induction motor impact of rotor bar skewing on electromagnetic torque pulsations in steady state condition is conducted in natural frame of reference. Impact of skewing of rotor bars on motor starting ability in case of inadequate stator slot/rotor slot combination is illustrated, too.

Mechanical and Electrical Faults Detection in Uncontrolled Drives with AC Motors

Bratislav Trojić, Vladislav Lazić, Uroš Ilić and Milutin Petronijević, *member IEEE*

***Abstract*—This paper shows new and contemporary possibilities for faults detection and operation conditions estimation of electric drives. The implementation of the machine learning and the artificial intelligence is technique that is increasingly represented in the recent times. Here it was dealt with theoretical and practical support for the implementation of machine learning for the purpose of mechanical and electrical faults detection in uncontrolled drives. The sequence of work and data flow is shown through several stages, from data processing through the developing classification technique, i.e. optimal machine learning algorithm to the evaluation of that algorithm. All development phases of the algorithm were made in MATLAB.**

***Keywords*—Machine learning; electric drives; mechanical faults; electrical faults; preprocessing; algorithm.**

I. INTRODUCTION

Electric drives with AC motors are the basis of today's and future industrial applications. The most prevalent motors are still Tesla's asynchronous motors, and for this reason, engineering progress and mass of scientific work are based on these machines. However, faults are a regular occurrence for all machines. They can be roughly divided into mechanical and electrical faults. Mechanical faults are mainly related to the misalignments [1],[2], soft foot and other mechanical unbalances [3], that lead to vibration of the machine [4]. On the other hand, electrical faults apply to short circuits, open circuits, as well as to asymmetrical power supply to the motor [5], which leads to further side effects, but here is the focus on voltage asymmetry [6],[7]. One of the most effective ways to diagnose and monitor drives is to implement machine learning for these purposes. Through the collected literature, a similar topic was dealt in various possible ways, by monitoring the data of vibrations or stator currents, on motor defects and developing algorithms for detection [8]. Some papers deal with fault monitoring in controlled drives [9],[10], and some are specifically based on the improvement of different algorithms [11],[12].

This paper should explain the process of applying the machine learning on electric power drives and to develop a diagnostic system that has the ability to accurately detect and distinguish the condition of electric drive by measuring vibrations of motor. Conditions should be able to define through three operating modes. These states are normal operating mode, mechanical and electrical faults (especially voltage asymmetry). The machine learning algorithm has been developed from representative examples of machine behavior, so that the algorithm could recognize certain modes precisely enough in the future.

The paper is organized as follows. The collecting of large data sets, with vibration measurements of motor is given in chapter II. In chapter III is presented some laboratory results of measuring. The next step, preprocessing data and feature extraction is given in chapter IV. Chapter V presents the building of the machine learning algorithm via training data. After building the model, it is shown algorithm evaluation. If the evaluation gives positive assessment, this means that the algorithm is ready for application on the new data. That is given in chapter VI. The paper ends with conclusions and the used literature.

II. DATA ACQUISITION

The usual approach for faults supervision is monitoring of vibrations or stator currents. Often, because of the nature of mechanics fault, the effect is best showed on the vibration of the motor. A cheaper method is based on the measurement of stator currents [9]. In this paper, the goal is to achieve fault detection by observing vibrations of induction motor. The reason for gathering only vibrations is because the machine learning algorithms showed better performances in distinguishing faults observing only vibrations rather than only stator currents.

The measuring data were obtained in laboratory condition. In fact, various electrical and mechanical failures were recreated, for measuring vibrations condition along vertical and horizontal axis.

A. Drive and Load Setup

Our drive consists from a main motor, whose condition we monitor and an auxiliary motor, coupled to the shaft of the main motor, in order to simulate the load. For the main motor was used induction motor, SIEMENS *1LA7096-4AA10-Z A11*. The motor characteristics are shown in the TABLE I

TABLE I
DATA FOR THREE-PHASE SQUIRREL-CAGE-MOTOR

Motor data	
Rated voltage:	230/400 V
Rated power:	1.5 kW
Rated speed:	1420 1/min
Rated torque:	10.1 Nm

In Fig. 1. is shown the measuring setup which was used in laboratory for data acquisition. The upper mentioned motor is supplied through 2 three-phase autotransformer. The load is emulated with the servo motor *BMH1401P16A1A*. Unlike the induction motor, servo motor is supplied and controlled

Bratislav Trojić is with the Department of Power Engineering, Faculty of Electrical Engineering, University of Nis, Aleksandra Medvedeva 14, 18000 Nis, Serbia (e-mail: bratislav.trojic@gmail.com).
Vladislav Lazić is with the Department of Power Engineering,Faculty of Electrical Engineering, University of Nis, Aleksandra Medvedeva 14, 18000 Nis, Serbia (e-mail: vladislav.lazic@gmail.com).
Uroš Ilić is with the Department of Power Engineering, Faculty of Electrical Engineering, University of Nis, Aleksandra Medvedeva 14, 18000 Nis, Serbia (e-mail: urosilic@elfak.rs).
Milutin Petronijević is with the Department of Power Engineering, Faculty of Electrical Engineering, University of Nis, Aleksandra Medvedeva 14, 18000 Nis, Serbia (e-mail: milutin.petronijevic@elfak.ni.ac.rs).

by the matching drive *LXM32CD30N4*. This motor had to be controlled through drive, so that it could be used as a load emulator. In order to emulate constant load on the shaft of the induction motor, servo motor is operated in **torque mode**.

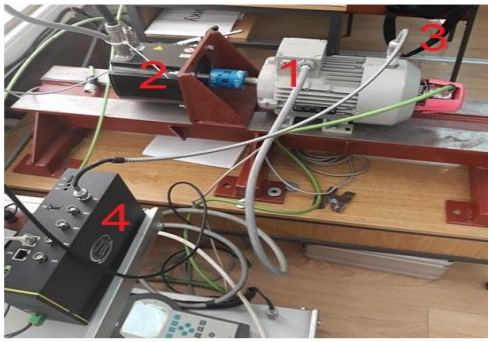

Fig. 1. The measuring setup: 1- Induction motor; 2- Servo motor for load emulation; 3- piezoelectric sensor; 4- Data acquisition device.

B. *Vibrations measuring*

The most commonly used vibration sensors nowadays are based on piezoelectric effect. Piezoelectric sensor accepts vibrations and through the transmission ratio, translates that value into *mV*, with which the device is capable of working and collecting data. The transmission ratio of used sensor is 100 *mV/g*, where is $g = 9.81\ m/s^2$.

The data acquisition device that the sensor is attached to is still under development and presents a prototype of the future series developed for similar purpose. It was programmed in program language Python, so that it could acquire vibrations and writing them in the *.txt* file. Sampling frequency of data collection is 25.6 *kHz*, for 10 *s* time, with 256 000 points per one signal.

C. *Failures Simulation*

In above-mentioned conditions, data of several different motor states were collected. First, electrical undesirable effects on the motor were simulated. Because of the laboratory conditions, it was possible only to simulate the voltage supply asymmetry. These electric faults were simulated by suppling induction motor through 2 three-phase autotransformer. By suppling one or two phases with separate autotransformer, thus, it was simulated the single-phase and two-phase asymmetry of *3%*, and then *5%*. Then, mechanical undesirable effects and faults were simulated on the motor. In our conditions it was possible to achieve soft foot, angular and parallel misalignment. These faults were set by moving motor through horizontal or vertical axis. Every simulated condition was recorded with more various load values.

Based on this recorded states of the induction motor, the data were categorized into three main conditions: normal operation, electrical faults and mechanical faults. In TABLE II is shown recorded failures.

TABLE II
SCHEDULE OF MOTOR OPERATING CONDITIONS

Normal mode	Normal operating mode
Electrical faults	3% asymmetry–single-phase
	5% asymmetry–single-phase
	3% asymmetry–two-phase
	5% asymmetry–two-phase
Mechanical faults	Soft foot
	Angular misalignment
	Parallel misalignment

Data recorded like this, is used for machine learning process. First, these data must be preprocessed, for further training of the algorithm from the data sets.

III. LABORATORY RESULTS

In the below figures, it is shown vibration results measured in laboratory conditions. There were presented signals in smaller range then measured, for better review.

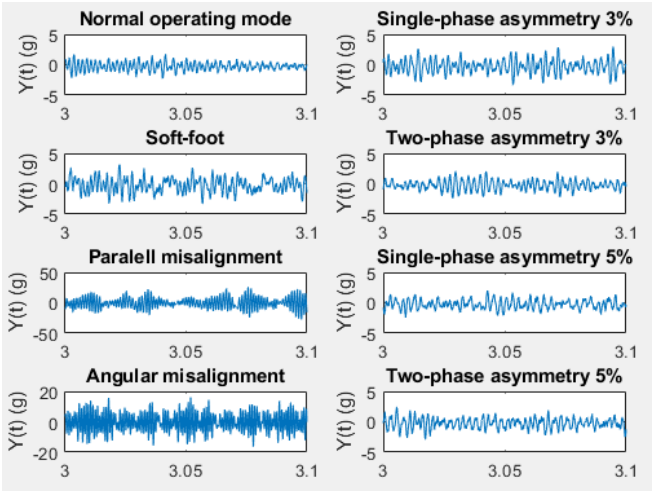

Fig. 2. Vibrations in mentioned operating modes in time domain for vertical axis, where $g = 9.81\ m/s^2$.

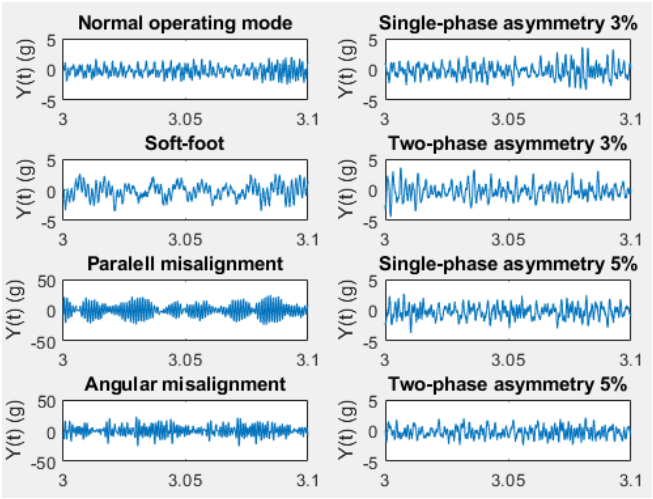

Fig. 3. Vibrations in mentioned operating modes in time domain for horizontal axis, where $g = 9.81\ m/s^2$.

In Fig. 2. from vibration in time domain signals for vertical axis, we can see that there are not much difference between the waveforms of normal operating mode and voltage asymmetries i.e. electric faults. The amplitudes are higher for asymmetry, but that can lead to misclassification sometimes. On the other hand soft foot is not so different from asymmetry waveforms, but parallel and angular misalignments have similar waves to each other, but so different from other motor conditions. In Fig. 3. from horizontal axis, we can notice almost similarly conclusions. Because on the basis on this representation, it is more difficult to make good differentiation between faults, we use preprocessing and features extraction methods like Fourier transform.

IV. PREPROCESSING

Raw data sets may possess missing values, outliers, some noisy parts of data which could have influence on the algorithm, for that reason, the preprocessing is an important

step in data analysis [13]. In this paper were used several important methods for data preprocessing techniques, including the detection and removing of the missing values from time domain signal, next the detection and removing of the outliers, then normalization. After that Fast Fourier Transform was done. The whole development is programmed through the script in MATLAB.

A. *Normalization*

To avoid dependence on the choice of measurement units, the data should be normalized or standardized. This involves transforming the data to fall within a smaller or common range such as [-1, 1] or [0.0, 1.0]. In our case, it was the second range. There are a few normalization techniques, but in this paper is used *min-max normalization*.

Min-max normalization performs a linear transformation on the original data. Suppose that X_{min} and X_{max} are the minimum and maximum values of a signal vector X, respectively. *Min-max normalization* maps a value v_i , of vector X to $v_i^{'}$ in the range [$X_{\min}^{new}$, $X_{\max}^{new}$] by computing:

$$v_i^{'} = \frac{v_i - X_{\min}}{X_{\max} - X_{\min}} \left(X_{\max}^{new} - X_{\min}^{new} \right) + X_{\min}^{new} \qquad (1)$$

By picking new values of maximum and minimum, we determine in what range we want the data to be. *Min-max normalization* preserves the relationship among the original data values [13].

B. *Fast Fourier Transform (FFT)*

Preprocessing of data is usually followed by Fourier transform. Basically, Fourier transform is also one of the methods for dimensionality reduction and feature extraction.

Fast Fourier Transform or *FFT* is almost inevitable algorithm for signal processing analysis of faults. That is because the different faults are expressed differently in the frequency spectrum. Some faults have characteristic peaks at certain frequencies, which makes it easier for algorithm to find characteristic pattern for recognizing certain faults and to distinguish from another. By noticing that, picking the right features makes it easier for detection and training algorithm.

C. *Feature Selection*

The direct measured signals are not suitable for on-line use since short sampling number is deficient for diagnosis, and enough sampling number is a burden for transferring and calculation. So feature selection of the signal is a critical initial step in any monitoring and fault diagnosis system. Its accuracy directly affects the final monitoring results [12].

Many papers are dealt with studying of frequency spectrum signals like in [4]. That is because many fault diagnosis tasks in induction motors depend on feature extraction from the measured signals. The feature characteristics directly affect effectiveness of fault recognition. In the existing literature, many feature extraction methods are suitable for fault diagnosis tasks and in using various training algorithm like neural network for decision [12] and other algorithms [8].

Based on above-mentioned literature, it was concluded that the best solution in feature selection is to take the highest peaks with its characteristic frequencies. In the Fig. 4. and 5. is shown model of peaks selection of the frequency signals by axis. Here were selected four highest peaks of every drive condition with constant load of 6.1 Nm. There can be noticed model by which peaks occur for some examples.

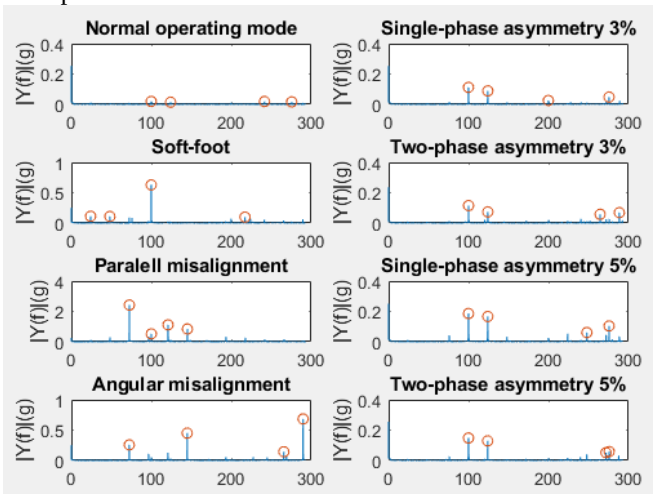

Fig. 4. Characteristic peaks selection on frequency signals of vibrations on vertical axis, where $g = 9.81\ m/s^2$ (before normalization).

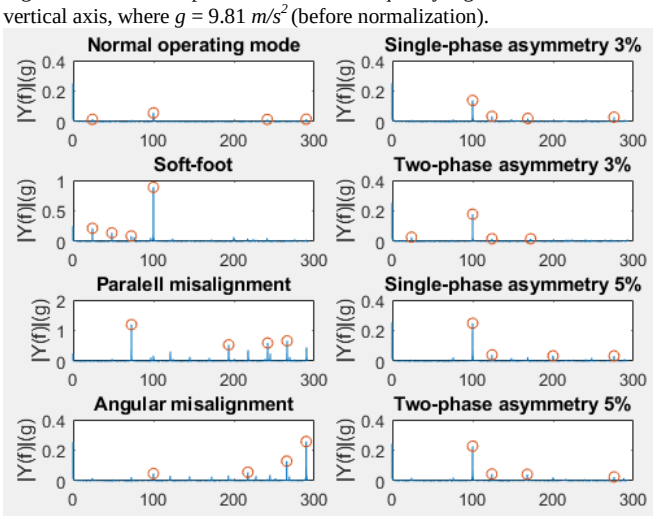

Fig. 5. Characteristic peaks selection on frequency signals of vibrations on horizontal axis, where $g = 9.81\ m/s^2$ (before normalization).

Frequency spectrum for normal operating mode is simple and its peaks are quite similar to low asymmetry levels but amplitude is much smaller. That fact can lead to misclassification of faults. From the frequency spectrum of electrical faults, we can see that the characteristic peaks are occurring in frequencies of approximately 100 and 125 Hz, according to the vertical axis, as far as the horizontal is concerned, the most significant component is in 100 Hz. Based on this, the algorithm can find a clear difference in electrical asymmetry faults in compared to others. On the other hand, mechanical faults do not have such a clear common difference compared to electric faults and normal mode. The soft foot shows the most visible component of 100 Hz, however, it is several times higher than the components of asymmetries at the same frequency, and from that side the difference is easy to conclude, but also sometimes could make trouble. In parallel misalignment, the largest peaks are at approximately 75 and 125 Hz, while for angular misalignment, at some 150 and 290 Hz.

Keeping all this in mind, after preprocessing, features were selected. Because it is difficult to find a similar difference for mechanical faults against other, which could separate them from the electrical ones, and because of the overall reliability of the algorithm, there were selected more features. From the signal in frequency domain, it has been selected 9 amplitudes of characteristic peaks followed by their locations i.e. 9 frequencies on which characteristic

peaks are occurring. It goes up to the frequency of 300Hz, for every signal that represents machine condition or fault, because that is enough range for faults representation. In this way we have 18 values for features i.e. 9 pairs of peak-location value. The selected number for pairs of features was chosen after a certain analysis of algorithms with other features. So number of features is reduced from 256000 to 18. Now every training signal has only 18 features which are adequately prepared for the training algorithm. It is still necessary for the data to be arranged properly before entering the algorithm.

V. Machine Learning Algorithm

Machine learning algorithms use methods for learning from data directly, without relying on a pre-programmed model. The higher the learning database the more accurate algorithm is. In the Fig. 6. we can see flow of data and building machine learning algorithm for faults diagnosis system. This flow chart shows the real application of machine learning in creating an algorithm for these purposes.

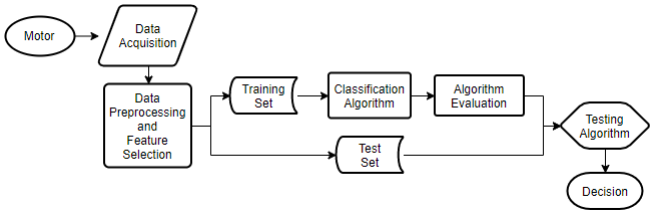

Fig. 6. Architecture of faults diagnosis procedure.

A. Data preparing

Here was used *supervised learning* [13],[14]. This method takes input data sets, obtained from experiment, along with known output data, trains a model that will generate precise predictions for new data. For algorithm training, it was used the *Classification Learner* application, that is part of MATLAB. In order to do this type of training in *Classification Learner*, it is necessary to provide the algorithm with the appropriate sets of input data, and in addition, known responses about what these data represent.

Input in application must be in form of matrix, with column reserved for features of the training signals (in our case 18), and rows reserved for number of training examples (in our case 264). It is better to have as many training examples as possible, because that affects the performances of an algorithm. But that affect is good to a certain point, after that the differences are minor. In addition, the last column is for responses of data in previous columns. In our case, we have only tree classes. Normal operating mode was assigned with class 0, electric failures were assigned with class 1, and mechanical failures with class 2. In this way, the classifier will be able to recognize what are the known data on which the classification is to be made, and what the answers are, on the basis of which the model should be trained. Input matrix is size *264x19*. That is shown on the TABLE III.

TABLE III
Response classes for Motor operating conditions

Normal mode	Normal operating mode	Class
Electrical faults	3% asymmetry–single-phase	1
	5% asymmetry–single-phase	1
	3% asymmetry–two-phase	1
	5% asymmetry–two-phase	1
Mechanical faults	Soft foot	2
	Angular misalignment	2
	Parallel misalignment	2

B. Training Model

Data derived from the preprocessing and preparing, described in the previous chapters are ready to enter the machine learning algorithm. *Classification Learner* application provides the ability to enter the input data (in a given form), then train the model, select the classifier, and finally evaluate the precision of the work and results. An automatic training can also be performed, which allows you to search for the best classification model for the given data. When a model is built, it can be exported to the workspace and used for predictions of new data.

Supervised learning uses methods of classification and regression such as *Support Vector Machine (SVM), K – Nearest Neighbors (KNN), Decision Tree* etc. After training model based on the data, *Classification Learner* gives as an accuracy percentage the particular prediction algorithm. That is shown in the Fig. 7.

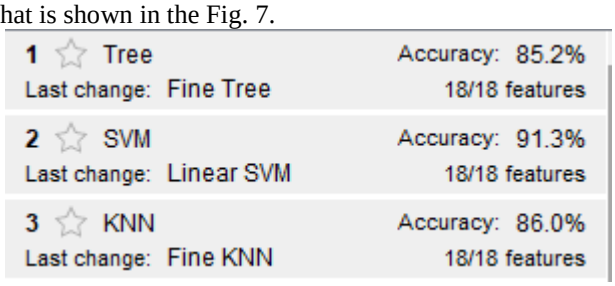

Fig. 7. The accuracy of machine learning algorithms.

By training various models for various classification algorithms, we get accuracy for three main algorithms: *Decision Tree*, *Support Vector Machine (SVM), K – Nearest Neighbors (KNN).* If we evaluate on accuracy, *SVM* would be the best choice. After that it was trained advanced models for *SVM*, and got that better accuracy with *Gaussian SVM*, with value of **92.8%**. However, accuracy will not be used as a solo decision factor and because its small difference, both training algorithms will be evaluated with further investigation methods.

C. Support Vector Machine (SVM)

Support Vector Machine or *SVM* is a supervised machine learning algorithm which is often used for classification problems. This algorithm finds pattern, which classifies data based on position of the them in *n*-dimensional space, where *n* is number of features. The *SVM* classifies data by finding the best *hyper-plane* that separates data points of one class from those of the other class. The best *hyper-plane* for an *SVM* means the one with the largest margin between the two classes. Margin means the maximal distance between nearest data point and *hyper-plane*. The *support vectors* are the data points that are closest to the separating *hyper-plane*. These points present the boundary of a class and they have the most influence on the position and orientation of *hyper-*

plane [13], [15].

This algorithm has technique called kernel. These are functions which take low dimensional input space and transform it to a higher dimensional space for separating non-separable points. Advanced model *Gaussian SVM* use Gaussian distribution.

VI. Algorithm Evaluation

In previous chapter was shown training and development of algorithms in *Classification Learner*. Beside shown accuracy, there are still many unresolved issues, so it is necessary to find the best evaluation procedure and check performances of training *SVM* algorithms.

Performance scores can be classified according to the return values. The results can be presented in a table form (*Confusion Matrix*) or graphically (*ROC Curves*) [11]. Here it will be considered both forms of our two best trained algorithms: *Linear SVM* and *Gaussian SVM*.

A. Confusion Matrix

A Confusion Matrix provides general information about the classifier performance. In our case *Confusion Matrix* (in further text *CM)* is three by three, because here we have three classes. Regular *CM* for *Linear SVM* and *Gaussian SVM* algorithms is shown in the Fig. 8.

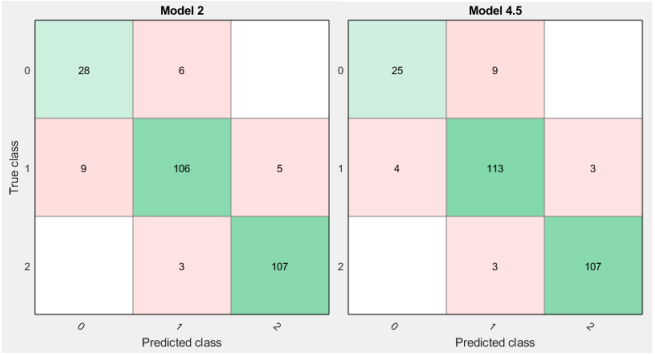

Fig. 8. Regular *CM* for *Linear SVM* (on the left) and *Gaussian SVM* algorithm (on the right)

In Fig. 8. on the left, we can cee that prediction power of every class with *Linear SVM*. For 34 training examples for class 0 (normal operating mode), 6 were predicted wrong, while the rest are predicted correctly. From the *CM* can be observed that the normal mode is confused with the electrical asymmetry, but never with mechanical problems. When it comes to class 1 (electrical faults), prediction is correct in 106 examples from 120. Here we can see that electrical asymmetry can be misclassified with normal mode and mechanical faults. From frequency and time domain waveforms, we can conclude that it is because of similarity of vibrations signals low asymmetry with normal mode and soft foot with asymmetry. That can occur because in some cases locations of peaks are matching for different faults, and only way to differentiate that is by value of amplitude.

In Fig. 8. on the right, we can see regular *CM* for *Gaussian SVM*. This algorithm is dealing with similar issues like *Linear SVM*. The conclusion is almost the same, but here we have better classification for electric faults, and a bit more misclassification for normal operating mode. The reason for this is because we have much less training examples for class 0, then for other 2 classes. Generally it is better to misclassify normal operating mode, then to have fault and label that like normal mode. That can be observed on Fig. 9.

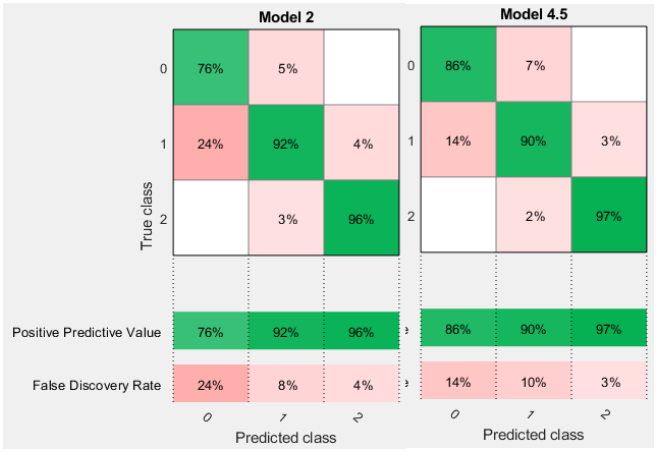

Fig. 9. *CM* with False Discovery Rate

Here we can see that the False Discovery Rate for classes is bigger with *Linear SVM* (on the left), especially with false prediction of normal mode, if it is electric fault condition. It is 24%, and with *Gaussian SVM* (on the right), we have 10% lower. Other 2 classes are mostly similar.

B. ROC Curves

ROC curve is showing true and false positive rates. The curve on the plot shows the values of the *False Positive Rate* (*FPR*), the *True Positive Rate* (*TPR*) and through that the performance of currently selected classifier.

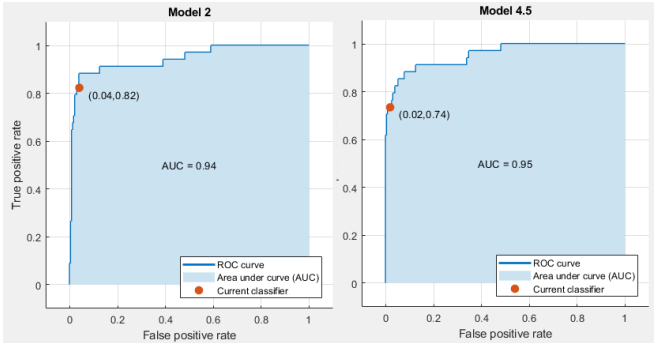

Fig. 10. *ROC* curve classifier 0 against classes 1 and 2.

In Fig. 10. on the left is shown *ROC* curve of *Linear SVM*, for the worst classifier 0, normal operating mode. Here we can see a *FPR* of 0.04 indicates that the current classifier assigns 4% of the observations incorrectly to the positive class (other 2 classes). A *TPR* of 0.82 indicates that the current classifier assigns 82% of the observations correctly to the positive class. The *Area Under Curve (AUC)* number is a measure of the overall quality of the classifier. Larger *AUC* values indicate better classifier performance. In this case it is 0.94 or almost 94%. For other two classes performances are better. In case class 1, we have performances (0.06, 0.88) with *AUC* = 0.95 for *Linear SVM* and (0.08, 0.94) with *AUC* = 0.98 for *Gaussian SVM*. In case class 2, we have (0.03, 0.97) with *AUC* = 0.99 for *Linear SVM* and (0.02, 0.97) with *AUC* = 1 for *Gaussian SVM*. That all indicates that, *Gaussian SVM* shows a bit better performances of an algorithm.

According to all parameters of evaluation, we conclude that these two training algorithms (*Linear SVM* and *Gaussian SVM*) can work with high precision of prediction power. Now this algorithm can be used for prediction of new data.

C. Predictions on New Data

After a good evaluation, the algorithms were exported for using with the new data. In process of data collecting, we

gather data for one more malfunction of electric drive. In addition to all mechanical faults, it was simulated also a rotor unbalance of the induction motor. This additional fault and its data set were used for test set, with which we can test our training algorithms. In Fig. 11. is shown signals of rotor unbalance of horizontal and vertical axis when load of a motor is 6.1Nm. In this figure we can see prominence of characteristic peaks on various frequencies, like 25 and 100Hz. Because the highest peak is in 25Hz, this signal isn't similar to any electrical fault (asymmetry) in our case neither the normal operating mode, but there is some resemblance with soft foot or even parallel misalignment.

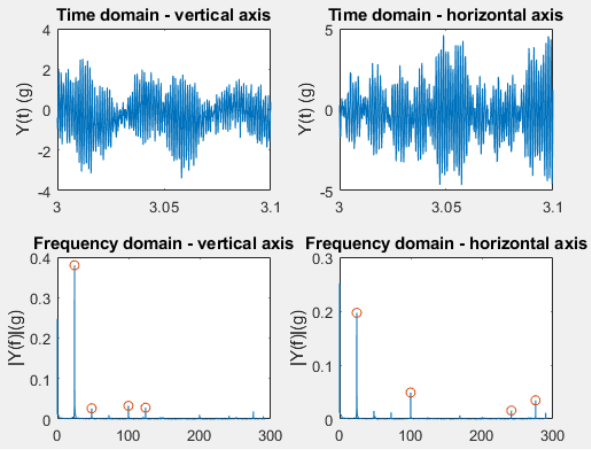

Fig. 11. Rotor unbalance signals in time and frequency domain.

For input new data in existing model, we must prepare that data, in the same way as we prepared all training data. In the end of preprocessing, there were 18 features for every of 30 testing example unbalance condition (for various load). Input matrix of size of *30x18*. After applying our *Linear SVM* and *Gaussian SVM*, we got the same results. Output in both algorithms was a new matrix with size *30x1*, where all elements were number 2. That means that all 30 new test examples belong to class 2, which represent a mechanical fault. From the previous can be concluded that on the same induction motor, previously unseen mechanical fault was successfully classified by both training algorithms. We can also conclude that the algorithms weren't so sensitive to the load change, because all 30 training examples were gathered for various loads. This way it was tested that both algorithms work excellent with detecting mechanical faults.

Regardless of the accuracy, the *Gaussian SVM* algorithm has shown through other evaluation methods that it is a better option for predicting new motor faults.

VII. Conclusion

In this paper, it was presented a study of the data analysis and machine learning implemented for the purpose of predictive maintenance in electric motor drive. Here was shown a development of training algorithm, which can predict malfunction in uncontrollable electric drive and conclude whether the fault is of an electrical or mechanical nature. This can be very helpful with the detection of failures, because the fault can be easily found and removed when we know if the problem is of electrical or mechanical nature.

This paper presents a complete data analysis, from the method of collection, preprocessing, classification and evaluation. It was applied *SVM* algorithm (*Linear* and *Gaussian*). The evaluation showed that algorithms have great efficiency and accuracy. After the trained model is provided with the new data, it was able to successfully classify the type of fault.

The diagnosis of electrical machine's working conditions presented here follows the trend of implementation of artificial intelligence. The artificial intelligence presents an alluring solution for this type of problem, because it enables detection algorithm to improve over time and also to follow the changing parameters of the motors during the exploitation life. Proposed approach could be able to implement in real time faults diagnosis with optimization in data preprocessing and then implementation of classification algorithm in real time processors. The future researches will be devoted to the preparation of these methods for real-time applications.

Detection of Supply Voltage Unbalance Condition in Induction Motor Using Machine Learning

Vladislav Lazić, Uroš Ilić, Bratislav Trojić, and Milutin Petronijević, *Member, IEEE*

***Abstract*—This paper presents possibilities of detecting supply voltage unbalance condition in induction motor using machine learning algorithms. Supply voltage unbalance condition can be dangerous for motor and can invoke bigger faults. Early detection of this condition is important in order to prevent costly outages. This paper aims to show results and analyze the performance of these algorithms, using MATLAB application Classification Learner. Mechanical vibration and stator current measurements have been taken into consideration, as they are easily accessible for measuring and hold a lot of important information. These signals were preprocessed in an appropriate way in order to gain valuable features, which are then used in the algorithm. Results were analyzed and displayed in the paper.**

***Index Terms*— Supply Voltage Unbalance, Squirrel-Cage Induction Motor, Machine Learning, Condition Monitoring**

I. Introduction

The electrical energy that is used in the industry is in the largest part being converted into mechanical energy [1]. In the center of this conversion is an electric motor. The industry is today more developed than ever and large amounts of goods are produced every second. In order to avoid costly production halts, the motors that drive this production need to be reliable. The high reliability is the very reason why the squirrel-cage induction motor is the most commonly used electric motor in the industry [2].

However, despite the high reliability and other advantages that the induction motor has, it is still subjected to many faults [3-4]. Depending on the severity of these faults, they can cause additional losses in the motor, or even the motor shut down. Many times, it is possible to detect a fault in the initial stage, which is essential in preventing the complete failure of the motor. In accordance with the above, one can conclude that it is necessary to monitor the condition in some way and to extract key features from monitored signals which show us that fault occurred.

Numerous fault detection methods have been analyzed and presented in the literature. One of the methods, that is becoming more important as technology advances, is a knowledge-based approach [5]. Knowledge-based approaches are based on soft computing techniques and they are used to solve complex calculations with non-linear big data problems. This type of problems requires a probabilistic approach as there is a lot of imprecision and uncertainty in the data. Machine learning techniques fall into this category. In recent times, machine learning approaches, such as K-nearest neighbors, Support vector machine and Decision tree algorithms were suggested as a way of detection of a fault occurrence in the induction motor at the early stages and it showed some viable results [5-8].

This type of fault detection methods gets even more significant as the fourth industrial revolution is on the way. Among other things, the fourth industrial revolution is characterized by mass production and automation of the processes, as well as more efficient use of energy. Machine learning approach has not still found its place as the number one condition monitoring system for induction motors in the industry, but it could be more used in this field in the upcoming years as an answer to the demands of the fourth industrial revolution.

In this paper, it was dealt with the detection of an unbalanced voltage condition in induction motor using machine learning algorithms. In section II, general remarks regarding the supply voltage unbalance condition and the possibilities of its detection are given. This condition has an effect on both stator currents and motor vibrations, so these two quantities were taken into consideration and two models were built using these measurements. The experimental setup for data collection, the strategy for dataset creation and final results are presented in section III. The fifth and the seventh harmonic were present in stator currents and their effect on the detection process is evaluated, as they are the most common harmonics in the grid [9].

II. Supply Voltage Unbalance

The normal working condition of a motor presumes balanced supply voltage. Ideally, magnitudes of all three phase voltages are the same and phases are equally shifted between each other at an angle of 120 degrees. A described three-phase system is completely symmetrical. If either magnitudes or phase angles differ from each other, it comes to

unbalanced voltage condition and certain asymmetry is inserted into the motor.

The causes of the unbalanced condition can either be external, where common reason is an occurrence of load variations and uneven load distribution among the phases, so motor supply voltage becomes unbalanced, or internal if the three-phase winding has some defects and is not symmetrical.

Analysis of the motor operation under the unbalanced condition is usually performed using the method of symmetrical components. This means that the asymmetrical system is divided into three symmetrical systems; direct (positive), inverse (negative) and zero (homopolar). In the ideally symmetrical system, there is only one component, the direct one. When the three-phase stator winding gets connected to the unbalanced voltage supply, asymmetrical stator currents are formed, hence the inverse sequence currents are generated. These currents form a magnetic field that rotates in the opposite direction of the rotor rotation. As a consequence, resulting torque is smaller than the torque motor has under the balanced condition. Also, negative sequence currents cause additional heating in the stator windings, which can lead to isolation deterioration and ultimately to a short circuit in the stator winding.

This is the reason why it is important to detect the presence of the supply voltage unbalance. If this condition is detected at the early stages, isolation may not be completely damaged and it may not come to the short circuit inside the stator windings. Also, it is important that the motor runs more efficiently. If the unbalanced condition is not detected and motor runs under it, then it would run with the smaller torque, increased slip, bigger losses, and overall efficiency factor would be smaller.

In order to detect the presence of the supply unbalance condition, one could focus on detecting the presence of negative sequence currents. This is possible as the negative sequence magnetic field creates a 100 Hz component in the frequency spectrum of the rotor currents [10]. Knowing that the magnetic field of negative sequence components is rotating in the opposite direction from the rotor, we can write

$$s_i = \frac{n_s - (-n)}{n_s} = \frac{n_s + n}{n_s} = 1 + \frac{n}{n_s} = 1 + 1 - s = 2 - s. \qquad (1)$$

In the previous equation, we see that the inverse sequence slip s_i is equal to the $2-s$, where s is the motor slip in the normal working condition. As s is a small value, then $2-s$ is approximately equal to 2. If we write the equation for finding the rotor frequency of the negative sequence electrical values in the rotor, we get

$$f_{ri} = s_i f = (2-s) f. \qquad (2)$$

This shows us that voltage unbalance condition creates frequency components at the double of the supply frequency, while the frequency of the rotor electric values under normal conditions is usually 1-3 Hz. This gives the opportunity to extract this feature using some of the condition monitoring methods and to conclude that inverse sequence components are present, which definitely means that there is a certain asymmetry in the motor.

However, rotor currents are not accessible for measurement in case of a squirrel-cage induction motor. This is why in this paper stator currents and vibrations were used to detect the unbalanced condition.

A. Definitions of the Voltage Unbalance

There are three definitions of voltage unbalance, where three different parameters are calculated [11]. They are NEMA (National Equipment Manufacturer's Association) definition, IEEE definition and True definition, which is adopted by the IEC.

In NEMA and IEEE definitions LVUR and PVUR parameters are calculated, respectively. LVUR – line voltage unbalance rate is calculated as a percentage value of the ratio between the maximum voltage deviation from the average line voltage and the average line voltage value. PVUR - phase voltage unbalance rate is calculated like the LVUR, except the average phase voltage is considered, along with the maximum deviation of one phase voltage from the average.

In this paper, voltage unbalance is calculated using the True definition, where voltage unbalance factor (VUF) is calculated as the percentage value of the ratio between the negative sequence voltage component and the positive sequence voltage component. To perform this calculation one would have to use complex algebra. To avoid this (2) is derived as a good approximation to the True definition [11]:

$$\%VUF = \frac{82 \cdot \sqrt{(V_{ab} - V_{avg})^2 + (V_{bc} - V_{avg})^2 + (V_{ac} - V_{avg})^2}}{V_{avg}} \qquad (2)$$

where V_{avg} is the average line voltage.

NEMA standard defines the derating factor [11]. This factor shows how much overall motor performance deteriorates with the rise of voltage unbalance.

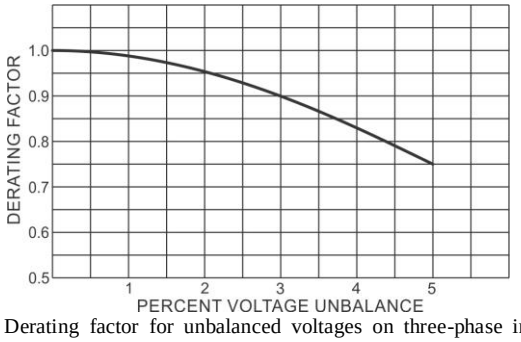

Fig. 1. Derating factor for unbalanced voltages on three-phase induction motor (adapted from [11])

Fig. 1 shows how it is expected that the motor performs well if voltage unbalance is below 1%. Above this value, motor performance starts to slow down. It is not recommended to run a motor under the circumstances of voltage unbalance factor being bigger than 5%.

B. Effect of the Voltage Unbalance on Stator Currents and Vibration

It is already mentioned that stator currents under supply

voltage unbalance are unbalanced as well. Unbalanced stator currents are the source of power and torque oscillation which leads to higher vibration levels than normal. Higher vibration levels can lead to deterioration of the mechanical parts of the motor, which is one more reason that the supply voltage unbalance should be fixed as soon as possible.

Due to the existence of the asymmetry in the motor quantities and thereby the existence of the negative sequence currents, vibrations occur at the double supply frequency in the vibration frequency spectrum. This is the case with the supply voltage unbalance condition [12-14], among some other faults [15-17]. The possibility of detecting the occurrence of vibrations at the double supply frequency in the frequency spectrum is processing the signal via Fast Fourier transformation and extracting key features. This was used in this paper.

According to expectations, there is a larger 100 Hz component in the vibration frequency spectrum when the motor was under unbalanced condition than in a normal motor (Fig.2). A very large 300 Hz component is present in both normal and a faulty case and it is a consequence of the presence of the 5th and the 7th harmonic in stator currents (Fig. 3), as expected in case of harmonics polluted supply voltage [9].

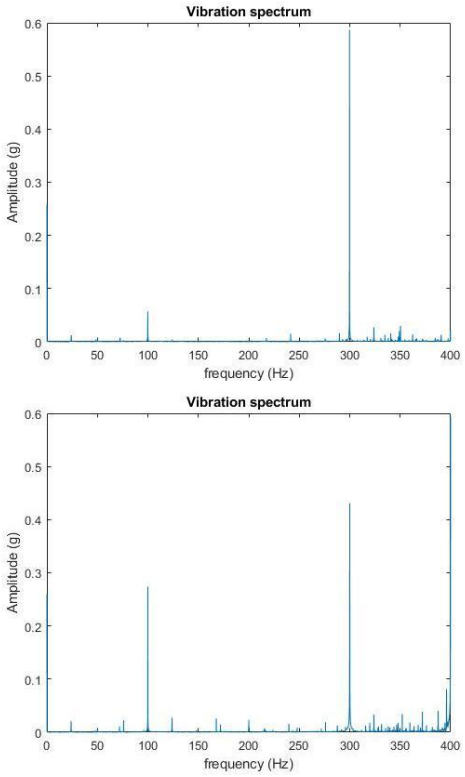

Fig. 2. The vibration spectrum of the motor used in this experiment without voltage unbalance (top) and with voltage unbalance of 5% (bottom) at 75% load

The stator current frequency spectrum is not as conclusive as rotor currents spectrum would be. The frequency spectrum of stator currents in normal and in unbalanced voltage condition is presented in Fig. 3. As can be seen, there is no significant difference in harmonic content between these two cases, as normal motor also has some asymmetry.

It is interesting to see if machine learning algorithms could find the pattern in stator current as well, even though it does not seem plausible by just looking at the stator currents frequency spectrum. Stator currents are easily accessible and it would be good if one could conclude if there is voltage unbalance condition by extracting features from the stator currents.

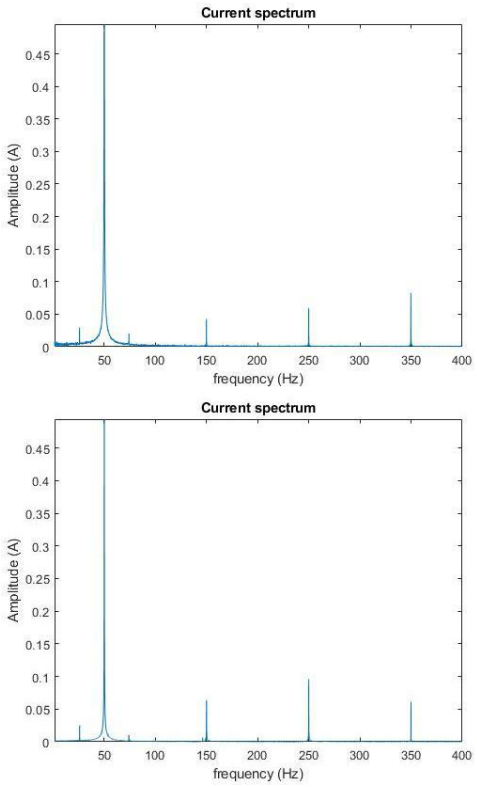

Fig. 3. The current spectrum of the motor used in this experiment without voltage unbalance (top) and with voltage unbalance of 5% (bottom) at 75% load

III. Experimental Results

A. Experimental Setup

In order to check if a machine learning algorithm can adequately detect voltage unbalance, first data had to be collected. The motor used in this experiment was three-phase induction motor Siemens 1LA7096-4AA10-Z. Its nameplate parameters are given in Table 1 below.

TABLE I
MOTOR PARAMETERS

Rated voltage	400 V
Rated current	3.45 A
Rated power	1.5 kW
Rated speed	1420 1/min
Rated torque	10.1 Nm
Power factor	0.81
Efficiency	77.2%

This motor was supplied from the 3x400V, 50Hz grid through two three-phase autotransformers (Fig. 4) in order to

create voltage unbalance while maintaining the same phase angle between phases. In this way, both one-phase and two-phase voltage asymmetry could be created, depending on which autotransformer's output voltages were changed from the grid voltage.

This motor was coupled with Schneider Electric servo motor BMH1401P16A1A, which was controlled with the proper servo drive. In this way, the second motor served as a load and was controlled in such a way to cover 5 states: no load (Siemens motor only had Schneider Electric motor's inertia on the way), 25% of the full load, 50% of the full load, 75% of the full load and full load state.

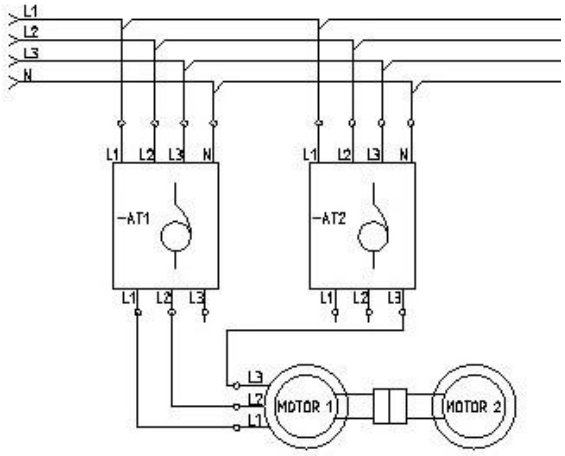

Fig. 4. Schematic diagram of the experimental setup

B. Data Collection

Stator currents and vibration signals were intended to be measured. Stator currents signals were acquired with the current probes and displayed using a four-channel oscilloscope. Each current measurement was recorded for a period of 10 s with the sampling frequency of 10000 Hz. Vibrations were measured in the horizontal and vertical axis. Vibration signal data were acquired using a dedicated device adjusted and programmed to collect data from the vibration sensor. Measurement length was also 10 s with the sampling frequency of 25600 Hz. A total of 90 current measurements and 150 vibration measurements were collected.

The data were collected for three different voltage unbalance conditions: VUF=0-1% (normal conditions), VUF=3% and VUF=5% (one-phase and two-phase unbalance). The main idea investigated in this paper is to determine how well machine learning algorithms deal with the detection of voltage unbalance as a source of vibrations or as a source of unbalanced currents. In this sense, the results are compared between two models where vibration signals and stator currents are used as a dataset. Additionally, it is checked whether algorithms can properly distinguish between different levels of voltage unbalance.

C. Dataset Preparation and Feature Selection

These raw data are preprocessed in order to create adequate datasets. It was already mentioned that valuable information can be extracted from the signals if Fast Fourier transformation was performed.

Important information about measured signals was extracted in a way that 10 highest peaks and their corresponding locations were found in each measurement's frequency spectrum inside of 0-300 Hz range, forming 20 features which machine learning algorithm should use to identify the pattern. In order to retrieve only these peaks, frequency spectrums were cut off outside this range.

The justification for this approach was derived from MATLAB's Neighborhood Component Analysis method for feature selection [18]. The graph in Fig. 5 represents the significance of each feature for having a more accurate distinction between classes in the model based on vibration measurements. The first 20 dots represent 20 highest peaks that were obtained, and the next 20 dots are their corresponding frequencies. It can be seen that higher peaks have a bigger influence on the classification. It can be noted that frequencies of those peaks are also highly influential on the classification process. That is why 10 highest peaks and their corresponding frequencies are used as features for each measurement in creating a prediction model. These 10 peaks have a stronger impact than the remaining 10 peaks and machine learning algorithms work better and faster with fewer features.

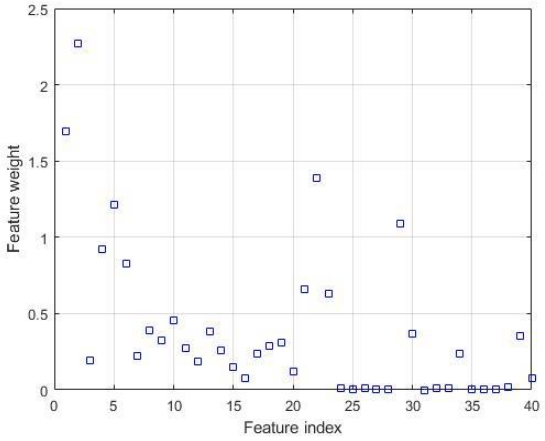

Fig. 5. Relative significance of features for the accurate classification

The dataset matrix is formed in a way that each row consists of 20 features that are selected to represent one measurement. At the end of each row class labels were added, forming the complete dataset, suitable for creating a prediction model in MATLAB Classification Learner toolbox. Classes were labeled as in Table 2. Group of measurements that represented normal conditions were labeled as 0. The signals that were measured under the faulty conditions of 3% and 5% voltage unbalance were labeled as 1 and 2, respectively.

TABLE II
CLASS LABELS

%VUF	Class label
0%	0
3%	1
5%	2

All of this applies to both current measurements and vibration measurements models. The only difference is that in the model based on vibration measurements the accuracy was better when 0-250 Hz range was observed. The reason for this range reduction is the existence of a significant 300 Hz component in the vibration spectrum, which was present in the normal conditions as well as in the faulty condition. This component is induced due to the presence of the 5th and the 7th voltage harmonic [9]. It affected the detection process by lowering the accuracy of the proposed method, and this component is excluded from the model. The effect of mentioned harmonics on the detection process in the vibration model is eliminated in this way.

On the other hand, harmonics in stator currents changed as operation mode changed, in such a way that they were not worsening the voltage unbalance condition detection accuracy in the model based on stator currents. The accuracy was even better when these harmonics were included. Particularly, the 5th harmonic had more impact, so the 0-300 Hz range was chosen. This frequency range provided the best accuracy, but the accuracy was not much lower when both 5th and 7th harmonic were taken into consideration, or when none of them was.

D. Prediction Model Based on Current Measurements

After the prediction model is created, the results were obtained and analyzed. Results will be presented in the form of a Confusion matrix (Fig. 6).

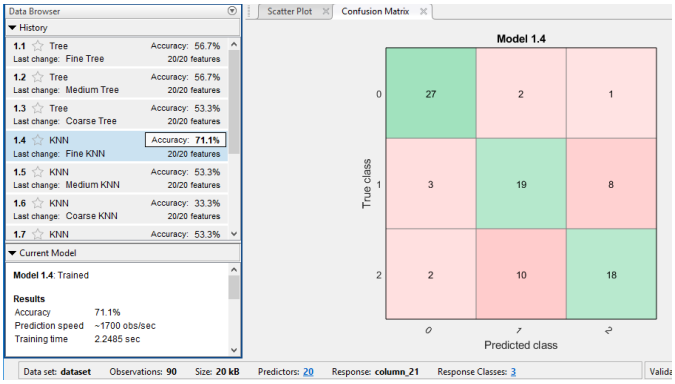

Fig. 6. Confusion matrix of a prediction model based on stator currents dataset

It is shown that Fine KNN had the highest accuracy, 71.1%. Weighted KNN was also close with 67.8%. This accuracy of 71.1% is not high, but it is important to notice that the low accuracy was caused because the algorithms mixed up classes 1 and 2 (3% and 5% voltage unbalance), while they correctly understood in most cases when there was no voltage unbalance.

As can be seen in Fig. 6, Fine KNN correctly predicted normal conditions in 27 out of 30 normal condition measurements. Also, the model predicted wrongly that there is no voltage unbalance, when there was, 5 times in total out of 60 measurements.

Reasons for the mix up between the class 0 and other two classes can be found in the uncertainty in data and not in the capabilities of the algorithms themselves, as normal condition measurements were never symmetrical, especially at the lower load. The reason for this is that autotransformers were not able to pass through fully symmetrical voltages, so the certain asymmetry was inserted into stator currents. It is possible that some of the class 0 measurements were degraded by this in such a manner that they seemed more like an unbalanced condition than a normal one to the algorithm.

As for the distinction between different levels of voltage unbalance, it can be concluded that the algorithm did not perform well, as it mixed up classes 1 and 2 in numerous instances. For the better prediction of voltage unbalance operation conditions, additional modifications in the process of preparation of the dataset are necessary.

E. Prediction Model Based on Vibration Measurements

Confusion matrix of the prediction model based on vibration measurements is given in Fig. 7.

The best accuracy in this model is 78.7%, shown by the Coarse Tree algorithm and SVM had 76% in this case, but other algorithms showed better accuracies as well in comparison with the current measurements model. Again, 27 of 30 predictions were performed correctly for normal motor conditions, but in this case, it was predicted only once out of 120 times that there is no fault, when there was.

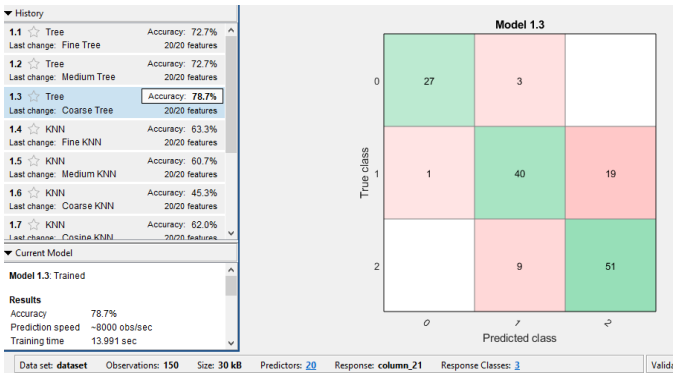

Fig. 7. Confusion matrix of a prediction model based on vibrations dataset

Unlike in the current model, the vibration model did not mix up classes 0 and 2 even once. Also, it showed a better distinction between classes 1 and 2. This leads to the conclusion that the vibration model has presented a better prediction of the voltage unbalance level and better overall prediction of a voltage unbalance condition. This is expected, given that the vibration frequency spectrum seems much more conclusive than the current frequency spectrum. It should be stated here as well that there were more vibration measurements and it might have had a positive influence on the machine learning algorithms performance, as it had more training data.

IV. CONCLUSION

This paper aimed to show and compare the possibilities of machine learning detection of an unbalanced supply condition using current and vibration data and the results were presented. The vibration model displayed better results. The main reason for this could be the fact that the vibration frequency spectrum of the unbalanced supply condition is

clearly different than that of a normal one, which is not the case with the current frequency spectrum. Despite this fact, it is shown that machine learning algorithms managed to find some pattern in the current frequency spectrum as well and to separate the normal condition from the faulty one.

The presented results are not conclusive, as the dataset was not big enough. Also, the results could have been better with additional data preprocessing, especially for the current model. More precise sensors, programmable voltage sources, and additional experimental tests are necessary in order to make further improvements in creating datasets. However, these first results are promising and machine learning algorithms displayed capabilities of finding the pattern that is necessary to distinguish between the normal working conditions and the unbalanced voltage supply condition in both models. On the other hand, they could not differentiate between different levels of voltage unbalance with satisfactory accuracy. The vibration model showed somewhat better results in this case as well.

Further work could include different ways of raw data preprocessing and preparing the dataset, which could provide better results, especially in the distinction between different levels of the voltage unbalance. The effect of the 5th and the 7th harmonic on the prediction models has been mentioned in the paper, but more investigation of the harmonic impact on the supply voltage unbalance detection results should be conducted, as there are also other voltage harmonics which may have an influence. It should also be dealt with the fact that other sources can mask the essential information for voltage unbalance detection, such as some mechanical imperfections which also induce 100 Hz component in the vibration spectrum, and that can potentially affect the detection process. Lastly, this approach should be tried with bigger datasets, as that could help machine learning algorithms to be trained better and display better results.

ACKNOWLEDGMENT

We would like to express gratitude towards our colleagues Filip Filipović and Lazar Sladojević, who kindly helped by sharing their thoughts on this subject. Thanks to company Netico which provided us with the device that was used for vibration measuring. This work was supported by the Ministry of Science and Technological Development, Republic of Serbia (Project number: III 44006).

Classification models of machine learning for vibration analysis of induction motor

Uroš Ilić, Bratislav Trojić, Vladislav Lazić and Filip Filipović

***Abstract* — The main aim of writing this paper is the idea to use machine learning techniques to recognize possible faulty operating modes of induction motor drives using only mechanical vibrations. In this paper, the vibrations of one induction motor were recorded for different operation modes: normal, soft foot, rotor imbalance, angle and parallel misalignment. Recorded data is transferred from the time into a frequency domain using Discrete Fourier Transformation (DFT) to be used as an input for machine learning algorithms. The input into the algorithm consists of ten components of frequency spectra (peaks) with the highest amplitude and corresponding frequencies in frequency range up to 300 Hz. Classification models of machine learning obtained in the end, have a very good ability to easily classify unlabeled data.**

***Index Terms*—induction motor, vibrations, machine learning**

I. Introduction

Cost optimization in industrial drives is a dominant goal that tends in today's time. In industrial plants, there are fixed and variable costs. The first are regular costs that go to the spare parts and maintenance, and significant part of the second is unexpected costs that go to the remediation of defective equipment. Induction motors (IMs) are a part of a drive that can generate the greatest additional loss of money if, for some reason, it enters in a faulty operating mode that could lead to equipment failure. In order to avoid failures in electrical machines, it is necessary to monitor and analyze the condition in which a machine is running, i.e. it requires the implementation of a condition-based maintenance system [1]. Efficiency of drives and savings achieved in this way have led to increased money investing in systems that would have the ability not only to analyze the current operating condition of the machine, but also to predict future events.

Fault detection at their initial stage contributes to increasing the efficiency of the entire drive [2]. Modern technologies have contributed to the development of many techniques for monitoring the operating conditions of machines and early fault detection. Methods of fault detection are based on measurement different variables: mechanical (vibrations, shock pulses, acoustic noise, speed fluctuations), electro-mechanical (currents, partial discharges, leakage fluxes) and temperature, oil analysis, gas analysis, and overall performance monitoring [3]. These techniques are often based on the processing and analyzing of a large number of data. The main problem is extraction of useful information from raw data [4].

Using machine learning in data analysis allows a large number of tools for understanding the data obtained directly from industrial drive. In the paper, three machine learning algorithms were used to form classification models: support vector machine (SVM), k-Nearest Neighbors, decision tree.

Support vector machine was first introduced in 1995 by Cortes & Vapnik [5]. This type of classifier is based on the foundations of statistical learning theory. Using SVM algorithm in classification problem is explained in [6].

K-NN algorithm is among the simplest of all machine learning algorithms. It is a type of instance-based learning, or lazy learning, where the function is only approximated locally and all computation is deferred until classification. Application of both algorithms (SVM and k-NN) for classification of IM faults described in [7].

Decision tree is a machine learning algorithm that builds a knowledge-based system by inductive inference from case histories. In [8] vibration data were used for training decision tree algorithm that was used in the detection of failures.

Section II describes the process of vibration analysis: detecting characteristic frequencies, data collection, analysis of the frequency spectrum. Section III describes the process for creating a dataset, while Section IV provides an analysis of the obtained classification models. Finally, the conclusion is drawn based on presented results.

II. Vibration Analysis

Motor vibrations exist even though the motor is fully healthy, so it is necessary to understand the causes that lead to vibration change. Regular vibration monitoring can detect deteriorating or defective bearings, mechanical looseness and worn or broken gears. Vibration analysis can also detect misalignment and unbalance before these conditions result in bearing or shaft deterioration [9]. Vibration analysis is an effective, non-intrusive method to monitor machine condition during start-ups, shutdowns and normal operation. The most important advantage is that the reaction to the changes is instantaneous which makes it possible to use in current, but also occasional analysis of operating conditions. Also, a very important feature of the vibration analysis is the possibility of widespread use of signal processing techniques in order to easily identify the fault indicators that are not visible in the source signal.

A vibration analysis system usually consists of four basic parts:

Uroš Ilić is with the Faculty of Electronic Engineering, University of Nis, Aleksandra Medvedeva 14, 18000 Nis, Serbia (e-mail: urosilic@elfak.rs).

Bratislav Trojić is with the Faculty of Electronic Engineering, University of Nis, Aleksandra Medvedeva 14, 18000 Nis, Serbia (e-mail: bratislav.trojic@gmail.com).

Vladislav Lazić is with the Faculty of Electronic Engineering, University of Nis, Aleksandra Medvedeva 14, 18000 Nis, Serbia (e-mail: vladislav.lazic@gmail.com).

Filip Filipović is with the Faculty of Electronic Engineering, University of Nis, Aleksandra Medvedeva 14, 18000 Nis, Serbia (e-mail: filip.filipovic@elfak.ni.ac.rs).

1. Signal pickup, also called a transducer
2. A signal analyzer
3. Analysis software
4. A computer for data analysis and storage.

A. *Dominant Frequencies of Mechanical Faults*

Mechanical failures where the vibration analysis is the most commonly used tool for detection are rotor unbalance, shaft misalignment (parallel and angle) and soft foot. Characteristic frequencies in the vibrational spectrum on the basis of which mechanical problems can be detected are defined in [10], and shown in Table I.

TABLE I
DOMINANT FREQUENCY IN VIBRATIONAL SPECTRA

Type of failure	Dominant Frequency	Dominant Plane
Unbalance	1 x rpm	Radial
Misalignment (angle)	1 x, 2 x rpm	Radial
Misalignment (parallel)	1 x, 2 x rpm	Radial
Soft foot	1 x, 2 x rpm	Radial

Thus, failures listed in Table I, are manifested by increasing the amplitude of components in the frequency spectrum on a single or double frequency of rotation of the shaft. The component of dual frequency signal appears in the majority of failures. This means that misalignment and soft foot can be distinguished from rotor unbalance if there is a 2 x rpm component, but in case it does not exist, the distinction of failures is very difficult to make.

Experiments made in [11] show that, depending on the coupling method and applications in which the motors are used, misalignment can occur in the frequency spectrum at all frequencies from one to six times the frequency of rotation.

Soft foot usually occurs at a frequency of 1x rpm, but is occasionally present at two and three times rpm [12], which once again confirms that detection of faults only by observing characteristic frequencies does not always lead to clear conclusions.

B. *Data Collection*

The most commonly used transducer for measuring vibration is a piezoelectric accelerometer. The construction of accelerometer is such that the piezoelectric properties of certain crystals and ceramics are used to generate an electric signal proportional to strain. Due to its design, this sensor does not require any additional power source, which makes it easy to transform a mechanical signal into an electrical signal. The wide frequency and dynamic range with good linearity in all ranges represent the most important advantages of this transducer [13].

C. *Frequency Analysis*

The transition from the time domain, in which the data were recorded, to the frequency domain, is done via the Discrete Fourier Transformation (DFT). DFT is obtained by discretizing the Fourier transform of a discrete signal into N frequencies uniformly distributed over an interval of length 2π [14]:

$$\omega_k = \frac{2\pi}{n} k, k = 0,1,2 \ldots N-1. \quad (1)$$

The discrete Fourier transform of the signal $x(n)$ into N points is calculated by the formula (2).

$$X(k) = \sum_{n=0}^{N-1} x(n) e^{-j\omega_k n}, k = 0,1,2 \ldots N-1. \quad (2)$$

In the frequency domain, analysis of mechanical failure becomes easier, due to knowledge of characteristic frequencies, but mechanical failures can be hardly distinguishable among them self.

III. CREATING A DATASET

All data were recorded at a laboratory drive located at the Faculty of Electronic Engineering in Nis, in the laboratory for Electric Drives. Fig. 2. shows a drive consisting of an induction motor on which the vibration was measured and the permanent magnet motor which is served for load emulation. The drive is coupled with a flexible coupling.

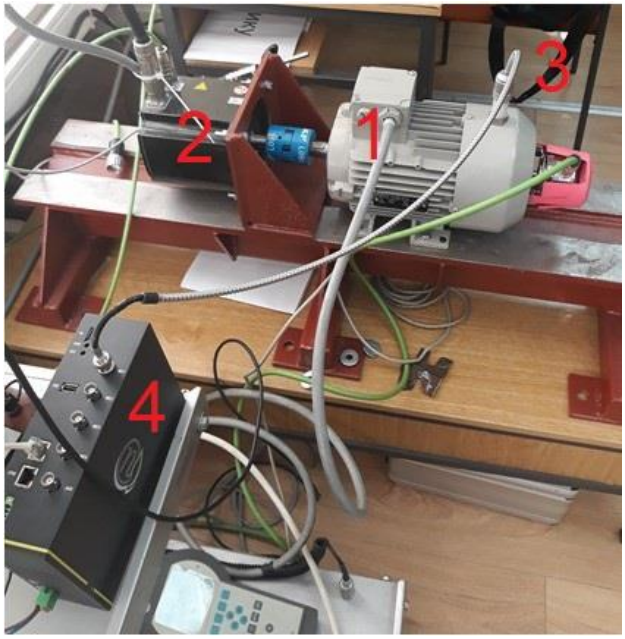

Fig. 2. Laboratory test setup: 1 – IM under test, 2 – PMSM for load emulation, 3 – piezoelectric accelerometer, 4 – DAQ system

Induction motor, 1.5 kW, was connected via an autotransformer to the power grid, which enabled the gradual commissioning. There was no speed control, and the IM worked at a nominal speed of 1420 revolutions per minute. Horizontal and vertical vibrations were measured. The load is changed in the range from 0 to nominal, with a step of 25% of the nominal load. To collect signals of horizontal and vertical vibrations, we used a high-sensitivity (100 mV/g) Metrix accelerometer. Data acquisition is done

using a device that has the ability to collect data from 25600 samples per second. Data collection took 10 seconds for each signal.

In Fig. 3, typical vibration signal without load variations for five operating conditions are displayed. From here it can be concluded that angle and parallel misalignment have far greater amplitude of vibration than normal operating mode, soft foot and rotator imbalance. Also, the soft foot signal behaves variable in time, with a period of 2.5 seconds. This means high frequencies fade in and fade out every 2.5 seconds. Detecting the fault is possible with a window length of 2.5 seconds. However, observing windows of this width can lead to an alternate change in the detected operating conditions and therefore a window with a width of 10 seconds is observed. This provides more information to the machine learning algorithm.

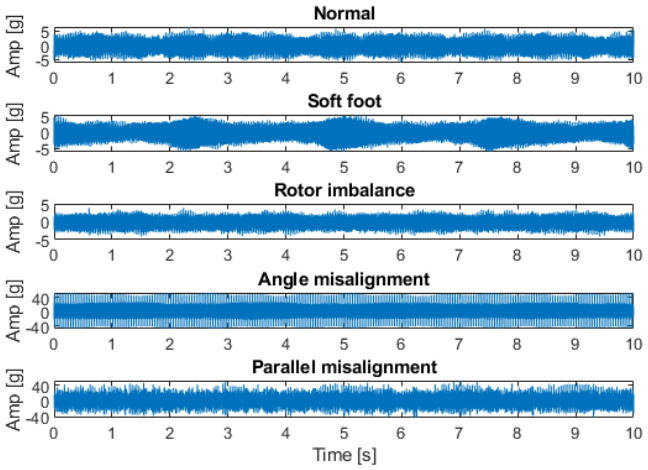

Fig. 3. Vibration signals of operating states in the time domain

The transformation of a signal from a time domain into a frequency domain is performed using algorithm of Fast Fourier transformation. Schematic representation of the data collection process is shown in Fig. 4.

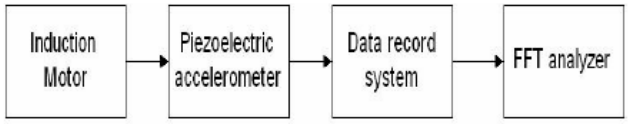

Fig. 4. Schematic representation of the data collection process

As expected, different anomalies result in different frequency vibration spectrum. Literature [10] - [12] suggest usage of frequency up to six times of the shaft rotational frequency (125 Hz in our case). With data inspection, distinguishable signature of different anomalies was observed even on higher frequencies (this can be seen in Fig.5.). Due to the lack of a clear difference between mechanical failures, because most failures occur on the same characteristic frequencies, which are shown in Section II, for this analysis, a wider frequency spectrum (up to 350 Hz) is used.

Fig. 5. shows the frequency spectrum of the signals of all five operating states. To distinguish operating modes, in addition to the characteristic frequency components other components in the frequency spectrum can be observed. This analysis provides more information to machine learning algorithms, which use them to make decisions about the affiliation of the failure class.

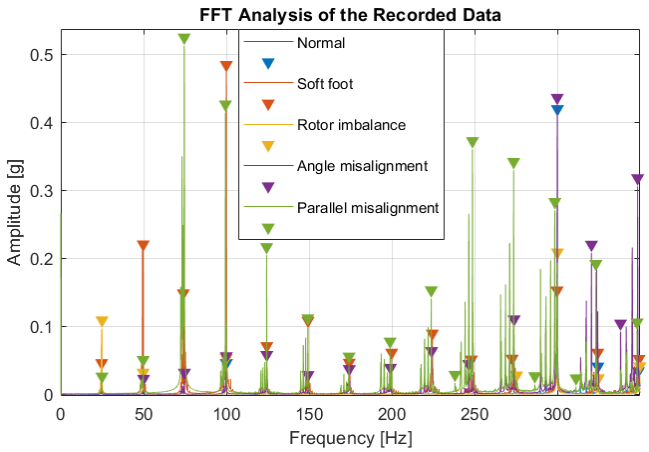

Fig. 5. Frequency spectrum of vibration signals for five operating modes

Components with the largest amplitude, as well as the frequencies at which they occur, are expected to have the greatest influence on the correct detection of the operating mode. In Fig. 5., frequency spectrum of vibration from several examples of all working conditions is presented.

As a tool for justification of selected features, MATLAB's feature selection using neighborhood component analysis for classification is used [15]. For the test in the feature selection algorithm, 30 features in total are used. The first 15 are amplitudes of 15 highest peaks in frequency spectrum in range up to 300 Hz. The other half of the features are their corresponding frequencies. The obtained results are shown in Fig. 6.

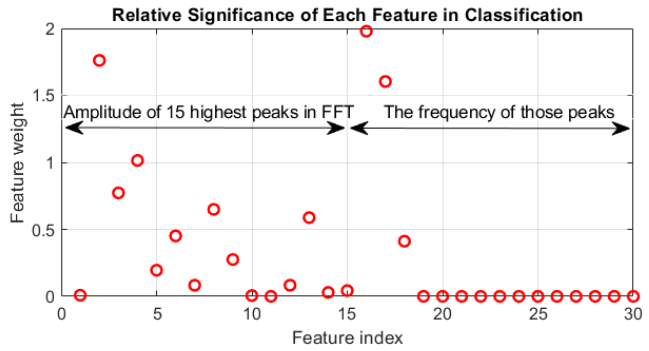

Fig. 6. Impact of features on the correct detection of the operating mode

The results confirm the dominant impact of the components with the highest amplitudes. It also concludes that it is sufficient to use the dataset that consists of ten components of frequency spectra (peaks) with the highest amplitude and corresponding frequencies, because the last five components have no significant impacts. Machine learning algorithms decide about affiliation of the class of failure, based on twenty features. Because of the reduced number of features, classification models are faster in prediction than if all thirty features are used.

Table II gives an overview of the operating conditions of the induction motor and class labels that are necessary for using the dataset in supervised machine learning.

TABLE II
OVERVIEW OF OPERATING MODES AND CLASS LABELS

Operating mode	Class label
Normal operating mode	0
Soft foot	1
Imbalance	2
Angle Misalignment	3
Parallel Misalignment	4

Share of each class in the dataset is presented in Fig. 7.

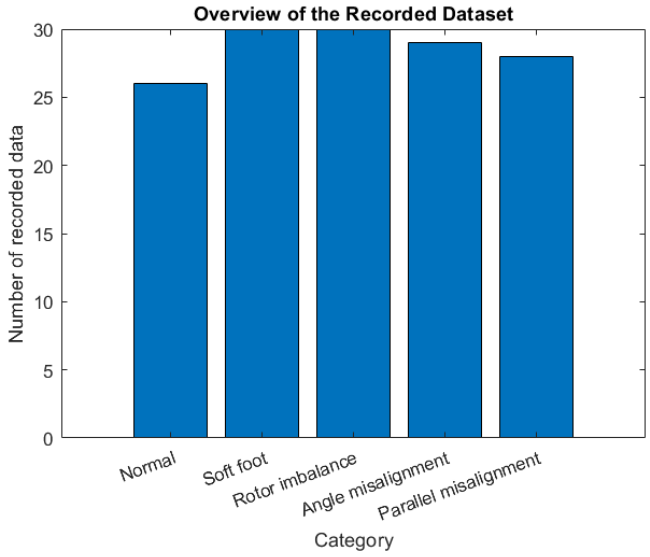

Fig. 7. Overview of recorded dataset

This dataset is loaded into the MATLAB application *Classificaton Learner*. The method of using the MATLAB application *Classification Learner* is described in [16].

IV. ANALYSIS OF CLASSIFICATION MODELS

The measure for assessing the quality of the formed classification model is defined as the ratio of the number of correctly classified examples to the total number of classification examples (*Accuracy*). Confusion matrix and Receiver operating characteristic curve, also called *ROC* curve are tools for analyzing the obtained classification models.

Observing only the *Accuracy* of the classification model for a multi-class problem can lead to misleading information, because there is no insight into the accuracy of the classes. The Confusion matrix is used to analyze the multi-class problem. Each row of the matrix corresponds to a predicted class. Each column of the matrix corresponds to an actual class. Correct and incorrect classifications are then filled in in the table. The total number of correct predictions for a class go into the expected row for that class value and the predicted column for that class value. In the same way, the total number of incorrect predictions for a class go into the expected row for that class value and the predicted column for that class value. At the end, matrix on the main diagonal contains information on properly classified examples. Fields above the diagonal are false positives, and under the diagonal are false negative examples. False positives are examples that are predicted as positive but it is actually negative. False negatives are examples that are predicted as negative but it is actually positive.

The *ROC* curve is the most commonly used way to visualize the performance of a classifier and this is a good way to visualize the performance of a classifier in order to select a suitable operating point, or decision threshold. Area Under Curve (AUC) is the best way to summarize classifier's performance in a single number. The *ROC* curve is a two-dimensional representation that contains data from the confusion matrix, which has a false positive rate on the x-axis of the selected class, and at the y-axis has a true positive rate. A false positive rate is the proportion of negative examples that are wrongly classified as positive, and the true positive rate represents the proportion of correctly classified examples from the total number of examples. Point (0,1) is the perfect classifier: classifies all positive and all negative examples correctly [17].

The first classification model was formed using the decision tree algorithm. The accuracy of prediction of new (unlabeled) data is 89.5%, while the success of data prediction by class is shown in Fig. 8.

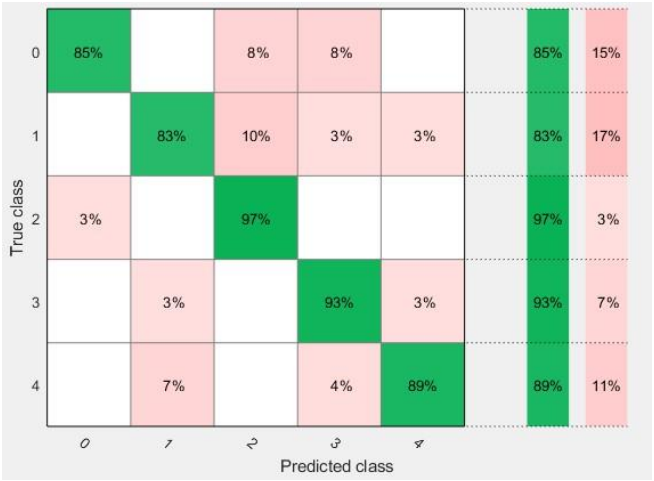

Fig. 8. Confusion matrix – decision tree

From the confusion matrix of this model we can conclude that all data by class is classified with high precision. The results show that the algorithm clearly separates the imbalance rotor from parallel and angle misalignment, and has certain problems with the distinction in classes 0 and 1. This happens because the soft foot at some moments during oscillation has similar characteristics as the rotor imbalance. Also, under load that is close to nominal, vibrations in all operating modes are damped, which affects the possibility of differentiation.

Fig. 9. shows the *ROC* curve of the decision tree algorithm whose x-axis has a false positive rate of Class 2, and on the y-axis, a true positive rate of the same class. This class is shown because it has the highest rate of positively classed examples and the current classifier is closest to the ideal classifier.

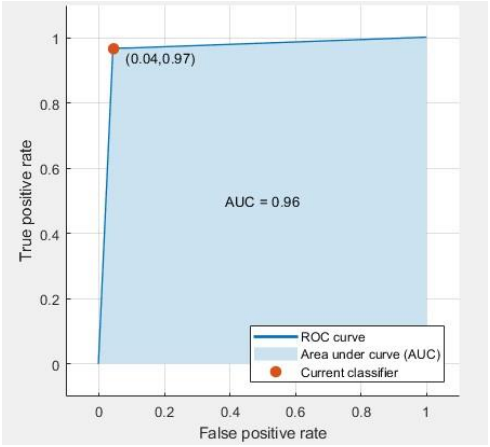

Fig. 9. *ROC* curve for class 2 – decision tree

The second observed model was formed by quadratic support vector machine algorithm (SVM). The accuracy of this model is 90.9%. The confusion matrix is shown in Fig. 10.

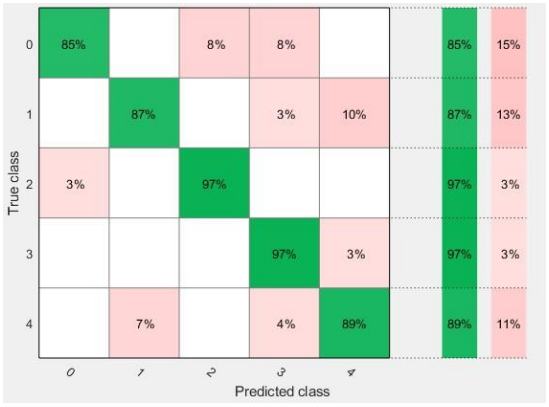

Fig. 10. Confusion matrix – support vector machine

The classification model formed by this algorithm shows the highest accuracy in distinguishing faults, but also in some cases makes mistakes because the characteristic frequencies of faults are similar.

Observing the *ROC* curve of Class 3 shown in Fig. 11, it can be concluded that this class is most precisely classified because the current classifier is very close to the ideal classifier.

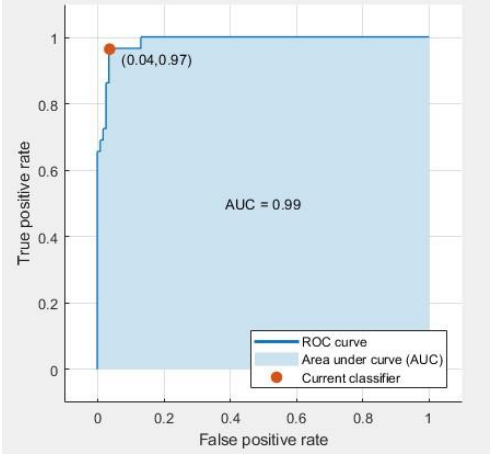

Fig. 11. *ROC* curve for class 23 – support vector machine

The last considered classification model was formed by the k-Nearest Neighbors algorithm (k-NN). A model with the highest precision is obtained when a decision on belonging to the class is made by observing the 10 nearest neighbors. The accuracy in this case is 83.2%. The confusion matrix is shown in Fig. 12.

Fig. 12. Confusion matrix – k-NN

This model has an additional problem with Class 0 and Class 3, which this model does not recommend in the analysis of faults for classes 0 to 2, but to distinguish misalignments compared to other operating modes can be used.

V. Conclusion

The obtained results show very good qualities of classification models trained with decision tree and machine support vectors algorithms. The quality of these models is primarily reflected in the ability to very well distinguish correctly from an incorrect operating condition, but also to classify vibrating signals of faulty operating modes. Software that can predict the future operating conditions of the motor by measuring vibrations would allow undesired operating states not to occur frequently. This would also reduce the variable operating costs of the plant, which was the aim that was set at the beginning. For the development and implementation of such software, it is necessary to create a classification model that will have a large database for training. This is exactly the task for future research. Also, in the future work will be considered motor with two or more defective operating conditions that exist at the same time, in order to obtain a more robust classification model.

Design and Analysis of the Droop Control Method for Parallel Inverters Operation in the Autonomous Microgrid

Bojan Banković, Nebojša Mitrović, Milutin Petronijević, Filip Filipović and Vojkan Kostić

***Abstract*—This paper evaluates the stability of the autonomous low inertia low voltage microgrid. Tested microgrid consists of two inverters connected to the load via power lines of different impedance. The decentralized control of the inverters is realised through the application of the conventional and opposite droop method. For both control methods dynamic phasor model is derived for stability analysis. Validation of initially selected and then retuned droop control parameters for both methods is done by simulation in order to show credibility of stability analysis method. Dynamic and steady state active and reactive power sharing is shown along with the roots of the characteristic equation. Simulation of the autonomous microgrid operation with applied droop control strategies is performed in MATLAB/Simulink software.**

***Index Terms*— Autonomous microgrid, conventional droop control, opposite droop control, parallel inverter operation.**

I. INTRODUCTION

THE contribution of the Renewable Energy Sources (RES) to the total electricity power production is increasing, taking over the majority share in relation to traditional energy sources [1]. The systems based on local energy production increase the reliability of the power supply, efficiency and cost effectiveness. Such systems integrate a large number of low-power energy sources in different locations forming microgrids with Distributed Energy Sources (DES). The most of the energy sources in the microgrid are connected through the power electronic devices in its various topologies [2]. These devices are connected in parallel bringing the new challenges in the power delivery, system stability, reliability and energy efficiency comparing to the traditional power systems [3]. Substantial efforts are made in order to find more efficient, reliable and robust control algorithms for its control.

A definition of the microgrid is given in [4] as a group of interconnected loads and distributed energy resources within clearly defined electrical boundaries, that acts as a single controllable entity with respect to the grid. Some rural areas due to lack of the technical possibility for connection to the main power grid, operate as an autonomous microgrid. Coordination of power sources in microgrid is done through multistage management and control structures, followed by an optional communication infrastructure [5]. A decentralized control of each generation unit with communication-less control algorithm is performed in order to secure reliability, power flow control and safe operation, with the application of the droop control concept. The droop control is implemented in grid-supporting inverters to regulate the exchange of active and reactive power with the grid in order to keep the voltage frequency and amplitude in desired boundaries [6].

In literature, droop control strategy is usually selected according to the ratio of line resistance and inductance. For a grid with dominantly inductive lines, active power control is linked to the frequency and reactive power is linked to the voltage (P-ω/Q-V). Basic droop control that utilises this dependence is called conventional, or direct droop. For a low voltage grid with a dominant active resistance, the voltage amplitude depends mainly on the active power, while the voltage frequency is affected by the reactive power (P-V/Q-ω). If this basic droop control concept is used, it is called opposite droop. The problem with opposite droop is inability of proportional active power sharing, thus the tendency for the load to be supplied by the closest inverter in the grid [7].

The purpose of this paper is examination of the microgrid system stability and load sharing capabilities among the inverters for different designed droop control strategies. The testing was done on a model of two inverters in autonomous low voltage microgrid with low inertia, supplying the load through different line impedances. Along with opposite droop recommended for this case, direct droop strategy is also tested with coefficients calculated according to [9]. Validity of selected coefficients is verified using dynamic phasor model (DPM) analysis [10]. The transient response in the load step change and steady state power sharing performance are presented. The microgrid system of the two DES is modelled and simulated in MATLAB/Simulink R2018b software. Inverter, power lines, load and measurements are built using generic components from Simulink Simscape library, while the complete control subsystem is developed by authors.

II. Basic Droop Control Methods

The microgrid system examined in this paper is presented in Fig. 1. It consists of two DESs with the Voltage Source Inverters (VSI) along with their LCL filters, connected in parallel and supplying consumers concentrated at one connection point. The LCL filter is used to mitigate VSI's switching harmonics. The consumers are at different distances from DESs. This implies the difference in power line impedance between two inverters ($\underline{Z}_{l1}$ and $\underline{Z}_{l2}$).

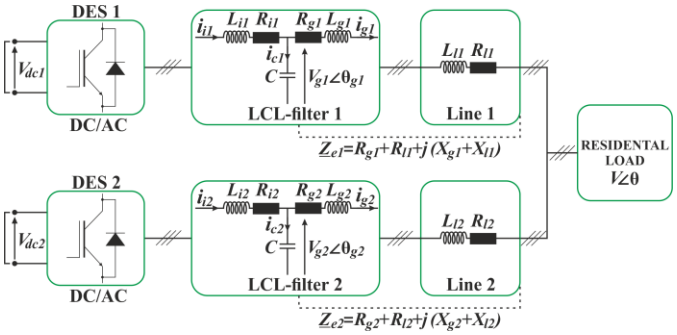

Fig. 1. The autonomous microgrid system with two DES.

The inverter output active and reactive power are given by [10]:

$$P_n = \frac{3}{R_{en}^2 + X_{en}^2}\left(R_{en}V_{gn}^2 - R_{en}V_{gn}V\cos(\delta_n) + X_{en}V_{gn}V\sin(\delta_n)\right), \quad (1)$$

$$Q_n = \frac{3}{R_{en}^2 + X_{en}^2}\left(X_{en}V_{gn}^2 - X_{en}V_{gn}V\cos(\delta_n) - R_{en}V_{gn}V\sin(\delta_n)\right), \quad (2)$$

where subscript n denotes n-th inverter branch information, δ_n (power angle), represent the phase angle difference between the capacitor voltage V_{gn} and load voltage V. Namely, the capacitor voltages are selected as output voltage control variables. In above equations, the LCL filter grid side impedance $\underline{Z}_{gn}$ is added to the power line impedance $\underline{Z}_{ln}$ and equivalent impedance $\underline{Z}_{en}=\underline{Z}_{gn}+\underline{Z}_{ln}=R_{en}+jX_{en}$. Typical line parameters for different voltage levels are given in Table I according to [6] and [8].

TABLE I
Line Parameter for Different Voltage Levels

Type of Line	R [Ω/km]	X [Ω/km]	Ratio, R/X
Low Voltage	0.642	0.083	7.7
Medium Voltage	0.161	0.190	0.85
High Voltage	0.06	0.191	0.31

A. Direct Droop Method

A P-ω/Q-V droop method has been introduced for microgrid control in [10]. This control method represents the simple communication-less/decentralized control with plug and play feature for new DES installation.

For a microgrid with dominantly inductive impedance, line active resistance can be neglected, thus simplifying the expression (1) and (2) in the form presented in (3) and (4):

$$P_n = 3\frac{V_{gn}V}{X_{en}}\sin\delta_n, \quad (3)$$

$$Q_n = 3\frac{V_{gn}\left(V_{gn} - V\cos\delta_n\right)}{X_{en}}. \quad (4)$$

Strong active power-power angle and reactive power-inverter output voltage correlation can be observed from the equations (3) and (4). Using direct droop method, the inverter output frequency ω and the inverter output voltage V_g can be controlled by means of the droop characteristics:

$$\omega_n = \omega_n^* - k_{pn}(P_n - P_n^*), \quad (5)$$

$$V_{gn} = V_{gn}^* - k_{qn}(Q_n - Q_n^*), \quad (6)$$

where k_{pn} and k_{qn} are the frequency and voltage magnitude droop coefficients of the n-th inverter. In the expressions (5) and (6) ω_n^* and V_{gn}^* presents capacitor voltage frequency and phase amplitude setpoint, while ω_n and V_{gn} are measured values of the same variables. The active power P and reactive power Q are filtered references from power calculation block in droop controller presented in Fig. 2.

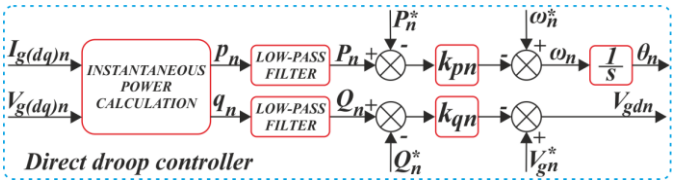

Fig. 2. Direct droop control structure.

The power sharing via direct droop control techniques is highly affected by the value of the line impedance and grid elements like transformers between the load's connection and the power supply side [5].

B. Opposite Droop Method

The modification of direct droop method suitable for operation in grid with dominant active resistance in lines is described in [7]. By neglecting the inductance in lines, equations (1) and (2) can be presented in the following form:

$$P_n = 3\frac{V_{gn}\left(V_{gn} - V\cos\delta_n\right)}{R_{en}}, \quad (7)$$

$$Q_n = -3\frac{V_{gn}V}{R_{en}}\sin\delta_n. \quad (8)$$

Opposite of direct droop, here can be seen strong active power-inverter output voltage and reactive power-power angle correlation. Using opposite droop method, the inverter output frequency ω and the inverter output voltage V_g are controlled

by means of the opposite characteristics:

$$\omega_n = \omega_n^* + k_{qon}(Q_n - Q_n^*), \tag{9}$$

$$V_{gn} = V_{gn}^* - k_{pon}(P_n - P_n^*), \tag{10}$$

where the k_{qon} and k_{pon} are voltage frequency and amplitude opposite droop coefficients of the n-th inverter. The advantages of the opposite droop method compared to the conventional droop control are presented in [11]. The opposite droop control structure is shown in Fig. 3.

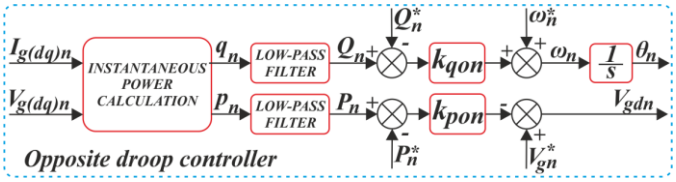

Fig. 3. Opposite droop control structure.

C. Additional Considerations

For the parallel connected VSIs, the power distribution has been achieved according to proper droop coefficient selection for each inverter. Their initial selection is done according to the desired voltage frequency and amplitude change for the maximum appropriate power component change ((11) for direct and (12) for opposite droop).

$$k_{pn} = \frac{\Delta\omega_n}{\Delta P_{\max,n}} \wedge k_{qn} = \frac{\Delta V_{gn}}{\Delta Q_{\max,n}}, \tag{11}$$

$$k_{pon} = \frac{\Delta V_{gn}}{\Delta P_{\max,n}} \wedge k_{qon} = \frac{\Delta\omega_n}{\Delta Q_{\max,n}}. \tag{12}$$

If the load share among the inverters proportional to their rated power is desired, conditions (13) or (14) must be fulfilled for direct or opposite control, respectively:

$$\Delta P_1 k_{p1} = \ldots = \Delta P_n k_{pn} \wedge \Delta Q_1 k_{q1} = \ldots = \Delta Q_n k_{qn}, \tag{13}$$

$$\Delta P_1 k_{po1} = \ldots = \Delta P_n k_{pon} \wedge \Delta Q_1 k_{qo1} = \ldots = \Delta Q_n k_{qon}. \tag{14}$$

Output voltage amplitude and frequency of each inverter is generated according to its calculated active and reactive power. If instantaneous output active (p) and reactive power (q) are estimated in synchronous (dq) frame, equations for power calculation are given in (15):

$$p = \frac{3}{2}\left(V_{gd}I_{gd} + V_{gq}I_{gq}\right) \wedge q = \frac{3}{2}\left(V_{gd}I_{gq} - V_{gq}I_{gd}\right). \tag{15}$$

Instantaneous active and reactive power are not used per se in the droop control algorithm. These quantities are averaged over certain time period, usually using a first order low pass filter.

A complete structure of the droop controller for one inverter with inner current control loop and outer voltage control loop is presented in Fig. 4, according to [6].

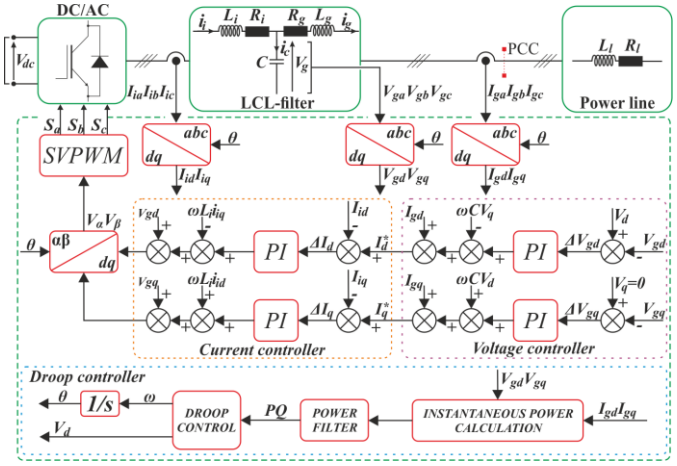

Fig. 4. Applied droop control structure for one inverter.

The output quantities from droop control block are voltage reference V_d and frequency ω. The angle θ for ($abc \rightarrow dq$) transformation is obtained through frequency integration.

III. Droop Coefficients Tuning for Low Voltage Grid

For the system stability analysis, dynamic phasor modelling is used [10]. Impact of the power low pass filter on the system stability cannot be neglected due to relatively large time constant. The influence of the current and voltage control structures is neglected in this stability analysis. In order to obtain characteristic equation of the system using DPM, equations (1) and (2) have to be rewritten and power low pass filter transfer function is induced as:

$$P_n = \frac{3\left(L_{en}s + R_{en}\right)\left(V_{gn}^2 - V_{gn}V\cos(\delta_n)\right)}{\left(L_{en}s + R_{en}\right)^2 + \left(\omega L_{en}\right)^2} + \frac{3\left(\omega L_{en}\right)V_{gn}V\sin(\delta_n)}{\left(L_{en}s + R_{en}\right)^2 + \left(\omega L_{en}\right)^2}, \tag{16}$$

$$Q_n = \frac{3\left(\omega L_{en}\right)\left(V_{gn}^2 - V_{gn}V\cos(\delta_n)\right)}{\left(L_{en}s + R_{en}\right)^2 + \left(\omega L_{en}\right)^2} - \frac{3\left(L_{en}s + R_{en}\right)V_{gn}V\sin(\delta_n)}{\left(L_{en}s + R_{en}\right)^2 + \left(\omega L_{en}\right)^2}, \tag{17}$$

$$P = \frac{\omega_f}{s + \omega_f}p \wedge Q = \frac{\omega_f}{s + \omega_f}q, \tag{18}$$

where s denotes Laplace variable and ω_f is a crossover frequency of first order low pass filter. For small disturbances around equilibrium point (δ_e, V_{ge}, V_e), linearized version of equations (16) and (17) can be obtained along with appropriate coefficients as:

$$\Delta P_n = k_{pen}\Delta V_{gn} + k_{pdn}\Delta\delta_n, \tag{19}$$

$$\Delta Q_n = k_{qen}\Delta V_{gn} + k_{qdn}\Delta\delta_n, \tag{20}$$

$$k_{pen} = \frac{3\left(L_{en}s + R_{en}\right)V_{gn}}{\left(L_{en}s + R_{en}\right)^2 + \left(\omega L_{en}\right)^2}, \tag{21}$$

$$k_{pdn} = \frac{3\omega L_{en}V_{gn}^2}{\left(L_{en}s + R_{en}\right)^2 + \left(\omega L_{en}\right)^2}, \tag{22}$$

$$k_{qen} = \frac{3\omega L_{en}V_{gn}}{\left(L_{en}s + R_{en}\right)^2 + \left(\omega L_{en}\right)^2}, \tag{23}$$

$$k_{qdn}=\frac{-3\left(L_{en}s+R_{en}\right)V_{gn}^2}{\left(L_{en}s+R_{en}\right)^2+\left(\omega L_{en}\right)^2}. \quad (24)$$

Equations (19)-(24) have to comply in direct and opposite method. Derivation of the model used for dynamic phasor analysis will be conducted separately for direct and opposite droop control in the next two sections.

A. Direct Droop Method Dynamic Phasor Model

Application of direct droop control on the specified low voltage grid would be considered inadequate following general recommendations. It is shown in [8] that direct droop control has indeed desired behaviour in grid with high active resistance, if droop coefficients from certain range are selected. In this paper droop coefficients will be selected according to the stability analysis from the DFM. Linearized version of equations (5) and (6) can be written in form:

$$s\Delta\delta_n=\Delta\omega_n^*-k_{pn}\Delta P_n+k_{pn}\Delta P_n^*, \quad (25)$$

$$\Delta V_{gn}=\Delta V_{gn}^*-k_{qn}\Delta Q_n+k_{qn}\Delta Q_n^*. \quad (26)$$

Combination of equations (18)-(20) and (25)-(26) provides following relations:

$$\Delta\omega_n\Big|_{\Delta\omega_n^*=\Delta P_n^*=0}=\frac{-k_{pn}\omega_f}{s+\omega_f}\left(k_{pen}\Delta V_{gn}+k_{pdn}\Delta\delta_n\right), \quad (27)$$

$$\Delta V_{gn}\Big|_{\Delta\omega_n^*=\Delta P_n^*=0}=\frac{-k_{qn}\omega_f}{s+\omega_f}\left(k_{qen}\Delta V_{gn}+k_{qdn}\Delta\delta_n\right). \quad (28)$$

Characteristic equation is obtained with combination (18)-(20) and (25)-(28) in the form:

$$as^5+bs^4+cs^3+ds^2+es+f=0, \quad (29)$$

where appropriate coefficient *a* to *f* can be found in [10].

B. Opposite Droop Method Dynamic Phasor Model

Linearized version of equations (9) and (10) is derived in equations (30) and (31) as:

$$s\Delta\delta_n=\Delta\omega_n^*+k_{qon}\Delta Q_n-k_{qon}\Delta Q_n^*, \quad (30)$$

$$\Delta V_{gn}=\Delta V_{gn}^*-k_{pon}\Delta P_n+k_{pon}\Delta P_n^*. \quad (31)$$

With combination of (18)-(20) and (30)-(31) relations (32) and (33) are provided as:

$$\Delta\omega_n=\frac{k_{qon}\omega_f}{s+\omega_f}\left(k_{qen}\Delta V_{gn}+k_{qdn}\Delta\delta_n\right), \quad (32)$$

$$\Delta V_{gn}=\frac{-k_{pon}\omega_f}{s+\omega_f}\left(k_{pen}\Delta V_{gn}+k_{pdn}\Delta\delta_n\right). \quad (33)$$

From previous two equations, characteristic equation of the form presented in (29) can be obtained, with the coefficients:

$$a=L_{en}^2, \quad (34)$$

$$b=2R_{en}L_{en}+2\omega_f L_{en}^2, \quad (35)$$

$$c=R_{en}^2+\omega^2L_{en}^2+4\omega_f R_{en}L_{en}+\omega_f^2L_{en}^2+3\omega_f L_{en}V_{gn}k_{pon}, \quad (36)$$

$$d=2\omega_f R_{en}^2+2\omega_f\omega^2L_{en}^2+2\omega_f^2R_{en}L_{en}+3\omega_f L_{en}V_{gn}^2k_{qon}+ +3\omega_f^2L_{en}V_{gn}k_{pon}+3\omega_f R_{en}V_{gn}k_{pon}, \quad (37)$$

$$e=\omega_f^2R_{en}^2+\omega_f^2\omega^2L_{en}^2+3\omega_f^2R_{en}V_{gn}k_{pon}+ +3\omega_f R_{en}V_{gn}^2k_{qon}+3\omega_f^2L_{en}V_{gn}^2k_{qon}, \quad (38)$$

$$f=3\omega_f^2R_{en}V_{gn}^2k_{qon}+9\omega_f^2V_{gn}^3k_{pon}k_{qon}. \quad (39)$$

C. Initial Coefficient Selection and Validity

Selection of droop control coefficients has a direct impact on stability of the microgrid. Their initial selection is done according to the desired voltage frequency and amplitude deviations. In this case, initial coefficient selection is made with desired voltage amplitude and frequency droop of 10 % and 1 % for rated appropriate power, respectively. Details of the analysed microgrid system are shown in Table II. It can be observed that although low voltage lines are dominantly resistive, combination of inverter inductance and lines provides dominantly inductive equivalent impedance.

TABLE II
PARAMETER OF TWO PARALLEL INVERTERS AND DISTRIBUTION LINES IN SIMULATION

DES 1 = DES 2	
DC voltage V_{dc1}, V_{dc2}	650 V
Rated active power P_1, P_2	7.5 kW
Rated reactive power Q_1, Q_2	3.75 kVAR
Inverter switching frequency f_{sw1}, f_{sw1}	10 kHz
Inverter filter resistance R_{i1}, R_{i2}	0.02 Ω
Inverter filter inductance L_{i1}, L_{i2}	4 mH
Inverter filter capacitance C_1, C_2	3.5 μF
Grid side filter resistance R_{g1}, R_{g2}	0.015 Ω
Grid side filter inductance L_{g1}, L_{g2}	2.4 mH
LINE PARAMETERS	
Line 1 $\underline{Z}_{l1}$ (l≈50 m)	(0.0321+j0.00415) Ω
Line 2 $\underline{Z}_{l2}$ (l≈250 m)	(0.1605+j0.02075) Ω
LOAD PARAMETERS	
Load 1 (pure active load R)	P=8 kW
Load 2 (RL load cosφ=0.8)	S=7.5 kVA

Initial value of coefficients according to desired droop are k_p=4.18·10^{-4} rad/(Ws), k_q=8.7·10^{-3} V/(VAR), k_{po}=4.3·10^{-3} V/(W), k_{qo}=8.37·10^{-4} rad/(VARs). Coefficients are calculated on maximum value of phase voltage. Crossover frequency of the low pass filter is held constant at ω_f=62.8 rad/s.

In Fig. 5, locations of characteristic equation poles are shown for the direct droop method. It can be observed that initial coefficients result in unstable system. If power sharing balance is to be maintained, coefficients k_p and k_q have to be coordinated selected so that all solutions of characteristic equation of every inverter have negative real part and ratio presented in (13) is maintained.

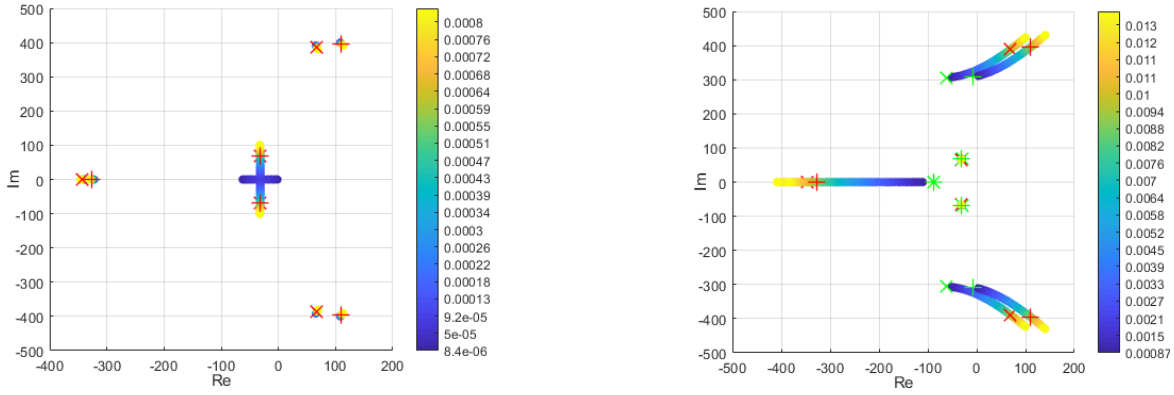

Fig. 5. Direct droop method: location of characteristic equation poles with variation of k_p (left) and k_q (right) of both inverters. Colour bar denotes value of the appropriate coefficient in the specific point. Red (green) marks represent poles of the initial (retuned) system. Inverter with shorter power line is denoted with "+", while inverter with longer supply line is denoted with "x". Selected values are k_p=4.18·10^{-4} rad/(Ws), k_q=4.3·10^{-4} V/(VAR).

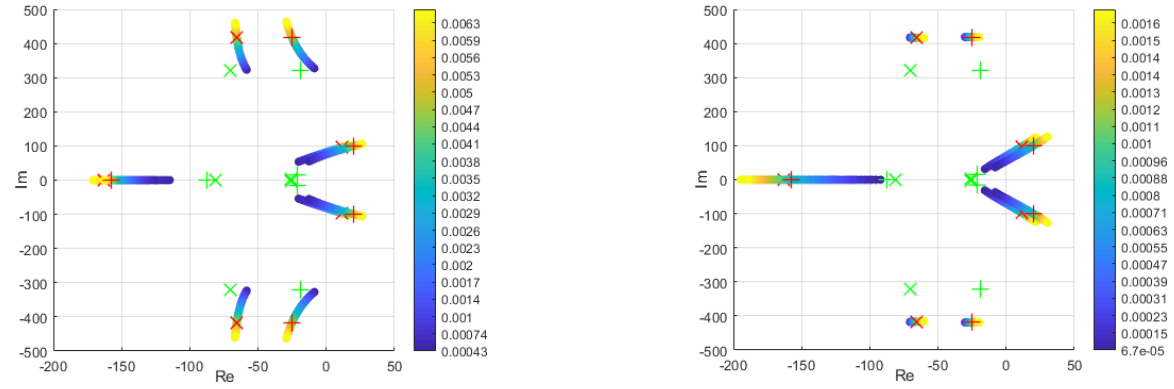

Fig. 6. Opposite droop method location of characteristic equation poles with variation of k_{po} (left) and k_{qo} (right) of both inverters. Colour bar denotes value of the appropriate coefficient in the specific point. Red (green) marks represent poles of the initial (retuned) system. Inverter with shorter power line is denoted with "+", while inverter with longer supply line is denoted with "x". Selected values are k_{po}=2.17·10^{-4} V/(W), k_{qo}=1.67·10^{-4} rad/(VARs).

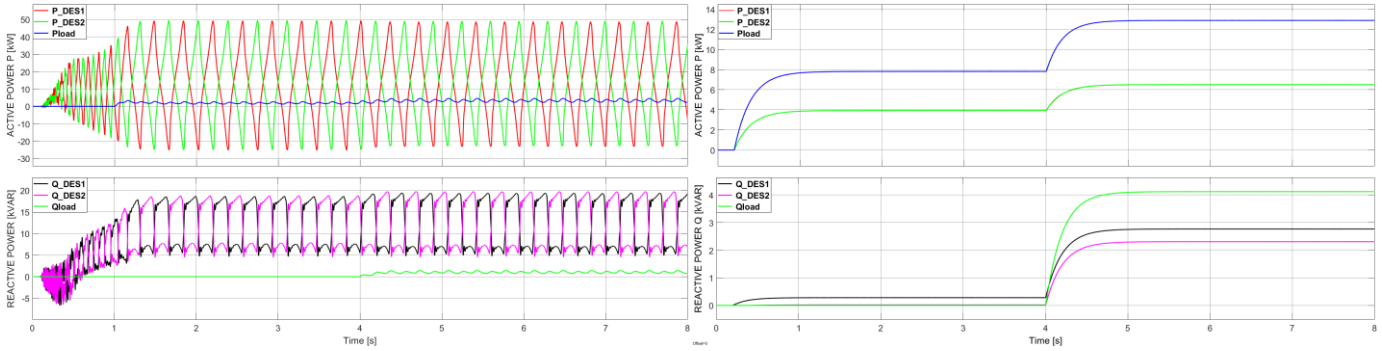

Fig. 7. Direct droop method active and reactive power sharing with initial droop coefficients (left) and with retuned coefficients (right).

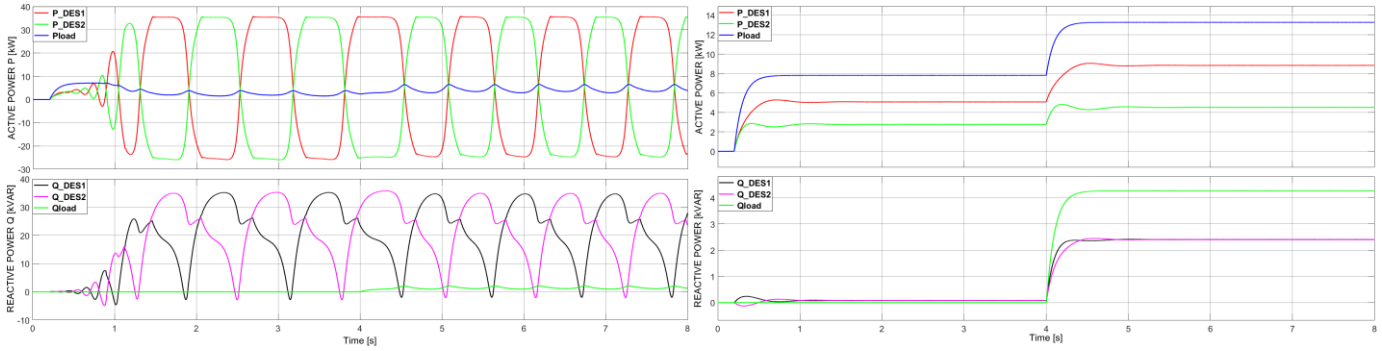

Fig. 8. Opposite droop method active and reactive power sharing with initial droop coefficients (left) and with retuned coefficients (right).

From the Fig 5. can be observed that variation of k_p has low impact on stability for selected k_q. System is retuned with only k_q variation.

Fig. 6. shows location of characteristic equation poles for k_{po} and k_{qo} variation in opposite droop method. Initial coefficients values result in unstable system. Stabilization is done with change of both parameters.

The detailed model of the system from Fig. 1 is done in MATLAB/Simulink, with the implementation of the control structure from Fig. 3 for each inverter. At the start of the simulation both inverters are operating in parallel, without load connected to the microgrid up to t=0.2 s. In that moment an active load R, power of 8 kW is connected as a consumption up to the time t=4 s. In the t=4 s the RL load of apparent power 7.5 kVA and cosφ=0.8 is added as a consumption.

Power sharing capability of inverters is presented in Figs. 7 and 8. Left graphs show active and reactive power sharing for initial droop setup and it can be observed that system is unstable. For a stable system on right graph in the same figure, characteristic power sharing can be seen. With the direct droop method, active power is shared proportionally among inverters, while the share of reactive power is disproportional. Opposite droop method enables equal share of reactive power, while closer inverter provides larger share of active power.

IV. Conclusion

Stability and load sharing performance of the conventional and opposite droop control is analysed in this paper for the load step change in the case of unequal line parameters of the microgrid. Basic direct and opposite droop control methods are presented along with typical control structure of the inverter. Validation of selected droop coefficients is done through stability analysis using dynamic phasor model of autonomous microgrid.

Direct droop method is applicable in this case in low voltage grid. Although power lines have dominantly resistive character, combination of inverter inductance and line impedance results in equivalent impedance that is predominately inductive. Active power is shared as desired, while reactive power has a sharing disbalance. Further improvements of basic droop method that address the issue of reactive power sharing will be considered in future work.

Opposite droop method, when properly tuned, enables desired sharing of reactive power, with a drawback of disproportional active power share. As expected, closer inverter supplies load with higher share of active power.

Dynamic phasor method provides credible results for stability analysis of both direct and opposite droop control strategy. Using it, autonomous microgrid is modelled via characteristic equation or fifth order, that is relatively small compared to full model analysis. This small order of equation is possible because dynamic of inverter control is neglected. Dynamic of current and voltage control loops are neglected, thus implying that obtained stability results need to be taken in consideration with that in mind.

***Апстракт*—У овом раду представљен је пумпни систем реализован на Факултету техничких наука у Чачку. Систем се састоји од резервоара, трофазне вишестепене центрифугалне пумпе, фреквентног претварача, преливног (бајпас) и пригушног вентила. Помоћу сензора притиска и протока који су постављени на цевоводу врши се аквизиција на основу које се могу одредити параметри пумпног система, и помоћу којих се може вршити регулација протока и притиска. Процедура извођења лабораторијских вежби и добијени резултати са коментарима приказани су у експерименталном делу рада.**

***Кључне речи*—пумпни систем, мерење протока, мерење притиска, аквизиција, LabVIEW, регулација**

I. Увод

Основни закони везани за хидрауличне и пумпне системе се једноставно могу потврдити кроз едукативне лабораторијске поставке. За њихову реализацију довољан је резервоар, пумпа са електро мотором, цевовод и вентили. Снимање карактеристика пумпе или хидрауличног система могуће је постављањем мерача протока и притиска на цевовод. Ови уређаји могу бити аналогни или дигитални, повезани са мерно-аквизиционим системом који бележи податке на рачунару. Примери одређивања карактеристика хидрауличног система и пумпи дати су у [1]-[2].

Пумпни системи се могу користити за одређивање карактеристика компоненти које се налазе у цевоводу као што су турбине, вентили, колена, рачве итд. На овај начин се могу упоредити теоријске карактеристике са каталошким и експериментално добијеним карактеристикама одређене компоненте. За одређивање хидрауличне снаге (или губитка снаге) неке од хидрауличних компоненти потребно је пратити улазни и излазни притисак на испитиваној компоненти као и проток кроз ту компоненту. Лабораторијска поставка развијена на Факултету техничких наука у Чачку има могућност праћења наведених параметара што отвара могућност за извођење различитих испитивања и мерења на пумпном систему.

У раду је приказана поставка пумпног система, реализоване лабораторијске вежбе за одређивања карактеристика система и пумпе, као и регулационе структуре притиска и протока на овом систему. Зависност притиска и протока (p-Q) које описују систем и центрифугалну пумпу при различитим брзинама пумпе експериментално су добијене и графички су приказане кроз две реализоване лабораторијске вежбе. Регулација протока и притиска у систему реализована и приказана кроз друге две лабораторијске вежбе. Кроз реализацију наведених лабораторијских вежби постиже се боље разумевање и усвајање теоријских знања из хидраулике као и из регулације електромоторних погона.

II. Притисак, проток, и снага у пумпном систему

За одређивање радне тачке пумпног система потребно је одредити зависност притиска и протока пумпе у датом цевоводу. Измерене вредности притиска и протока се могу искористити за одређивање зависности: брзине пумпе (n) од протока (Q), притиска (p) од излазне снаге пумпе (P). Теоријска основа која описује утицај брзине пумпе на проток, притиска на снагу су дате у једначинама (1) [3]-[4].

$$\begin{aligned} Q &= Q_{\mathrm{n}}\left(n / n_{\mathrm{n}}\right) \\ p &= p_{\mathrm{n}}\left(n / n_{\mathrm{n}}\right)^2 \\ P &= P_{\mathrm{n}}\left(n / n_{\mathrm{n}}\right)^3 \end{aligned} \tag{1}$$

У претходној једначини називне вредности су дате са индексом n. Хидраулична снага центрифугалне пумпе се може одредити коришћењем измерених вредности притиска и протока применом једначине:

$$P = 100 Q \cdot p \tag{2}$$

где је: P – хидраулична снага [W], Q –проток [l/s], p –притисак [bar].

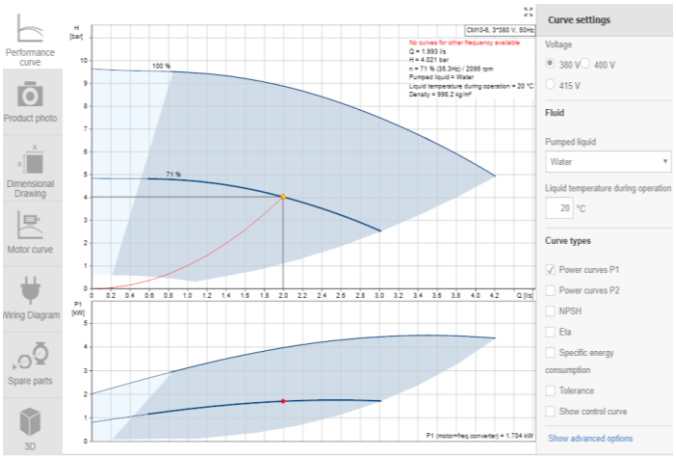
III. Експериментална поставка

У лабораторији за Процесну технику на Факултету техничких наука у Чачку, постављен је пумпни систем намењен за образовни и научно-истраживачки рад [5]. На слици 2 приказан је физички изглед пумпног система, док је на слици 3 приказана блок шема уграђених хидрауличних компоненти. Максималан притисак који се може постићи на овом систему је 6 бара, и максималан проток је 5 l/s.

Пумпни систем на слици 2 се састоји од отвореног резервоара капацитета 400 литара (1) из ког се систем напаја водом. Цевовод је направљен од 6/4" PVC цеви, које су спојене коленима и вентилима. Пумпа (3) је са шестостепеним центрифугалним радним колом које покреће асинхрони мотор. Произвођач пумпе је фирма *Grundfoss* тип CM10-6 A-R-I-E-AQQE F-A-A-N и постављена је у најнижој тачки (испод дна резервоара) [6]. Каталошки подаци одабране пумпе графички су приказани на слици 1.

Назначени подаци пумпе су: проток Q = 10 m^3/h (2,78 l/s), висина воденог стуба H = 78,3 m (притисак ≈7,7 bar), брзина обртања мотора n = 2900 min^{-1} и минимални индекс ефикасности MEI ≥ 0,52.

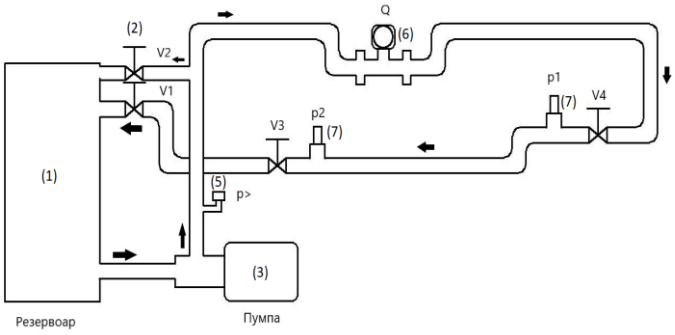
Пумпу покреће трофазни асинхрони мотор снаге 4 kW, фактора снаге 0,87-0,84, и степена искоришћења 85,5% (IE2 class).



Сл.1. Каталошки подаци произвођача [7]

За промену притиска и протока у систему (променом брзине обртања пумпе) користи се Danfoss VLT Aqua Drive FC 202 фреквентни претварач [8]. Овај претварач поседује додатне функције намењене раду са пумпним системима. Дефинисање референтне брзине пумпе се врши помоћу потенциометра (8) који се налази на вратима ормара у коме се налазе све електричне компоненте потребне за управљање системом.

Сл. 2. Изглед пумпног система у лабораторији



Сл. 3. Блок шема компоненти пумпног система

За мерење протока у цевоводу користи се електромагнетни мерач протока (6). Мерни опсег мерача протока је до 60 m^3/h (16,6 l/s). Мерач поседује екран осетљив на додир на коме се може пратити тренутна вредност протока. Проток се мери употребом струјног излаза 4 – 20 mA.

Мерење притиска врши се употребом два сензора притиска (7). Мерни опсег ових сензора је 0 – 10 бара, са струјним излазом 4 – 20 mA. Између два сензора притиска (10) налази се део цевовода који се може заменити са другим елементима који се испитују. Ти елементи могу бити вентили, колена, рачве, турбине, пумпе. У овом раду нису вршена испитивања других компоненти. За потребе предложених лабораторијских вежби између два сензора притиска постављена је цев, тако да ће притисак на оба сензора показивати исту вредност. На овај начин се одређују карактеристике пумпе и карактеристике система, као и регулација притиска и протока.

Струјни сигнали са мерача протока и притиска повезани су на NI 6009 картицу за снимање аналогних сигнала. Сигнали су прво преведени из струјних у напонске. Картица је галвански изолована од рачунара да би се избегле сметње при очитавању. Снимљени сигнали приказани су у LabVIEW програму у облику нумеричких података, а и у форми графика.

Пригушни вентил (2) се користи за дефинисање радне тачке система. Променом положаја вентила (затварањем вентила) може се снимити карактеристика пумпе и система. Лептир вентил има ручицу на себи и обележене положаје. Овим вентилом се такође омогућава уношење поремећаја у систем када се врши регулација притиска или протока.

Пресостат (5) је постављен на цевовод и има заштитну функцију. Овај електро-механички прекидач је постављен да би се спречило оштећење цевовода или неког другог елемента на цевоводу услед преоптерећења. У случају прекорачења притиска долази до прекидања струјног круга који напаја фреквентни претварач и искључује мотор. Поред пресостата налази се и аналогни барометар (4) који се користи за визуелни надзор притиска у систему.

IV. Реализоване лабораторијске вежбе

На описаном пумпном систему реализоване су следеће лабораторије вежбе:

А. снимање *p-Q* карактеристике пумпе,

Б. снимање карактеристике хидрауличног система,

В. регулација протока у систему, и

Г. регулација притиска у систему.

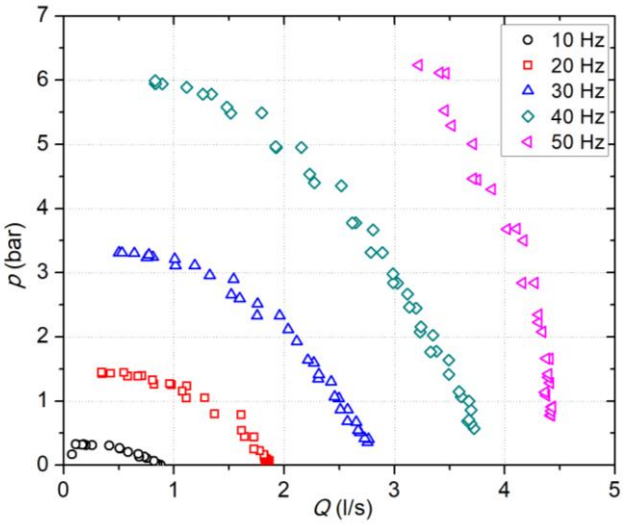
У наставку су дати задаци, поступци и примери резултат мерења – снимања карактеристика у стационарном стању и при регулацији притиска и протока.

А. Снимање p-Q карактеристике пумпе

Задатак вежбе: снимање *p-Q* карактеристика центрифугалне пумпе при различитим брзинама обртања.

Карактеристика пумпе се добија при одређеној брзини обртања, променом карактеристике хидрауличног система. Заправо, променом радне тачке врши се снимање карактеристике пумпе и то тако што се постепено затвара пригушни вентил. Снимање карактеристика пумпи врши се за више различитих брзина обртања пумпе (фреквенције прикључног напона асинхроног мотора).

На слици 4 дати су примери резултата снимања карактеристика пумпе. Приказане су карактеристике за пет различитих фреквенција прикључног напона асинхроног мотора.

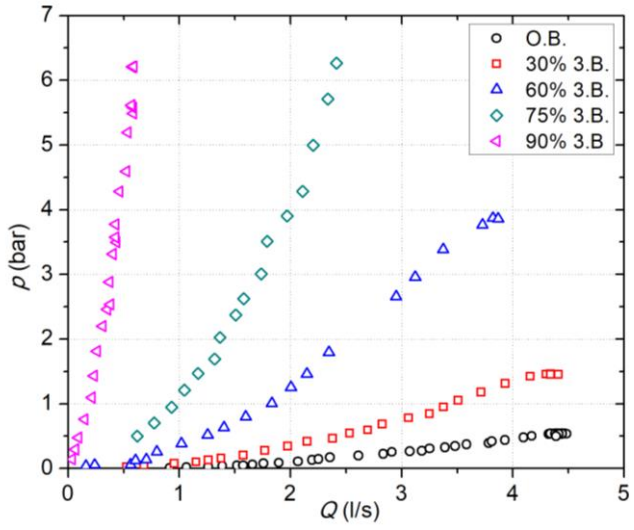


Сл. 4. *p-Q* карактеристика центрифугалне пумпе снимљена при различитим фреквенцијама (брзинама обртања)

Б. Снимање p-Q карактеристике хидрауличног система

Задатак вежбе: Снимање *p-Q* карактеристика хидрауличног система.

Карактеристике хидрауличног система добијају се при промени положаја радне тачке. У овом случају то је реализовано променом брзине радног кола пумпе. На слици 5 приказане се пет различитих карактеристика система које су добијене различитим положајима пригушног вентила: отворен вентил (О.В.), 30%, 60%, 75%, и 90% затвореног вентила (З.В.).



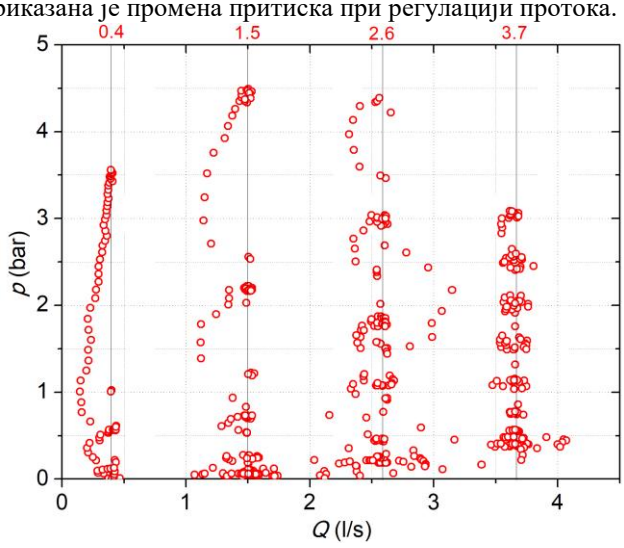
Сл. 5. Карактеристика *p-Q* хидрауличног система снимљена при различитим положајима пригушног вентила

B. Регулација протока у систему

Задатак вежбе: Реализовати систем са затвореном повратном спрегом по протоку. Снимити *p-Q* дијаграм при затварању пригушног вентила и при томе снимити промену фреквенције.

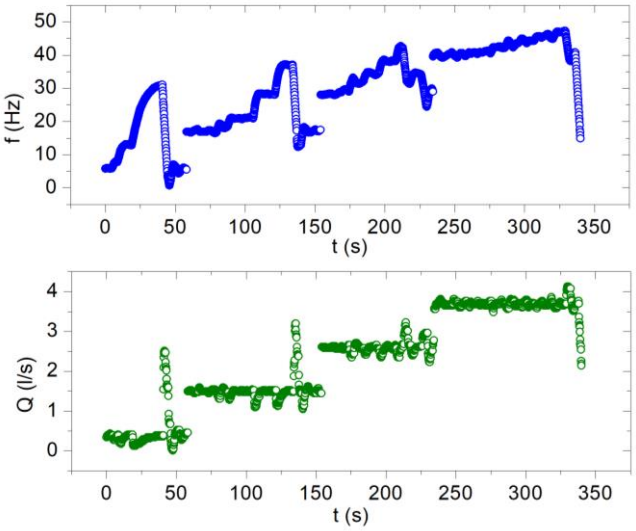
У овој вежби потребно извршити модификацију управљачког система додавањем повратне спреге. Потребно је сигнал са мерача протока довести на улаз за повратну спрегу на фреквентном претварачу. Када се изврше модификације управљачког кола, изврши активирање повратне спреге и дефинише опсег сигнала на фреквентном претварачу, потребно је покренути пумпу и унети поремећај у систем.

Поремећај се изазива затварањем или отварањем пригушног вентила. При задатој вредности протока уколико се нпр. у одређеном проценту затвори вентил, долази до тренутног пада протока и промене улазног сигнала на фреквентном претварачу. То доводи до повећања фреквенције и убрзавања пумпе. На слици 6 приказана је промена притиска при регулацији протока.



Сл. 6. Промена *p-Q* радних тачака при регулацији по протоку

Дати су примери за 4 различита референтна протока од 0,4; 1,5; 2,6 и 3,7 l/s. Са слике 4 је могуће уочити да поремећај у виду затварања вентила смањује проток, што изазива повећање фреквенције и постепено повећање притиска при поновном успостављању задатог протока. На слици 7 приказане су промене фреквенције и протока у времену при регулацији по протоку. За сваку референтну вредност протока након поремећаја у виду постепеног затварања вентила на крају је извршено отварање вентила чиме се радна тачка враћа у првобитан положај.



Сл. 7. Промена фреквенције и протока при уношењу поремећаја у систем са регулацијом протока

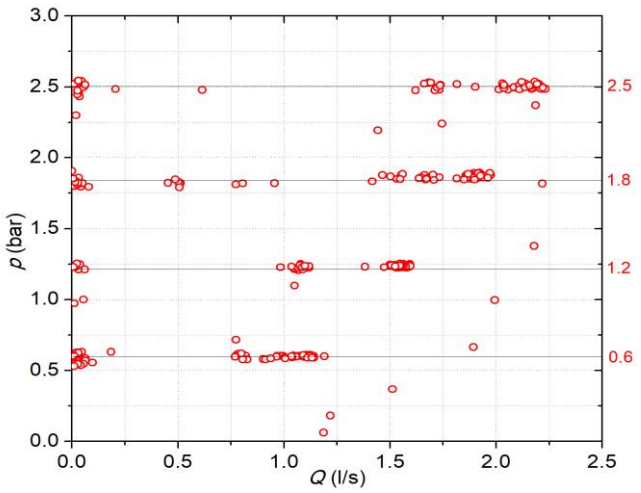
Г. Регулација притиска у систему

Задатак вежбе: Реализовати систем са затвореном повратном спрегом по притиску. Снимити промене притисака и фреквенције при отварању преливног (бајпас) вентила.

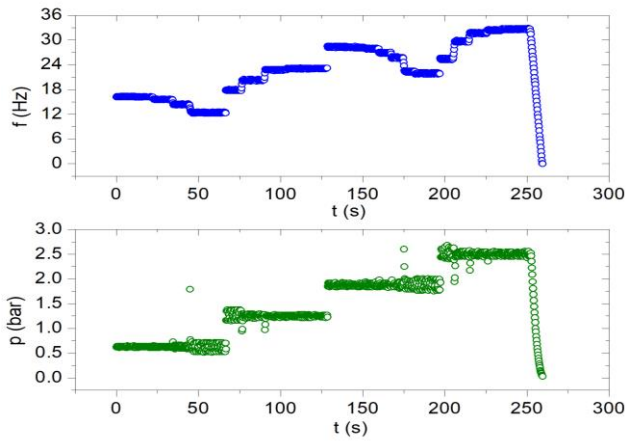
За ову лабораторијску вежбу потребно је модификовати управљачки систем додавањем повратне спреге, сигнала са сензора притиска. Потребно је сигнал са мерача притиска довести на улаз за повратну спрегу на фреквентном претварачу. Када се модификује управљачко коло, потребно је активирати опцију и подесити параметре за повратну спрегу на фреквентном претварачу. Након овог поступка може се приступити пуштању система у рад и вршити поремећај система.

Вежба се изводи тако што се пумпа пусти у рад, затвори се преливни вентил, којим се вода усмерава кроз цевовод. На фреквентном претварачу се подеси жељени притисак, пригушни вентил се постави у један од положаја (нпр. затвори се 30%). Када се достигне задати притисак, поремећај на систему се врши отварањем преливног вентила, чиме долази до пада притиска у систему. Повећањем брзине пумпе долази до пораста протока кроз систем и до враћања притиска на задату вредност. Поступак се понавља за неколико вредности задатог притиска. Дијаграм промене протока при

регулацији притиска дат је на слици 8 за примере референтних вредности од 0,6; 1,2; 1,8 и 2,5 бара. При регулацији притиска долази до промене протока, што је проузроковано повећањем брзине обртања пумпе тј. порастом фреквенције. На слици 9 приказани су дијаграми промене фреквенције и притиска у времену за различита оптерећења система при регулацији притиска.



Сл. 8. Промена *p-Q* радних тачака при регулацији по притиску



Сл. 9. Промена фреквенције и притиска при уношењу поремећаја у систем са регулацијом притиска

V. Закључак

Овај рад описује пумпни систем који ради у лабораторијским условима као и могућности његове примене у настави. Поред коришћења у истраживачке сврхе овај систем даје могућност примене у практичној настави кроз лабораторијске вежбе из области пумпних система, електромоторних погона, аутоматске регулације. Примена центрифугалне пумпе са мотором и фреквентним претварачем даје могућност снимања *p-Q* карактеристика пумпе и хидрауличног система. Поред тога, кроз резултате мерења у виду вежби показано је да коришћењем фреквентног претварача са повратном спрегом је могуће успешно остварити регулацију по протоку и притиску. Погодности рада на овој лабораторијској поставци је боље разумевање основних законитости пумпних система, електромоторних погона и регулацијоних структура притиска и протока. Студенти се радом на једном оваквом систему могу упознати са начином функционисања и подешавањем фреквентног претварача намењеног за пумпне системе. Уз све то могу директно уочити добити коришћења фреквентно регулисаних пумпних система у односу на класичну регулацију вентилима.

Захвалница

Овај рад је резултат пројекта ТР33016, чији је носилац Факултет техничких наука у Чачку и који је подржан од Министарства просвете, науке и технолошког развоја Републике Србије.

Abstract

In this work, pump system realized on the Faculty of technical sciences, is presented. System consists of the reservoir, three-phase multi-stage centrifugal pump, frequency converters, bypass and throttle valve. Parameters of the pump system can be determined by acquiring signals from the pressure and flow sensors placed in the pipeline. Using the acquired signals, flow and pressure regulation is performed. Procedure of laboratory exercise realization and the obtained results with comments are presented in the experimental part of the work.

Educational laboratory setup of the pump system with pressure and flow regulation

Optimizacija primene V2G tehnologije u mikromreži sa obnovljivim izvorima energije

Dario Javor, *Member, IEEE,* Nebojša Raičević, *Member, IEEE*

***Apstrakt*—U radu je prikazan postupak optimizacije funkcije troškova električne energije u slučaju korišćenja obnovljivih izvora energije u mikromreži povezanoj s mrežom za napajanje. Mikromreža ima mogućnosti punjenja i pražnjenja električnih vozila tj. omogućena je efikasna upotreba njihovih baterija za skladištenje energije. U slučajevima korišćenja vetrogeneratora i fotonaponskih panela ostvaruju se različite uštede troškova. Za rešavanje optimizacionih problema korišćen je program Lingo.**

***Ključne reči*—Fotonaponski paneli; vetrogenerator; električna vozila; optimizacija; troškovi energije.**

I. Uvod

PROBLEMI zagađenja okoline, globalnog zagrevanja i emisije gasova koji izazivaju efekat staklene bašte (GHG), povezani su sa proizvodnjom električne energije koja je neophodna za razvoj čovečanstva. Da bi razvoj bio održiv, intenzivirano je korišćenje obnovljivih izvora energije. Zbog intermitentne prirode proizvodnje električne energije vetrogeneratorima i fotonaponskim panelima, potrebno je korišćenje i drugih raspoloživih resursa kao što su različiti sistemi za skladištenje energije. Ubrzani razvoj u ovoj oblasti su dodatno omogućili: primena savremenih informacionih i komunikacionih tehnologija, koncept pametnih mreža i pametnih gradova, kao i poboljšanja sistema za upravljanje električnom energijom. Poseban izazov za istraživanja predstavljaju i električna vozila, kao i optimalno korišćenje V2G (vehicle-to-grid) tehnologije [1]-[6].

Korišćenje baterija električnih vozila za skladištenje električne energije, naročito u slučaju velikog broja vozila i dugih vremenskih intervala raspoloživosti za punjenje ili pražnjenje na parkinzima ili u garažama, pruža mogućnosti optimizacije troškova za električnu energiju. Moguće je da optimizacija ima i više ciljeva, kao što su smanjenje troškova investicija, povećanje efikasnosti energetskog sistema i smanjenje emisija GHG.

U ovom radu se razmatra problem minimizacije troškova energije u mikromreži koja sadrži vetrogeneratore, solarne panele i flotu električnih vozila koja ima mogućnost punjenja ili pražnjenja, izuzev u vremenskom intervalu kad se koristi za prevoz. Matematički modeli ovakvih problema mogu se predstaviti funkcijom cilja koju treba minimizirati, uz ograničenja, i zatim rešiti numerički. Radi primene nekog od optimizacionih metoda, moguće je koristiti programe kao što su MATLAB, Yalmip, Excel Solver, Lingo [7] itd., u kojima se različite metode mogu izabrati za rešavanje istog problema.

Dario Javor – Elektronski fakultet, Univerzitet u Nišu, Aleksandra Medvedeva 14, 18000 Niš, Srbija (e-mail: dariojavor@mts.rs).

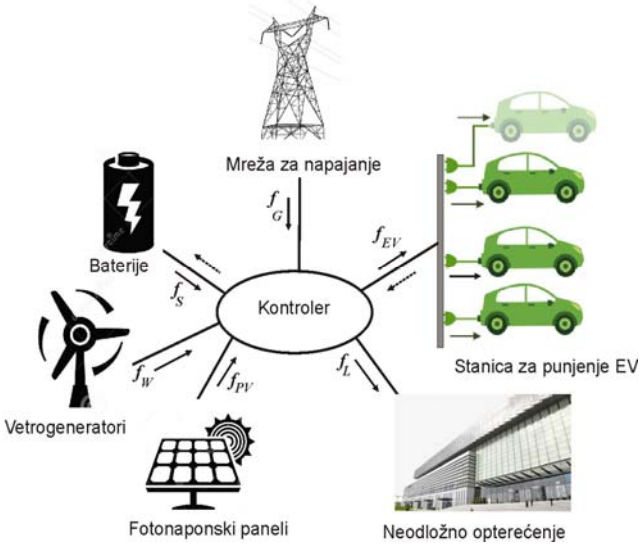
Nebojša Raičević – Elektronski fakultet, Univerzitet u Nišu, Aleksandra Medvedeva 14, 18000 Niš, Srbija (e-mail: nebojsa.raicevic@elfak.ni.ac.rs).

II. Optimizacioni problem

Pametne mreže i mikromreže sa distribuiranim izvorima energije imaju mogućnost bidirekcionog toka snage ka mreži za napajanje. Ovo omogućava uštede troškova energije, a može biti veoma značajno za očuvanje čovekove okoline. Ako se raspolaže dnevnim dijagramima očekivane proizvodnje energije solarnim panelima i vetrogeneratorima i ako su na raspolaganju baterije za skladištenje energije, mogu se minimizirati troškovi i proračunati optimalni kapaciteti ovih resursa i njihova isplativost.

Obnovljivi izvori energije (OIE) u 2018. god. predstavljali su čak 83% od instaliranih elektroenergetskih kapaciteta, čime su dostigli oko trećinu proizvodnje električne energije u svetu. Mikromreže koje koriste OIE mogu instalirati industrijske kompanije, univerzitetski kampusi i različite vrste korisnika. U ovom radu je uzet primer mikromreže (Sl.1) koja raspolaže sledećim resursima:

- vetrogeneratorima izabrane snage 33kW za koji je dnevni dijagram očekivane proizvodnje energije procenjen na osnovu brzine vetra u Banatu merene 24.04.2011. god. na svakih 10 minuta na visini 10m, usrednjene WAsP softverom (Wind energy industry standard software) [8] za satne vrednosti i određenu visinu turbine [9];



Sl. 1. Šema mikromreže (sa neodložnim opterećenjem, vetrogeneratorom, fotonaponskim panelima, baterijama i stanicom za punjenje električnih vozila) priključene na mrežu za napajanje.

- fotonaponskim panelima snage 33kW za koje je dnevni dijagram očekivane proizvodnje energije procenjen na osnovu solarne iradijacije i temperature vazduha merene u Južnom Banatu u opštini Kovin na lokaciji Bavanište za prosečan dan 2009. god. [10];
- stanicom koja ima dovoljan broj priključaka snage P_{ch}=3.3kW za punjenje/pražnjenje flote sa n_V vozila istog tipa čija je baterija pojedinačnog kapaciteta en_{EV}=30kWh;
- baterijama čije punjenje ili pražnjenje može dodatno umanjiti troškove energije.

Može se obaviti proračun i za veći broj vetrogeneratora n_W, kao i za veći broj n_{PV} fotonaponskih panela. Poznat je i dijagram kupovnih BP(i) i prodajnih cena SP(i) za svaki sat i=1,...,24. Dijagram BP(i) je dobijen na osnovu Hungarian Power Exchange podataka [11], a uzeto je SP(i)=0.75BP(i).

Ciljna funkcija C_{COST} koju treba minimizirati predstavlja sumu troškova za energiju preuzetu iz mreže za napajanje u toku jednog dana,

$$C_{COST} = \min\left\{\sum_{i=1}^{24} P_{ch}\cdot n_V\cdot[\mathrm{BP}(i)\cdot x_B(i)\text{-}\mathrm{SP}(i)\cdot x_S(i)]\right.$$
$$\left.\text{-}\mathrm{SP}(i)\cdot n_{PV}\cdot P_{PV}(i)\text{-}\mathrm{SP}(i)\cdot n_W\cdot P_W(i)+\mathrm{BP}(i)\cdot P_L(i)\right\}, \quad (1)$$

s obzirom na procenjeni dijagram neodložnog opterećenja u toku dana $P_L(i)$, i=1,...,24.

Promenljiva $x_B(i)$ ima vrednost 1 ako se kupuje energija iz mreže u i-tom satu, vrednost 0 ako se ne kupuje, dok $x_S(i)$ ima vrednost 1 ako se prodaje energija mreži za napajanje u i-tom satu, 0 ukoliko se ne prodaje. Umesto ove dve promenljive, može se definisati jedna promenljiva $x(i)$ koja ima vrednost 1 kada $x_B(i)$ ima vrednost 1, vrednost -1 kada je $x_S(i)$ jednako 1, a 0 ako bilo koja od ove dve promenljive ima vrednost 0 (kada je vozilo priključeno na stanici, ali se niti puni niti prazni, ili je u vožnji tj. nije priključeno na stanici). Ako je i redni broj satnog intervala u toku dana, stanje baterije električnog vozila mora biti uvek u opsegu od 20% do 100%, pa je definisano ograničenje:

$$20 \le SOC(i) \le 100, \qquad i = 1,...,24. \quad (2)$$

Stanje napunjenosti baterije $SOC(i)$ se određuje diskretno, na početku svakog vremenskog intervala i=1,...,24, na osnovu stanja iz prethodnog intervala, procenta punjenja/pražnjenja baterije na sat (P_{ch}/en_{EV}) i promenljive $x(i$-1) koja označava punjenje/pražnjenje u prethodnom intervalu.

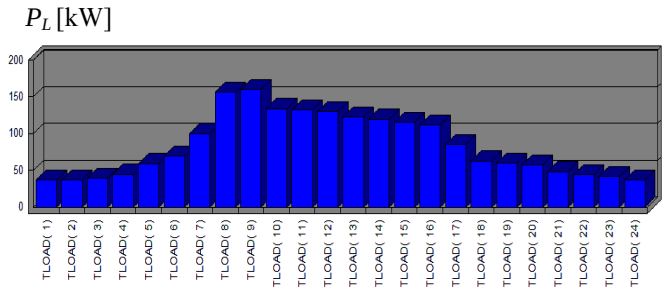
$$SOC(i) = SOC(i-1) + x(i-1)\cdot P_{ch}/en_{EV}\cdot 100. \quad (3)$$

Na početku vremenskog intervala od 6 sati kada vozila voze, baterije su napunjene na $SOC0$=100, a na kraju 67%. Izabrano je malo električno vozilo Nissan Leaf koje sa napunjenom baterijom može da pređe od 100 do 200km. U ovom radu, procenjeno je da vozilo može da pređe 167km sa 100% napunjenom baterijom, odnosno, da svako od vozila prelazi 55km za 6 sati vožnje, kao u [14]. SOC opada po 5.5% na sat kada se automobil vozi, a smanji se od 100% na 67% u vremenskom intervalu počev od 11-tog, a zaključno sa 16-tim. U preostalih 18 sati vozila su na raspolaganju na stanici. Kad se vozilo puni ili prazni na stanici, brzina punjenja/pražnjenja je 11% na sat, pošto je P_{ch}/en_{EV} =0.11. Usvojen je isti koeficijent efikasnosti i za punjenje i za pražnjenje.

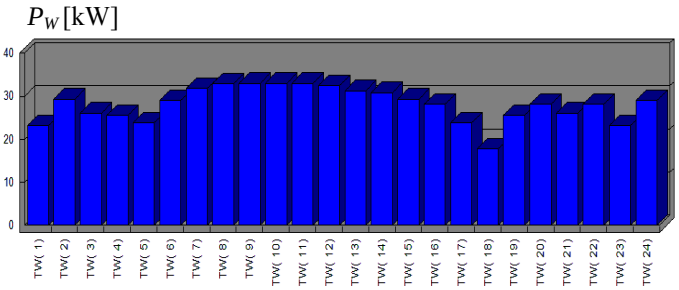
Dodatno ograničenje može biti maksimalna vrednost snage koja se može prenositi vodovima, kao i snaga P_{Gmax} koja se može zahtevati od mreže za napajanje. Za i=1,...,24, bilans snaga dat je sa

$$P_G(i) = P_L(i) - P_{PV}(i) - P_W(i) + P_{EV}(i). \quad (4)$$

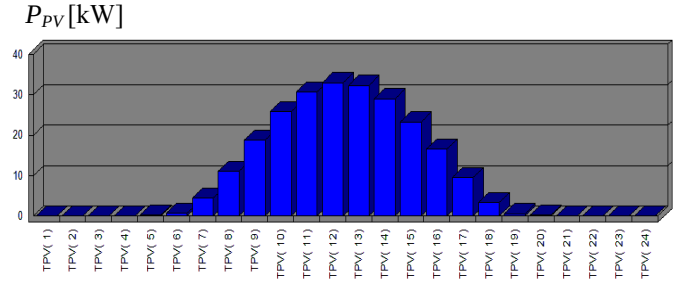
Na Sl.2 dat je dnevni dijagram neodložnog opterećenja kao u [12], [13]. Na Sl.3 prikazan je dijagram proizvodnje energije vetrogeneratora maksimalne snage 33kW, a na Sl.4 fotopanela maksimalne snage 33kW u toku dana. U Tabeli I su kupovne/prodajne cene električne energije [6], dok je dnevni dijagram cena na tržištu električne energije [11] dat na Sl.5.



Sl. 2. Dnevni dijagram snage neodložnog opterećenja u kW.

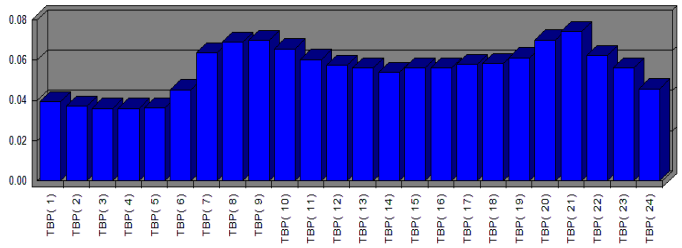


Sl. 3. Dnevni dijagram proizvodnje vetrogeneratora max snage 33kW.



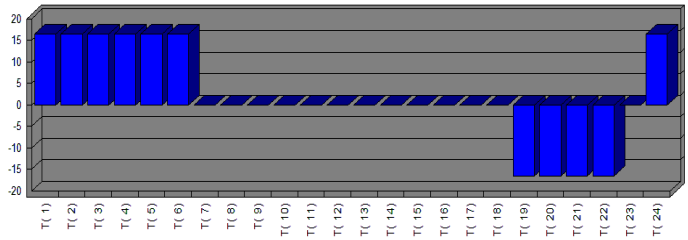
Sl. 4. Dnevni dijagram proizvodnje fotonaponskih panela max snage 33kW.

BP [€/kWh]



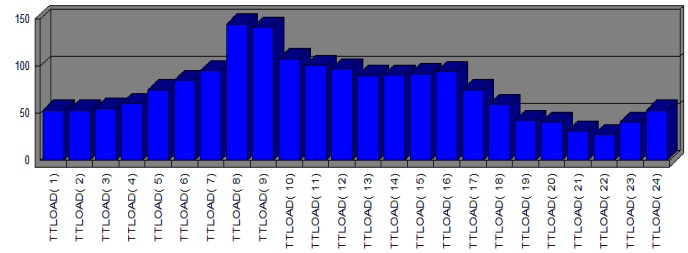
Sl. 5. Dnevni dijagram tržišnih kupovnih cena energije BP u € po kWh.

P_{EV} [kW]



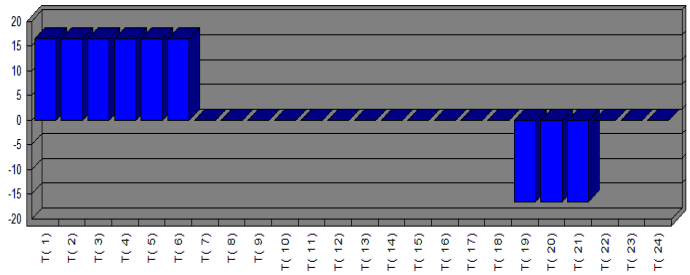
Sl. 6. Optimizovani dnevni raspored punjenja/pražnjenja vozila za n_V=5, P_{PV}=33kW, P_W=0, BP sa Sl.5 i SP=0.75BP.

P_{tot} [kW]



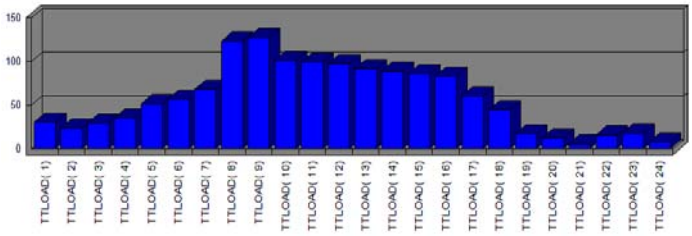
Sl. 7. Dnevni dijagram ukupne potrošnje u slučaju n_V=5, P_{PV}=33kW, P_W=0, BP sa Sl.5 i SP=0.75BP.

P_{EV} [kW]



Sl. 8 Optimizovani dnevni raspored punjenja/pražnjenja vozila za n_V=5, P_{PV}=0, P_W=33kW, BP sa Sl.5 i SP=0.75BP.

P_{tot} [kW]



Sl. 9. Dnevni dijagram ukupne potrošnje u slučaju n_V=5, P_{PV}=0, P_W=33kW, BP sa Sl.5 i SP=0.75BP.

III. Rezultat optimizacije primene V2G tehnologije

Izabran je scenario sa n_V=5 električnih vozila koja su na raspolaganju za punjenje/pražnjenje na stanici, odnosno za korišćenje njihovih baterija, u intervalu od početka 17-tog jednočasovnog intervala u toku dana do početka 11-tog intervala narednog dana. Ostalih 6 časova vozila nisu na raspolaganju, a troše energiju svojih baterija za vožnju. Za Scenario 1 i 2 izabrane su varijabilne cene električne energije kao na Sl.5, a za Scenario 3 i 4 cene iz Tabele I. Program Lingo ima ugrađene solvere za različite tipove optimizacionih problema i bira onaj koji je pogodniji za formulisani problem.

Scenario 1: rade fotopaneli snage 33kW, a vetrogeneratori ne rade. Poznat je dnevni dijagram kupovnih cena BP(i) za svaki sat, kao na Sl.5, i prodajnih cena SP(i)=0.75BP(i). Na osnovu optimizacije funkcije (1), uz ispunjene uslove (2) i (3), dobija se raspored punjenja/pražnjenja flote vozila kao na Sl.6 za minimalni dnevni trošak energije. Na Sl.7 prikazan je dijagram snage $P_G(i)$ koju mikromreža kupuje od mreže za napajanje (4).

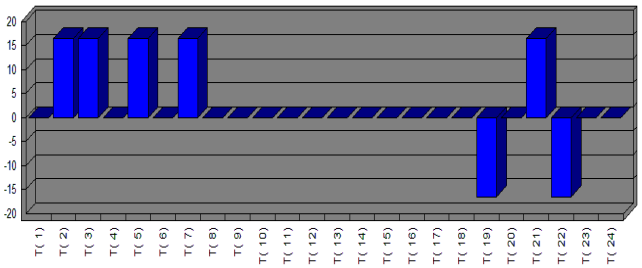
Scenario 2: rade vetrogeneratori snage 33kW, a fotopaneli ne rade. Na osnovu optimizacije funkcije (1), uz uslove (2) i (3), dobija se raspored punjenja/pražnjenja flote vozila kao na Sl. 8. Troškovi su 16.36% manji nego za Scenario 1. Na Sl.9 je prikazan dijagram $P_G(i)$. Bidirekcioni tok snage obezbeđen je ka mreži za napajanje, ali su za Scenario 1 i 2 snaga neodložne potrošnje $P_L(i)$ i snaga punjenja vozila $P_{EV}(i)$ veće od proizvodnje vetrogeneratorima $P_W(i)$ i fotopanelima $P_{PV}(i)$ u svakom satu, što se vidi i iz grafika na Sl.7 i Sl.9.

Scenario 3: rade fotopaneli snage 33kW, vetrogeneratori ne rade. Kupovne i prodajne cene BP(i) i SP(i) za svaki sat poznate su iz Tabele I. Na osnovu optimizacije funkcije (1), uz (2) i (3), dobija se raspored punjenja/pražnjenja flote vozila kao na Sl.10. Na Sl.11 prikazan je dijagram snage $P_G(i)$ koju mikromreža kupuje od mreže za napajanje.

TABELA I
KUPOVNE I PRODAJNE CENE ENERGIJE U TOKU DANA [6]

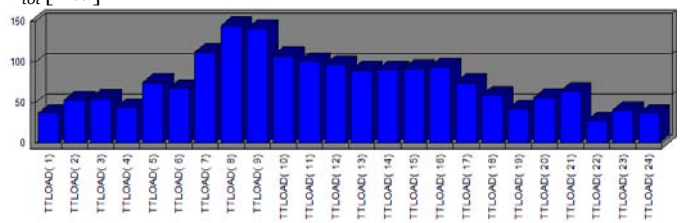
Kupovna (BP) i prodajna cena (SP)	Cena [€/kWh]
BP od 1-9. i od 20-24. sata	0.2
BP od 10-19. sata	0.26
SP od 1-24. sata	0.15

P_{EV} [kW]



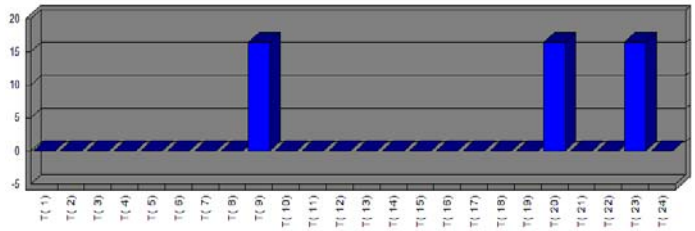
Sl. 10. Optimizovani dnevni raspored punjenja/pražnjenja vozila za n_V=5, P_{PV}=33kW, P_W=0 i BP/SP iz Tabele I.

P_{tot} [kW]



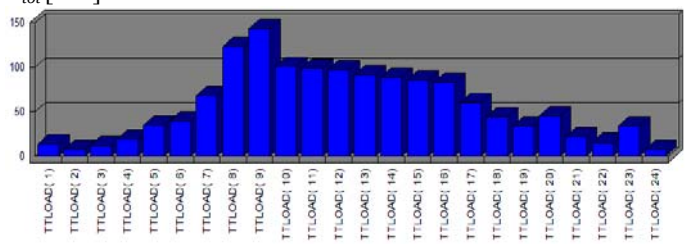
Sl. 11. Dnevni dijagram ukupne potrošnje u slučaju n_V=5, P_{PV}=33kW, P_W=0 i BP/SP iz Tabele I.

P_{EV} [kW]



Sl. 12. Optimizovani dnevni raspored punjenja/pražnjenja vozila za n_V=5, P_{PV}=0, P_W=33kW i BP/SP iz Tabele I.

P_{tot} [kW]



Sl. 13. Dnevni dijagram ukupne potrošnje u slučaju n_V=5, P_{PV}=0, P_W=33kW i BP/SP iz Tabele I.

Scenario 4: rade vetrogeneratori snage 33kW, fotopaneli ne rade. Kupovne i prodajne cene BP(i) i SP(i) za svaki sat poznate su iz Tabele I. Na osnovu optimizacije funkcije troškova dobija se raspored punjenja/pražnjenja flote vozila kao na Sl.12. Troškovi su 14.3% manji nego za Scenario 3. Na Sl.13 prikazan je dijagram snage $P_G(i)$.

Na osnovu proračuna određeno je da dodatne baterije kojima se može obezbediti veća ušteda energije za Scenario 1 i 2 treba izabrati sa snagom punjenja/pražnjenja 85kW, dok je za Scenario 3 i 4 dovoljno 70kW.

IV. Zaključak

Na osnovu rezultata datih u radu može se zaključiti da varijabilne cene električne energije iz sata u sat u toku dana omogućavaju veći procenat uštede. U radu je određeno i koliko instalirani kW snage vetrogeneratora omogućava veće uštede nego instalirani kW snage fotonaponskih panela, s obzirom na pogodniji dnevni dijagram proizvodnje električne energije od vetrogeneratora, ali su investicioni troškovi u tom slučaju znatno veći.

U radu su razmatrana električna vozila kao flota, ali bi drugačiji pojedinačni raspored vožnje i punjenja/pražnjenja u toku dana omogućio i dodatne uštede. Takođe, mogu se uzeti u obzir i troškovi korišćenja baterija u električnim vozilima.

Osim smanjenja troškova energije, moguće je proračunati i benefit od smanjene emisije GHG. Korišćenjem dobijenih dijagrama, može se odrediti i optimalni kapacitet baterija za skladištenje energije u datoj mikromreži.

Zahvalnica

Autori se zahvaljuju Ministarstvu prosvete, nauke i tehnološkog razvoja za finansijsku podršku rada u okviru projekta TR33008.

Abstract

The paper presents the procedure of optimizing the function of the cost of electricity in case of using renewable energy sources in a microgrid connected to the main grid. The microgrid has possibilities of charging and discharging electric vehicles, that is, the efficient use of their batteries as storage units is enabled. In cases of using wind generators and photovoltaic panels different cost savings are achieved. Lingo program is used for solving these optimization problems.

Optimization of V2G Technology Application in the Microgrid with Renewable Energy Sources

Osetljivost greške dinamičke estimacije stanja na promene pojedinih parametara Kalmanovog filtra

Dragan Ćetenović, Aleksandar Ranković

Fakultet tehničkih nauka u Čačku

***Apstrakt*— U kvazistacionarnom režimu rada distributivne mreže matrica kovarijansi grešaka dinamičkog modela Q obično se modeluje kao vremenski nepromenljiva u dijagonalnoj formi sa svim elementima na dijagonali međusobno jednakim, što dovodi do jednoparametarskog modela matrice. U tom slučaju se podešavanje matrice kovarijansi Q svodi na podešavanje jednog jedinog parametra q. Tačnost dinamičke estimacije stanja uslovljena je izborom vrednosti ovog parametra, ali i izborom inicijalnog rešenja, gde se pod inicijalnim rešenjem podrazumeva inicijalni vektor stanja x_0^+ i njemu pripadajuća matrica kovarijansi P_0^+. Cilj ovog rada je detaljno ispitati simultano dejstvo parametra q i inicijalnog rešenja na kvalitet dinamičke estimacije. Analize su sprovedene na modifikovanom IEEE distributivnom test sistemu sa 13 i 123 čvora korišćenjem EKF i UKF algoritma dinamičke estimacije stanja.**

***Ključne reči*—matrica kovarijansi grešaka dinamičkog modela; dinamički estimator; Kalmanov filtar.**

I. UVOD

Sa porastom stepena integracije distribuiranih resursa u distributivnu mrežu rastu i zahtevi za aktivnijim učešćem u monitoringu i upravljanju distributivnom mrežom. Takođe, rastu i zahtevi za boljim kvalitetom estimacije stanja kako bi se operateru distributivnog sistema omogućilo da preuzme odgovarjuće upravljačke akcije pravovremeno.

S druge strane, mali broj telemetrisanih merenja prisutnih u distributivnoj mreži vodi ka lošijem kvalitetu estimacije u poređenju sa prenosnom mrežom. Povećanje broja telemetrisanih merenja iziskuje nova ulaganja u mernu i telekomunikacionu infrastrukturu, pa ne predstavlja popularnu meru. Stoga, ideja je da se izbegnu dodatna ulaganja, a da se promeni algoritam estimacije stanja.

Estimacija stanja u savremenim upravljačkim centrima zasniva se na upotrebi statičkih estimatora stanja. Upotreba dinamičkih estimatora stanja pruža brojne prednosti [1], od kojih je jedna da se kvalitet estimacije može popraviti [2]. Međutim, njihova upotreba donosi nove probleme: koji Kalman filter odabrati, kako inicirati algoritam dinamičke estimacije stanja, koji model za opisivanje dinamike sistema upotrebiti, kako podesiti matricu kovarijansi kojom se obuhvataju neizvesnosti dinamičkog modela itd.

Neki od odgovora na prethodna pitanja su već dati u [2], gde je matrica kovarijansi grešaka dinamičkog modela predstavljena u sledećoj formi:

$$\boldsymbol{Q} = 10^{q} \cdot \boldsymbol{I}_n \tag{1}$$

gde je $\boldsymbol{I}_n$ $n-$dimenziona jedinična matrica (matrica identiteta), a n broj promenljivih stanja u sistemu. Pokazano je da ukoliko je vrednost parametra q adekvatno podešena, izbor inicijalnog rešenja, kao i tipa Kalmanovog filtra, ima zanemarljiv uticaj na kvalitet estimacije stanja [2]. Međutim, ukoliko vrednost ovog parametra nije adekvatno podešena, kvalitet estimacije stanja može značajno da varira zavisno od izbora inicijalnog rešenja i tipa Kalmanovog filtra.

Glavni cilj ovog rada je ispitati razloge zbog kojih je greška dinamičke estimacije osetljiva na promene pojednih parametara na način na koji je to prikazano u [2]. Rad sumira zaključke do kojih se došlo istraživanjem u okviru doktorske disertacije [3].

Rad je organizovan na sledeći način: u sekciji II predstavljeni su EKF i UKF algoritam dinamičke estimacije stanja, u sekciji III prikazana je osetljivost greške dinamičke estimacije stanja na promene pojedinih parametara Kalmanovog filtra, u sekciji IV izvedena je detaljna analiza dobijenih rezultata, da bi u sekciji V bili dati glavni zaključci.

II. ALGORITMI DINAMIČKE ESTIMACIJE STANJA

EKF algoritam se može opisati setom jednačina [4-6]:

$$\boldsymbol{x}_{k+1}^{-} = \boldsymbol{F}_k \boldsymbol{x}_k^{+} + \boldsymbol{g}_k \tag{2}$$

$$\boldsymbol{P}_{k+1}^{-} = \boldsymbol{F}_k \boldsymbol{P}_k^{+} \boldsymbol{F}_k^{\mathrm{T}} + \boldsymbol{Q}_k \tag{3}$$

$$\boldsymbol{z}_{k+1}^{-} = \boldsymbol{h}\left(\boldsymbol{x}_{k+1}^{-}\right) \tag{4}$$

$$\boldsymbol{T}_{k+1} = \boldsymbol{H}_{k+1} \boldsymbol{P}_{k+1}^{-} \boldsymbol{H}_{k+1}^{\mathrm{T}} \tag{5}$$

$$\boldsymbol{\nu}_{k+1} = \boldsymbol{z}_{k+1} - \boldsymbol{z}_{k+1}^{-} \tag{6}$$

$$\boldsymbol{S}_{k+1} = \boldsymbol{T}_{k+1} + \boldsymbol{R}_{k+1} \tag{7}$$

$$\boldsymbol{K}_{k+1} = \boldsymbol{P}_{k+1}^{-} \boldsymbol{H}_{k+1}^{\mathrm{T}} \boldsymbol{S}_{k+1}^{-1} \tag{8}$$

$$\boldsymbol{x}_{k+1}^{+} = \boldsymbol{x}_{k+1}^{-} + \boldsymbol{K}_{k+1} \boldsymbol{\nu}_{k+1} \tag{9}$$

$$\boldsymbol{P}_{k+1}^{+} = \boldsymbol{P}_{k+1}^{-} - \boldsymbol{K}_{k+1} \boldsymbol{S}_{k+1} \boldsymbol{K}_{k+1}^{\mathrm{T}} \tag{10}$$

gde su $\boldsymbol{x}^{-}$ i $\boldsymbol{x}^{+}$ predviđeni i estimirani vektor stanja, respektivno, $\boldsymbol{F}$ i $\boldsymbol{g}$ tranzicioni parametri dinamičkog

Dragan Ćetenović – Fakultet tehničkih nauka u Čačku, Univerzitet u Kragujevcu, Svetog Save 65, 32102 Čačak, Srbija (e-mail: dragan.cetenovic@ftn.kg.ac.rs).

Aleksandar Ranković – Fakultet tehničkih nauka u Čačku, Univerzitet u Kragujevcu, Svetog Save 65, 32102 Čačak, Srbija (e-mail: aleksandar.rankovic@ftn.kg.ac.rs).

modela, respektivno, $\boldsymbol{P}^-$ i $\boldsymbol{P}^+$ matrica kovarijansi predviđenog i estimiranog vektora stanja, respektivno, $\boldsymbol{z}^-$ i $\boldsymbol{T}$ predviđeni vektor merenja i njemu pripadajuća matrica kovarijansi, respektivno, $\boldsymbol{h}$ nelinearna vektorska funkcija merenja, $\boldsymbol{H}$ Jakobijeva matrica, $\boldsymbol{v}$ i $\boldsymbol{S}$ vektor inovacija i njemu pripadajuća matrica kovarijansi, respektivno, $\boldsymbol{z}$ i $\boldsymbol{R}$ vektor merenja i njemu pripadajuća matrica kovarijansi, respektivno, $\boldsymbol{K}$ matrica Kalmanovog pojačanja i k vremenski trenutak.

UKF algoritam se može predstaviti sledećim setom jednačina [7-9]:

$$\boldsymbol{Y}_k^+ = \boldsymbol{x}_k^+ \cdot \boldsymbol{1}^{\mathrm{T}} + \sqrt{n+\lambda_{ut}}\left[\boldsymbol{0} \quad \sqrt{\boldsymbol{P}_k^+} \quad -\sqrt{\boldsymbol{P}_k^+}\right] \tag{11}$$

$$\hat{\boldsymbol{X}}_{k+1} = \boldsymbol{F}_k \boldsymbol{Y}_k^+ + \boldsymbol{g}_k \cdot \boldsymbol{1}^{\mathrm{T}} \tag{12}$$

$$\boldsymbol{x}_{k+1}^- = \hat{\boldsymbol{X}}_{k+1} \boldsymbol{w}_m \tag{13}$$

$$\boldsymbol{P}_{k+1}^- = \hat{\boldsymbol{X}}_{k+1} \boldsymbol{W} \hat{\boldsymbol{X}}_{k+1}^{\mathrm{T}} + \boldsymbol{Q}_k \tag{14}$$

$$\boldsymbol{Y}_{k+1}^- = \boldsymbol{x}_{k+1}^- \cdot \boldsymbol{1}^{\mathrm{T}} + \sqrt{n+\lambda_{ut}}\left[\boldsymbol{0} \quad \sqrt{\boldsymbol{P}_{k+1}^-} \quad -\sqrt{\boldsymbol{P}_{k+1}^-}\right] \tag{15}$$

$$\hat{\boldsymbol{Z}}_{k+1}^- = \boldsymbol{h}\left(\boldsymbol{Y}_{k+1}^-\right) \tag{16}$$

$$\boldsymbol{z}_{k+1}^- = \hat{\boldsymbol{Z}}_{k+1}^- \boldsymbol{w}_m \tag{17}$$

$$\boldsymbol{T}_{k+1} = \hat{\boldsymbol{Z}}_{k+1}^- \boldsymbol{W} \left[\hat{\boldsymbol{Z}}_{k+1}^-\right]^{\mathrm{T}} \tag{18}$$

$$\boldsymbol{\nu}_{k+1} = \boldsymbol{z}_{k+1} - \boldsymbol{z}_{k+1}^- \tag{19}$$

$$\boldsymbol{S}_{k+1} = \boldsymbol{T}_{k+1} + \boldsymbol{R}_{k+1} \tag{20}$$

$$\boldsymbol{C}_{k+1} = \boldsymbol{Y}_{k+1}^- \boldsymbol{W} \left[\hat{\boldsymbol{Z}}_{k+1}^-\right]^{\mathrm{T}} \tag{21}$$

$$\boldsymbol{K}_{k+1} = \boldsymbol{C}_{k+1} \boldsymbol{S}_{k+1}^{-1} \tag{22}$$

gde je $\boldsymbol{Y}^+$ matrica sigma tačaka dobijenih aproksimacijom raspodele verovatnoće estimiranog vektora stanja, $\boldsymbol{1}$ jedinični vektor, λ_{ut} parametar skaliranja, $\boldsymbol{0}$ nula veltor, $\hat{\boldsymbol{X}}$ matrica sigma tačaka preslikanih pomoću dinamičkog modela, $\boldsymbol{w}_m$ i $\boldsymbol{W}$ vektor i matrica težinskih faktora, respektivno, $\boldsymbol{Y}^-$ matrica sigma tačaka dobijenih aproksimacijom raspodele verovatnoće predviđenog vektora stanja, $\hat{\boldsymbol{Z}}^-$ matrica sigma tačaka preslikanih pomoću modela merenja, $\boldsymbol{C}$ matrica unakrsnih kovarijansi stanja i merenja.

III. Osetljivost greške dinamičke estimacije na promene pojedinih parametara Kalamnovog filtra

Ukupna greška estimacije stanja dobija se kao:

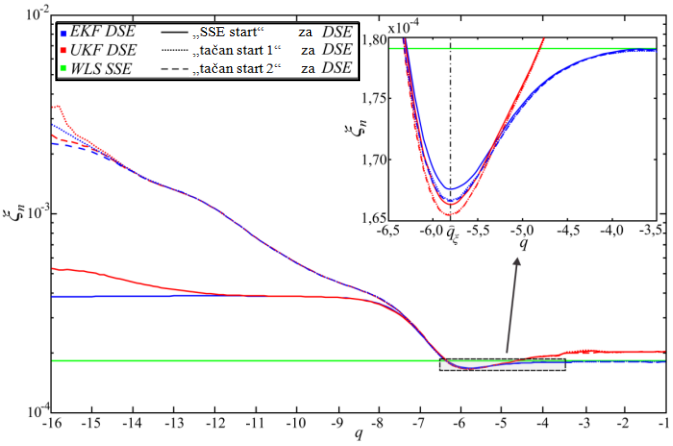
$$\xi_n(q) = \frac{1}{K}\sum_{k=1}^{K} \xi_{n,k}(q) \tag{23}$$

$$\xi_{n,k}(q) = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(x_{i,k}^+(q) - x_{i,k}^{true}\right)^2} \tag{24}$$

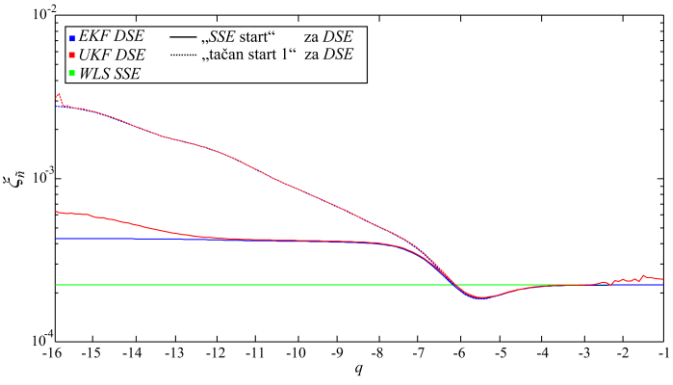
Ukupna greška estimacije stanja izračunata je na modifikovanom distributivnom IEEE 13 [2,10] i IEEE 123 [10] test sistemu korišćenjem EKF i UKF algoritma dinamičke estimacije i to za tri različita scenarija inicijalizacije:

1. „SSE start“: Inicijalne vrednosti $\boldsymbol{x}_0^+$ i $\boldsymbol{P}_0^+$ dobijene su korišćenjem *WLS* algoritma statičke estimacije,
2. „tačan start 1“: Inicijalna vrednost vektora stanja $\boldsymbol{x}_0^+$ dobijena je na osnovu proračuna tokova snaga i predstavlja tačan vektor stanja $\boldsymbol{x}_0^{true}$ u trenutku $k=0$, dok je inicijalna matrica kovarijansi grešaka estimacije podešena na $\boldsymbol{P}_0^+ = \boldsymbol{0}$
3. „tačan start 2“: Dinamička estimacija stanja takođe je inicirana s tačnim vektorom stanja $\boldsymbol{x}_0^{true}$, ali je matrica $\boldsymbol{P}_0^+$ sada podešena kao dijagonalna, tako da je $\boldsymbol{P}_0^+ = p_0 \cdot \boldsymbol{I}_n$ gde je p_0 skalapni broj konačno male vrednosti ($p_0 = 10^{-15}$). Ovaj scenario nije analiziran na IEEE 123 test sistemu.

Izračunata je i ukupna greška estimacije sprovedene statičkim WLS estimatorom. Na slici 1 je prikazana greška esimacije u funkciji parametra q za a) modifikovani IEEE 13 i b) IEEE 123 test sistem.



a)



b)

Slika 1. Ukupna greška estimacije za a) modifikovani IEEE 13 i b) IEEE 123 test sistem u funkciji parametra q za različite senarije inicijalizacije i različite algoritme estimacije

S obzirom da izbor parametra q i scenarija inicijalizacije na isti način utiče na grešku dinamičke estimacije stanja u slučaju oba test sistema, u nastavku će detaljno biti analizirani samo rezultati dobijeni na modifikovanom IEEE 13 test sistemu.

IV. ANALIZA REZULTATA

Na osnovu rezultata prikazanih na slici 1, prethodno definisani opseg parametra q može se podeliti na uže opsege (intervale) radi lakše analize rezultata:

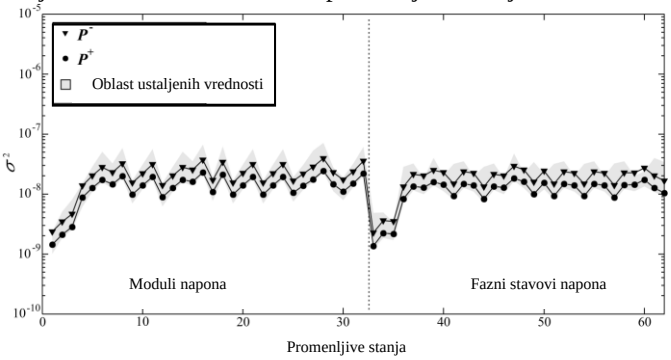
- $-16 \le q \le -8$, gde greška dinamičke estimacije dostiže izuzetno visoke vrednosti, pri čemu izbor scenarija inicijalizacije ima ogroman uticaj na kvalitet estimacije; na ovom intervalu greška dinamičke estimacije stanja je nerastuća funkcija parametra q za bilo koji scenario inicijalizacije,
- $-8 \le q \le \hat{q}_{\xi}$, gde se greška dinamičke estimacije i dalje smanjuje s porastom vrednosti parametra q, ali u ovom slučaju izbor scenarija inicijalizacije ne utiče značajnije na kvalitet estimacije,
- $q > \hat{q}_{\xi}$, gde greška estimacije raste s porastom vrednosti parametra q, pri čemu je izbor scenarija inicijalizacije i dalje zanemarljiv.

Interval vrednosti parametra $-16 \le q \le -8$

Za vrednosti parametra q rangirane na ovom intervalu greška dinamičke estimacije može biti značajno veća od greške statičkog estimatora, što zavisi od vrednosti parametra q, ali i od scenarija inicijalizacije (pogledati sliku 1). S obzirom da smanjenje vrednosti dijagonalnih elemenata matrice kovarijansi $\boldsymbol{Q}$ može dovesti do porasta prioriteta koji filtar daje rezultatima predviđanja u odnosu na sama merenja, porast greške dinamičkog estimatora na ovom intervalu je i očekivan. U kojoj meri će pri smanjivanju vrednosti parametra q rasti nivo prioriteta koji filtar daje rezultatima predviđanja zavisi od izbora scenarija inicijalizacije. Tačnost predviđenog vektora stanja $\boldsymbol{x}_{k+1}^{-}$ zavisi od tačnosti dinamičkog modela, ali i od tačnosti vektora stanja $\boldsymbol{x}_{k}^{+}$ estimiranog u prethodnom trenutku. Ukoliko je greška dinamičkog model zanemarljiva u odnosu na grešku koja je pri estimiranju stanja u prethodnom trenutku, onda će greška u predviđanju vektora stanja u najvećoj meri zavisiti od greške prethodno estimiranog vektora stanja. Sa matematičkog stanovišta, odnos grešaka dinamičkog modela i prethodno estimiranog vektora stanja opisuje se odnosom vrednosti dijagonalnih elementa matrice $\boldsymbol{Q}$ i matrice $\boldsymbol{P}^{+}$, koji predstavljaju varijanse grešaka dinamičkog modela i estimiranog vektora stanja, respektivno.

Scenario „SSE start“

Sa slike 1 vidi se da u slučaju scenarija „SSE start“ promena parametra q nema nikakvog uticaja na grešku estimacije EKF algoritma sve dok parametar ima vrednost manju od $q \approx -8{,}5$. Na tom intervalu vrednosti parametra q su takve da su varijanse grešaka dinamičkog modela i za nekoliko redova veličine manje od varijansi prethodno estimiranih vrednosti promenljivih stanja. Varijanse inicijalnih vrednosti promenljivih stanja su u opsegu $3{,}73 \cdot 10^{-9}$ do $1{,}06 \cdot 10^{-7}$ za IEEE 13 test sistem. S obzirom da su ove varijanse procenjene na osnovu varijansi merenja, koje se ne menjaju značajnije u kvazistacionarnom režimu, može se zaključiti da se i vrednosti elemenata matrice $\boldsymbol{P}^{+}$ neće značajnije menjati tokom vremena. Blage promene su jedino posledica blagih varijacija opterećenja. Sa stanovišta samog filtra može se reći da je matrica $\boldsymbol{P}^{+}$ dostigla ustaljenu (stvarnu) vrednost. Može se zaključiti i da će vrednosti elemenata matrice $\boldsymbol{P}^{-}$ biti približno jednake vrednostima odgovarajućih elemenata matrice $\boldsymbol{P}^{+}$, pri čemu će promene opterećenja imati isti efekat na matricu $\boldsymbol{P}^{-}$ kao što imaju i na matricu $\boldsymbol{P}^{+}$. Na slici 2 prikazane su varijanse predviđenih i estimiranih vrednosti svih promenljivih stanja (dijagonalni elementi matrice $\boldsymbol{P}^{-}$ i $\boldsymbol{P}^{+}$, respektivno) za proizvoljno izabran trenutak $k = 10$. Oblast ustaljenih vrednosti označena je sivom bojom. Ona prestavlja oblastu kojoj se kreću varijanse estimiranih vrednosti promenljivih stanja tokom dana.



Slika 2. Varijanse predviđenih i estimiranih vrednosti promenljivih stanja aproksimirane EKF algoritmom dinamičke estimacije stanja na trening periodu u trenutku $k = 10$

Iz prethodnih razmatranja mogu se izvesti sledeći zaključci:

1. Odgovarajući elementi matrica kovarijansi predviđenog vektora merenja $\boldsymbol{T}$ i grešaka merenja $\boldsymbol{R}$ biće približno jednaki, što znači da će nivoi prioriteta koje filtar daje predviđenim vrednostima merenja i trenutnom preseku merenja biti otprilike isti.

2. Predviđene vrednosti promenljivih stanja ulaze u proces filtriranja s istim nivoom prioriteta bez obzira koliko je q, pa se iz tog razloga greška dinamičke estimacije ne menja s promenama vrednosti parametra q.

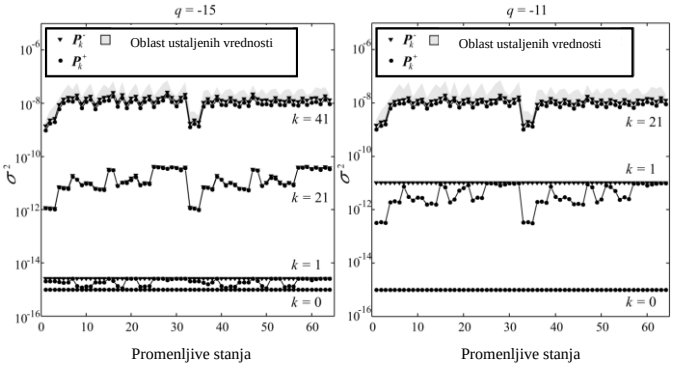
Scenario „tačan start 2“

U slučaju scenarija „tačan start 2“ inicijalne vrednosti promenljivih stanja imaju znatno manje varijanse, koje iznose 10^{-15}. Za vrednost parametra $q = -15$, varijanse grešaka dinamičkog modela i estimiranih promenljivih stanja u početku imaju podjednak udeo u aproksimiranim vrednostima

varijansi predviđenih promenljivih stanja. Zbog zoga su varijanse predviđenih vrednosti merenja znatno manje od varijansi grešaka merenja, pa filtar daje znatno veći prioritet predviđenim vrednostima nego trenutnom preseku merenja. Ovo će dovesti do izuzetno velike greške estimacije ξ_n, kao što se vidi sa slike 1. S druge strane, zbog malih varijansi predviđenog vektora stanja u trenutku $k=1$ i sama matrica kovarijansi $\boldsymbol{P}_1^+$ imaće vrednosti istog reda veličine. Ovde se dolazi do kontradikcije: rezultati estimacije su loši, a matrica kovarijansi estimiranog vektora stanja ima izuzetno niske vrednosti, što znači da bi rezultati estimacije trebalo da budu dobri. Treba imati u vidu da filtar jednačinom (10) samo aproksimira stvarnu matricu kovarijansi $\boldsymbol{P}^+$ (takođe, i matrica $\boldsymbol{P}^-$ data jednačinom (3) je aproksimacija). Razlog za lošu aproksimaciju u ovom slučaju je to što je greška dinamičkog modela neadekvatno modelovana, odnosno loše podešenje parametra q. Greška dinamičkog modela u ovom slučaju je potcenjena, što znači da je pretpostavljena varijansa greške znatno manja od stvarne.

Kako su Holtovi parametri izravnanja odabrani tako da dijagonalni elementi tranzicione matrice $\boldsymbol{F}$ imaju vrednosti nešto veće od 1, varijanse predviđenih promenljivih stanja će postepeno rasti tokom vremena. S obzirom da približna jednakost odgovarajućih elemenata matrica $\boldsymbol{P}^-$ i $\boldsymbol{P}^+$ važi i ovde, s porastom varijansi predviđenih promenljivih stanja rašće i varijanse estimiranih promenljivih stanja ka svojoj ustaljenoj (stvarnoj) vrednosti. To znači da će s vremenom opadati nivo prioriteta koji filtar daje rezultatima predviđanja, a rasti nivo prioriteta koji filtar daje merenjima. Ulaskom matrice $\boldsymbol{P}^+$ u oblast ustaljenih vrednosti ova dva nivoa prioriteta postaće približno isti.

Povećanjem varijansi grešaka dinamičkog modela ubrzaće se ulazak matrice $\boldsymbol{P}^+$ u oblast ustaljenih vrednosti, zbog čega se s porastom vrednosti parametra q greška estimacije ξ_n smanjuje. Na slici 3 prikazana je progresija dijagonalnih elemenata matrica $\boldsymbol{P}^-$ i $\boldsymbol{P}^+$ za dva različita podešenja parametra q. Vidi se da pri $q=-11$ matrica kovarijansi $\boldsymbol{P}^+$ dostiže svoju ustaljenu vrednost skoro dvostruko brže nego pri podešenju $q=-15$.



Slika 3. Progresija varijansi predviđenih i estimiranih vrednosti promenljivih stanja aproksimiranih EKF algoritmom dinamičke estimacije stanja na trening periodu za dva različita podešenja parametra q

Sa smanjenjem vrednosti parametra q ispod -15 opada i udeo koji imaju varijanse grešaka dinamičkog modela u aproksimiranim vrednostima varijansi predviđenih promenljivih stanja. Sa slike 1 vidi se da sa smanjenjem vrednosti parametra q ispod -15, greška estimacije ξ_n postaje sve manje osetljiva na promene parametra q.

Scenario „tačan start 1“

Za scenario „tačan start 1“ mogu se izvesti slični zaključci kao i za prethodno analizirani scenario, s tim da su varijanse inicijalnog rešenja jednake 0, pa filtar tretira inicijalni vektor stanja kao apsolutno tačan. Zbog toga varijanse grešaka dinamičkog modela u početnom trenutku imaju glavni udeo u aproksimiranim vrednostima varijansi predviđenih promenljivih stanja, pa je greška estimacije ξ_n osetljiva na promene parametra q i za vrednosti $q<-15$. U tom slučaju će u početku varijanse predviđenih promenljivih stanja biti još manje nego kod scenarija „tačan start 2“, što će produžiti vreme konvergencije matrice $\boldsymbol{P}^+$ ka svojoj stvarnoj vrednosti i time rezultovati još većom greškom estimacije ξ_n. Za scenario „tačan start 2“ važi da, s porastom vrednosti parametra q iznad -15, varijanse grešaka dinamičkog modela dobijaju, u početnom trenutku, sve veći udeo u aproksimiranim vrednostima varijansi predviđenih promenljivih stanja, zbog čega greške estimacije ξ_n dobijene za scenarija „tačan start 1“ i „tačan start 2“ teže da se izjednače. Drugim rečima, ako su dijagonalni elementi matrice $\boldsymbol{Q}$ samo za red veličine veći od 10^{-15}, onda je nebitno da li su dijagonalni elementi matrice $\boldsymbol{P}_0^+$ jednaki 0 ili 10^{-15}.

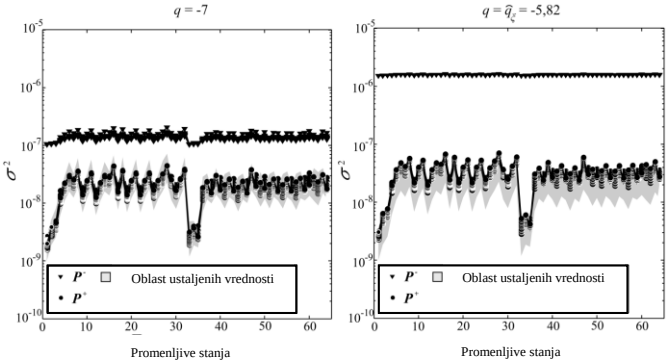
Slično važi i za UKF algoritam na ovom intervalu vrednosti parametra q, samo što on postaje osetljiviji na promene parametra q pri ekstremno niskim vrednostima.

Interval vrednosti parametra $-8 \le q \le \hat{q}_\xi$

Iako scenario „SSE start“ u intervalu vrednosti parametra $-16 \le q \le -8$ značajno popravlja kvalitet dinamičke estimacije u odnosu na preostala dva scenarija, greška dinamičke estimacije je i dalje prilično veća od greške statičkog estimatora (pogledati sliku 1). To znači da treba smanjiti nivo prioriteta koji filtar daje predviđenim vrednostima, a to se može postići povećanjem vrednosti parametra q. Već pri kraju prethodno navedenog intervala varijanse grešaka dinamičkog modela postepeno zalaze u oblast ustaljenih vrednosti varijansi estimiranih promenljivih stanja. Kako vrednost parametra q dalje raste, nivo prioriteta koji filtar daje rezultatima predviđanja opada, a nivo prioriteta koji filtar daje merenjima istovremeno raste, što smanjuje grešku dinamičke estimacije ξ_n. Ključno pitanje je koliko treba povećati vrednost parametra q da bi odnos u nivoima prioriteta koje filtar daje rezultatima predviđanja (s jedne strane) i merenjima (s druge strane) bio optimalan? U slučaju analiziranog test sistema to je vrednost $q=\hat{q}_\xi=-5{,}82$.

Čim vrednost parametra q poraste toliko da varijanse grešaka dinamičkog modela izađu iz oblasti ustaljenih vrednosti dijagonalnih elementa matrice $\boldsymbol{P}^+$, varijanse grešaka dinamičkog modela dobijaju dominantan uticaj pri aproksimaciji varijansi predviđenih promenljivih stanja. Zbog toga se, pri vrednostima većim od $q \approx -7{,}5$, rezultati estimacije sa scenarijom „SSE start“ gotovo identično poklapaju s rezultatima estimacije dobijenim s preostala dva scenarija (pogledati sliku 1).

S porastom vrednosti parametra q, sve više se narušava jednakost odgovarajućih elemenata matrica $\boldsymbol{P}^-$ i $\boldsymbol{P}^+$, što se vidi na slici 4. Veća vrednost parametra q modeluje grešku dinamičkog modela s većom varijansom. Usled toga se povećava neizvesnost u rezultatima predviđanja, a posledično, kroz proces filtriranja, dolazi i do povećanja varijansi estimiranih promenljivih stanja.



Slika 4. Varijanse predviđenih i estimiranih vrednosti promenljivih stanja aproksimirane EKF algoritmom dinamičke estimacije stanja na celom trening periodu za vrednosti parametra (a) $q = -7$ i (b) $q = \hat{q}_\xi = 5{,}82$

Sa slike 1 može se zapaziti da dinamička estimacija stanja ima manju grešku od statičke ukoliko je matrica kovarijansi $\boldsymbol{Q}$ adekvatno podešena. Bez obzira na scenario inicijalizacije ili tip Kalmanovog filtra, greška dinamičke estimacije stanja dostiže minimum za gotovo identičnu vrednost parametra $\hat{q}_\xi$. Osim toga, u okolini optimuma scenariji „tačan start 1“ i „tačan start 2“ daju apsolutno iste rezultate (krive se poklapaju). Iako su rezultati dobijeni s ova dva scenarija u okolini optimuma bolji nego oni dobijeni sa scenarijom „SSE start“, razlike u grešci estimacije su zanemarljivo male, što je značajno iz dva razloga:

1. Ako je matrica kovarijansi $\boldsymbol{Q}$ podešena optimalno, izbor inicijalnog vektora stanja i njemu pripadajuće matrice kovarijansi nije od velikog značaja.

2. Scenariji „tačan start 1“ i „tačan start 2“ su hipotetički, u smislu da su zasnovani na pretpostavci da je poznato tačno stanje u sistemu, što se može ostvariti samo u uslovima simulacije. Tačan vektor stanja nije moguće poznavati u praksi. S druge strane, scenario „SSE start“ može se koristiti u praktičnim aplikacijama. Male razlike u rezultatima ukazuju na to da se u praktičnim aplikacijama stanje u sistemu može estimirati s gotovo najvećim mogućim stepenom tačnosti.

Interval vrednosti parametra $q > \hat{q}_\xi$

Već na početnom delu ovog intervala vrednosti grešaka estimacije dobijene pomoću dva različita algoritma dinamičke estimacije stanja počinju da se razilaze, pri čemu greška UKF algoritma počinje naglo da raste (pogledati sliku 1).

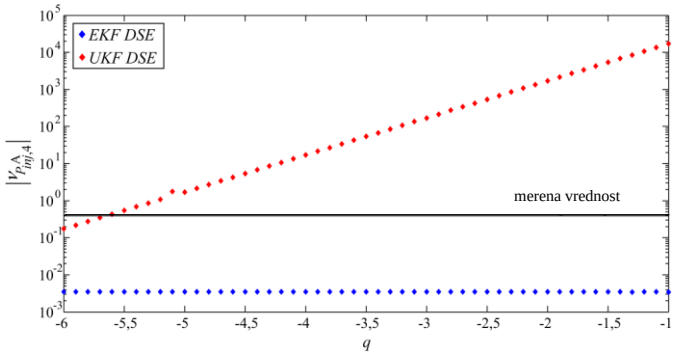
EKF algoritam koristi matricu kovarijansi $\boldsymbol{Q}$ samo pri aproksimiranju matrice kovarijansi predviđenog vektora merenja $\boldsymbol{T}$, ali ne i pri proračunu predviđenog vektora merenja $\boldsymbol{z}^-$ (pogledati jednačine (4) i (5)). Kako u ovom intervalu filtar daje veći nivo prioriteta merenjima nego rezultatima predviđanja, predviđeni vektor merenja se neće značajnije menjati s promenom parametra q. Osim toga, predviđene vrednosti merenja biće generalno blizu vrednosti samih merenja (biće istog reda veličine). S porastom vrednosti parametra q nivo prioriteta koji filtar daje predviđenim vrednostima merenja biće sve manji i manji. Može se zaključiti da greška estimacije ξ_n na ovom intervalu raste jer filtar ne daje dovoljan nivo prioriteta vrednostima predviđenim pomoću dinamičkog modela. Drugim rečima, greška dinamičkog modela je precenjena u smislu da je pretpostavljena varijansa greške veća od stvarne. Indikativno je da greška ξ_n, dobijena EKF algoritmom dinamičke estimacije stanja, teži grešci statičkog estimatora kako parametar q raste po vrednosti. To je i opravdano jer će se, pri velikim vrednostima parametra q, prioritet koji filtar daje rezultatima predviđanja svesti na toliko mali nivo da se može reći da filtar estimira samo na osnovu trenutnog preseka merenja.

Za razliku od EKF algoritma, kod UKF algoritma matrica kovarijansi $\boldsymbol{Q}$ ima udela i pri proračunu predviđenog vektora merenja $\boldsymbol{z}^-$ (pogledati jednačine (17) i (18)). Na prethodna dva intervala vrednosti parametra q taj udeo je bio zanemarljiv, ali na aktuelnom intervalu dolazi do izražaja. S porastom vrednosti parametra q rastu varijanse predviđenih vrednosti merenja (i to s istim trendom rasta kao kod EKF algoritma), ali ujedno raste i odstupanje predviđenih vrednosti merenja u odnosu na sama merenja, tj. rastu inovacije merenja (što kod EKF algoritma nije izraženo). Porast varijansi predviđenih vrednosti merenja odražava se na porast varijansi inovacija (jednačina (20)).

Na početnom delu intervala (oko optimuma) porast varijansi inovacija uspeva da prati porast inovacija. Međutim, već pri vrednostima većim od $q \approx -5$ inovacije počinju da rastu znatno brže tako da varijanse inovacija ne stižu da adekvatno isprate taj porast. Za pojedina merenja, predviđene vrednosti se pri $q = -5$ razlikuju od izmerenih vrednosti za red veličine. Iako pri ovom podešenju parametra q filtar daje veći nivo prioriteta merenjima, izvestan nivo prioriteta daje se i rezultatima predviđanja. Kako su za pojedina merenja razlike između predviđenih i izmerenih vrednosti velike, rezultati predviđanja će estimirane vrednosti „udaljiti“ od merenja više nego što je to slučaj kod EKF algoritma, a samim tim više i od tačnog vektora stanja. Zbog toga greška estimacije ξ_n raste. Zbog nesrazmernosti u brzini rasta inovacija i varijansi

inovacija, greška estimacije najpre naglo raste (do $q \approx -3$), da bi se daljim porastom parametra q ova nesrazmernost počela polako da opada i nestaje, zbog čega greška prestaje da raste. Osim toga, pri kraju ovog intervala vrednosti parametra q su takve da razlike između predviđenih vrednosti i samih merenja mogu biti enormne, što UKF algoritam potencijalno može uvesti u numeričke probleme [11].

Na slici 5 prikazano je kako izgleda apsolutna vrednost inovacije ν telemetrisanog merenja aktivne snage injektiranja u fazi A čvora 4 u trenutku $k = 15$ pri različitim podešenjima parametra q, dobijena pomoću dva različita algoritma dinamičke estimacije stanja. Takođe, na slici 5 je prikazana vrednost merenja u trenutku $k = 15$, kako bi se stekao utisak koliko iznosi relativno odstupanje predviđene vrednosti u odnosu na izmerenu.



Slika 5. Apsolutna vrednost inovacije telemetrisanog merenja aktivne snage injektiranja u fazi A čvora 4 dobijena EKF i UKF algoritmom dinamičke estimacije stanja na trening periodu u trenutku $k = 15$ pri različitim podešenjima parametra q

V. Zaključak

U ovom radu sprovedena je detaljna analiza osetljivosti greške dinamičke estimacije stanja na promene inicijalnog rešenja (inicijalno estimirani vektor stanja i njemu pripadajuća matrica kovarijansi) i matrice kovarijansi grešaka dinamičkog modela.

Utvrđeni su razlozi specifične osetljivosti greške dinamičke estimacije stanja na promenu analiziranih parametara Kalmanovog filtra, čime je načinu na koji se greška menja data čvrsta teorijska potvrda. Može se zaključiti da se osetljivost greške na promene ovih parametara ne može zanemariti čak ni u kvazistacionarnom režimu. Stoga je pravilan izbor ovih parametara, a pre svega parametra matrice kovarijansi grešaka dinamičkog modela, od presudnog značaja kada je u pitanju kvalitet dinamičke estimacije stanja u distributivnim mrežama.

Pokazano je da promena analiziranih parametara utiče na gotovo identičan način na grešku dinamičke estimacije stanja bez obzira koji tip Kalmanovog filtra je u upotrebi. Odstupanja postoje jedino pri izuzetno niskim i izuzetno visokim vrednostima parametra matrice kovarijansi grešaka dinamičkog modela. U tom slučaju EKF pokazuje bolje karakteristike u pogledu filtriranja.

Izbor inicijalnog rešenja i matrice kovarijansi grešaka dinamičkog modela odražava se na aproksimiranje neizvesnosti u predviđenom vektoru merenja, kao i vektoru inovacija, koje imaju presudnu ulogu u fazi detekcije i identifikacije anomalija kod ovakve vrste estimatora. Razumevanje načina na koji Kalmanov filtar aproksimira pojedine matrice kovarijansi je od velikog značaja u fazi detekcije i identifikacije anomalija. Stoga ovaj rad predstavlja dobru osnovu za buduća istraživanja novih metoda za detekciju i identifikaciju anomalija u dinamičkoj estimaciji stanja distributivnih mreža.

Abstract

When distribution network operates in steady state conditions the process noise covariance matrix $\boldsymbol{Q}$ is commonly modeled as time invariant in diagonal form with diagonal elements all equal, which leads to a one-parameter matrix model. In this case the assessment of process noise covariance matrix $\boldsymbol{Q}$ comes down to the assessment of a single parameter q. The accuracy of dynamic state estimation is conditioned by the choice of this parameter, but also by the choice of the initial solution, where initial solution encompasses initial state vector $\boldsymbol{x}_0^+$ and its error covariance matrix $\boldsymbol{P}_0^+$. The aim of this paper is to investigate in detail the simultaneous effect of parameter q and initial solution on the accuracy of dynamic state estimation. The analysis are carried out on modified IEEE distribution test system with 13 buses using the EKF and UKF dynamic state estimation algorithm.

The sensitivity of dynamic state estimation error to changes in Kalman filter parameters

MRTD Measurements Role in Thermal Imager Quality Assessment

Dragana Perić, *Member, IEEE*, Branko Livada, *Member, SPIE*

Abstract— **The MRTD is defined as thermal imager basic parameter that could be theoretically modelled and experimentally assessed in laboratory. The subjective MRTD measurement procedure that is practically implemented is presented. The MRTD theoretical models, possibilities for objective measurements, and alternative MRTD measurement methods are discussed. MRTD measurement results for selected thermal imagers and measurement results post processing for thermal imager range determination are presented**.

***Index Terms* — Thermal imager; Minimum resolvable temperature difference; MRTD subjective measurements; thermal imager range.**

I. INTRODUCTION

Modern long range electro-optical surveillance systems [1], [2] applications involve infrared focal plane based imager channel as a must. The current infrared detector technology development [3] provides that this technology is not exclusively military, but is also available for civilian surveillance/reconnaissance applications. In these applications the basic requirements are connected with knowledge of how far one can see the object of interest – target, and distinguish useful visual data about target.

Various measures and techniques are now available to characterize spatial information transfer, sensitivity and noise in thermal imagers that could help the system architect to predict imager range properties. Also, various figures of merit and measurement techniques were developed to assess the overall device performance. One of the most frequently used and relevant parameters is Minimum Resolvable Temperature Difference – MRTD [4]. MRTD represents thermal imager figure of merit that could be modelled [5] - [9], measured and used for range prediction calculations according to the selected visual data perception criteria. MRTD measurement procedures generally involve application of the selected target test pattern using controlled temperature blackbody source, projection collimator and generated image analysis (perception). The standard MRTD procedure involves human observer in the measurement loop.

In this article we described MRTD measurement procedure realized in the Vlatacom Electro-optical laboratory, we also presented selected measurement results and their post processing which is done in order to determine imagers range according to selected visual data perception criteria.

The subjective MRTD measurement methodology is described after more detailed MRTD definition. Also, we discuss the potential and issues with objective MRTD measurements and new alternative measurement methods using different test targets. At the end we are presenting measurement results for selected thermal imagers together with range predictions using MRTD measurement results.

Branko Livada is with Vlatacom Institute, Bulevar Milutina Milankovica 5, 11070 Belgrade, Serbia (e-mail: branko.livada@vlatacom.com).

II. MRTD DEFINITION

The MRTD is the minimum temperature difference which allows an observer to resolve a test pattern in accordance with a given criterion. MRTD is a function of spatial frequency of the test pattern. It depends on measurement temperature and may depend on the orientation of the test pattern.

Historically, the basic MRTD test pattern as shown in Fig.3 is selected according to Johnson's criteria [10] for visual data perception. Following results from experimental research of the visual data perception by human observer, Johnson determined the number of the periodic line pairs over target critical dimension that provide related level of the visual perception (detection - D, recognition - R, identification - I). His results were accepted as an industry standard. The spatial frequencies mean values for different visual data perception levels as defined by Johnson's criteria are listed in TABLE I. These criteria are derived for visual data transformation process that keep the same contrast ratio in basic and transformed image and perception level do not depends on of the signal to noise ratio, assuming 50% perception probability.

Typical test targets following D, R, I criteria used in laboratory testing are presented in Fig. 1.

TABLE I
VISUAL PERCEPTION LEVELS AGAINST CRITICAL SPATIAL FREQUENCY, AS DEFINED BY JOHNSON'S CRITERIA

Critical Spatial frequency	***Visual perception level***		
	D	**R**	**I**
lp/target size	**1,±0,25**	**4±0,8**	**6,4±1,5**

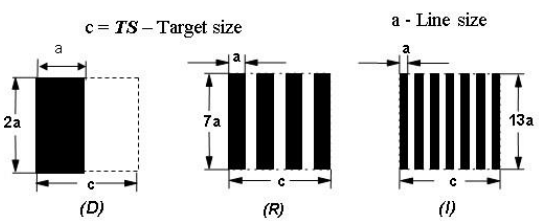

Fig. 1. Commonly used test target patterns following D, R, I visual perception criteria

As defined in the standard for the subjective MRTD test, human observer should determine and indicate when target is resolved. There are efforts to use automatic objective target resolution criteria but current implementations haven't reached yet required level of fidelity, because they require complex image processing techniques to be developed.

Also, there are efforts to use different target (Triangle orientation – TOD) that shows good results and eliminate some of the disadvantages of the concept with four bar target. Both, objective and alternative MRTD measurement methodology will be discusses separately.

In our approach we use the four bar target and subjective methodology that is described in details.

III. SUBJECTIVE MRTD MEASUREMENT METHODOLOGY

According to measurement best practices [10] – [13] and standards [14] – [17], MRTD measurement set up comprises IR reflexive collimator and differential blackbody in conjunction with 4 bar test pattern, as illustrated in Fig. 2 and Fig.3.

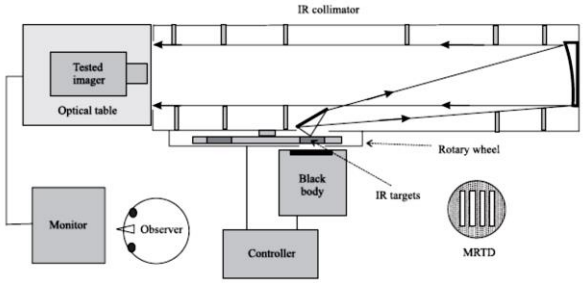

Fig. 2. MRTD Measurement set-up

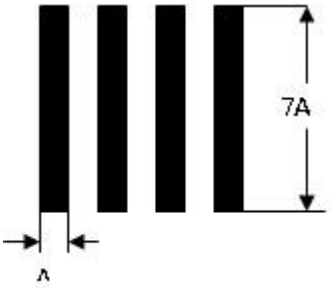

Fig. 3. MRTD four bar test pattern structure

During the MRTD measurements laboratory conditions and other measurement conditions should be established, as follows:

A. Laboratory conditions

Unless otherwise specified in the thermal imager specification, the ambient temperature during the test is set at the normal room temperature (20ºC ± 2ºC).

Relative humidity does not need to be controlled.

The illumination in the test area should be set as close as operational illumination providing that observer could set it as most convenient.

B. Observer

Observer shall have normal visual acuity (post-correction defects less than ±0,25 diopter, and good color vision.

Observer should be experienced (trained) in this type of measurements.

Observer is allowed to adjust room illumination, and the distance of his eye from display to provide optimal image perception.

C. IR collimator

It is recommended to use reflective off-axis collimator with known transmittance in the imager's spectral sensitivity region. The collimator transmittance should be known and could be used in measurement results correction, if necessary.

D. Test pattern

Four bar test pattern structure is illustrated in Fig 3.

Test pattern is placed in the collimator focal plane. In that case one bar angular size is:

$$\alpha_t[rad] = 2 \cdot arctg\frac{A}{2f} \approx \frac{A}{f} \quad (1)$$

Where A is bar width and f is collimator focal length.

Test target spatial frequency f_t^*, could be calculated as:

$$f_t^*\left[\frac{lp}{rad}\right] = \frac{2}{\alpha_t} \quad (2)$$

E. Differential blackbody

The emissivity of the test pattern surface and black body surface should be at least 0,95.

The blackbody must have the capability of achieving temperature difference of ±10 K. The temperature measurement accuracy must be better than 0,5% generally and 0,01 K, for temperature differences between 0 K and ±2K.

Test pattern and blackbody temperature measurement accuracy TR, temporal stability TS and spatial uniformity TU requirements are related to device under test (DUT) sensitivity limit, such as Noise Equivalent Temperature Difference NETD. These parameters should have the given ratio respectively: NETD ≥ 5TR, NETD ≥ TS and NETD≥5TU.

F. Monitor

Monitor characteristics (type, size and resolution) should be selected in correspond with the specification of the imager under test. Monitor should not be readjusted during measurements, it should keep initial settings.

G. Measurement Procedure

MRTD Measurement Preparation

STEP 1: Nyquist frequency (f_0) determination for device under test (DUT)

Using available DUT specification or measurement results Nyquist frequency should be determined, using one or all listed methods:

- According to DUT design data and related model application results, calculate Instantaneous Field of View (IFOV) and Nyquist frequency accordingly.
- Using USAF1951Test Chart determine DUT resolution frequency.
- Using DUT calibration procedure determine IFOV and

DUT Field of View (FOV).

STEP 2: Test target selection

To generate MRTD curve against spatial frequency, at least three targets with related spatial frequencies should be used. The selection of targets in the test depends on availability.

It is recommended to use targets with following spatial frequencies: ~f_0 , 0,8f_0, 0.5f_0 , 0,2f_0. In the case that DUT requirements define other test frequencies the additional targets with required spatial frequencies should be provided. The target spatial frequencies must be within ±5%, of the nominal value.

MRTD Measurement Execution

- Position the target with the bars oriented vertically to obtain the horizontal MRT or horizontally to measure the vertical response.
- Verify that four bars are visible when limiting test temperature difference (≤ 2K) is set.
- Using test set-up controller establish a positive sub-MRTD temperature differential and slowly increment the blackbody temperature differential.
- Allow the observer to continually adjust DUT controls to optimize the image for given focal length.
- Record the temperature difference (MRTD+) at which the observer can detect all four bars with 50% probability.
- Establish a negative sub-MRTD temperature differential and slowly decrement the blackbody temperature differential. Wait until temperature difference stabilized before apply next decrement step.
- Record the temperature difference (MRTD-) at which the observer can detect all four bars with 50% probability.
- Average the absolute values of positive and negative temperature differential recordings to obtain the MRTD.

$$MRTD(f^*) = \frac{MRTD_+ - MRTD_-}{2} \tag{3}$$

- Record measured values in the prepared measurement results template (it is recommended to use the separate measurement results EXCEL spreadsheet containing data processing and measurement report sheet).
- If a target cannot be resolved, record TNR.
- Repeat for other spatial frequencies.

NOTE 1: *Blackbody temperature differential controls*

MRTD measurements are time consuming. To economize measurement time it is recommended to follow best practice in selection of the starting temperature difference and temperature change step value. Some good recommendation could be applied.

- Following expected MRTD values and knowledge about DUT NETD, select starting temperature difference to minimize measurement time (Example: set starting temperature difference value to be 5 NETD).
- Select temperature difference step value accordingly to starting value following recommendations from table below:

ΔT [K]	Proposed Step
Below 0,5 K	0,01 K
0,5 K to 1,0 K	0,02 K
1,0 K to 2,0 K	0,05K

NOTE 2: *50% probability of detection criteria*

50% probability of detection during MRTD test could be derived from following recommendations.

- All four bars are visible during 50% of the observation time.
- All four bars are visible all the time but with height equal or higher than 50% of nominal height.
- In the case that several observers are involved in measurement the 50% detection probability is achieved if at least 50% of observers agree that target is resolved.

MRTD measurement results should be listed as table and plotted as MRTD measurement chart.

IV. Objective MRTD measurement issues

MRTD provides connection between thermal imager sensitivity represented by NETD (noise equivalent temperature difference), image transformation represented by MTF (modulation transfer function) and response represented by SNR (signal to noise ratio) [21], as:

$$MRTD(f) = \frac{SNR \cdot NETD}{MTF(f)} \cdot \boldsymbol{F}_{TIS}(f, DP) \tag{4}$$

Where: F_{TIS}(f, DP) – is thermal imager related design function depending on system design parameters - DP. This MRTD model could be proved by laboratory measurements.

The main goal of objective MRTD measurements [22] is to deliver results comparable with subjective method, but less costly and much faster. The key issue is how to automatically represent visual perception of the human observer and displayed image. Different techniques were applied but still nono of them delivered result which is considered good enough.

V. Alternative MRTD measurement methods

There are two general weaknesses with standard MRTD testing [23], [24]: (i) subjective test (depends of the observers that lead to higher inaccuracies in the test results obtained in different labs); (ii) the test target is a 3-bar or 4-bar pattern with a specific spatial frequency so limited bracket of test patterns is applied. Because of that some new test methods and concepts are considered.

MTDP (Minimum Temperature difference Perceived) [25] that uses the traditional static 3 or 4 bar target but allows that under-sampled thermal imagers could be evaluated above Nyquist frequency.

A new test should at least have the following properties [26], [27]: lab testing is objective and easy, the measure is representative for field performance, and modelling (sensor and human) the test should be relatively easy. Several alternative test methods and test patterns have already been proposed. An example is the TOD method [28] that uses non-periodic test patterns

The TOD (triangle orientation discrimination) method use test patterns (oriented equilateral triangles) that represent features or the relation between features of real targets. Triangle size is related to spatial frequency. If an observer is able to discriminate between the different triangle orientations, he also has information about the target features

necessary to identify a target. Observer is not able to determine the correct orientation of the original test target if: (i) the test pattern cannot be detected (because the SNR is too low); (ii) its shape cannot be determined (because corners and edges disappeared due to blur or sampling); or (iii) the shape is incorrectly judged (relative positions are disturbed due to under-sampling or to phase shifts introduced by electronics).

TOD metric has short observation window, provides better capability for evaluating sensors that exhibit non-negligible uniformity drift, and could be more effective for sensor dynamic evaluation. In addition, same methodology is applicable for IR and visible image sensors.

VI. MRTD MEASUREMENT RESULTS AND PROCESSING

MRTD measurement results could be used to calculate related perception range using predefined criteria and procedure [15], [16].

Nominal static range performances are determined for target size (TS=2,3m x 2,3m) and target effective temperature difference to background ΔT=2K. The atmospheric attenuation influence is calculated using

$$\tau(R) = e^{-\sigma \cdot R} \tag{5}$$

Where - R is distance in kilometers, σ is atmospheric transmission, that is that has following values:

σ_{gtc} = 0,2 km^{-1} , for good transmission conditions

σ_{ltc} = 1,0 km^{-1} , for limited transmission conditions

MRTD(*f*) must be transformed into MRTD(*R*) (R=R_D, R_R, R_I) using resolution criteria according to Johnson's criteria (Detection- N_D=1 lp/target size; Recognition - N_R = 3 lp/target size; Identification - N_I = 6 lp/target size)

Spatial frequency axis is transformed into related range axis using relation:

$$R[km] = \frac{TS \cdot f^*[lp/mRad]}{N} \tag{6}$$

Where N is resolution criteria value applied.

Both MRTD(R) and apparent temperature difference ΔTA = ΔT(R) should be plotted in the same chart The range coordinate of the cross section point of these two represent related perception range.

The example of the measurement results obtained in our laboratory are presented in Fig.4 (USAF 1951 – test chart showing thermal imager's limiting resolution, Fig. 5 showing MRTD raw measurement results, and Fig.6, Fig.7, Fig.8 are showing visual perception range processing results for standard target and atmospheric conditions in cases of detection, recognition and identification respectively. Three graphs show: apparent temperature difference (ATD – in case of detection, ATP - recognition, ATI - identification), measured values for the selected targets (MRTD_MEAS), and MRTD-FIT which is obtained from values MRTD-MEAS, in order to provide results for all values of range R. MRTD-FIT is calculated according to the function (7):

$$MRTD(f^*) = A + B \cdot f^* \cdot \exp(C \cdot f^{*2}) \tag{7}$$

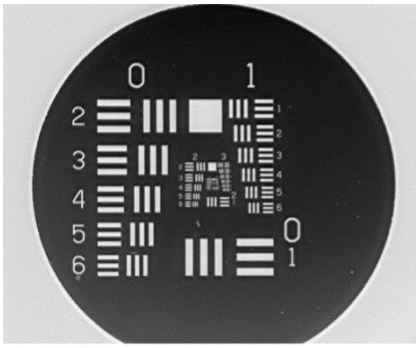

Fig. 4. USAF 1951 Test target image, G3E5 resolved

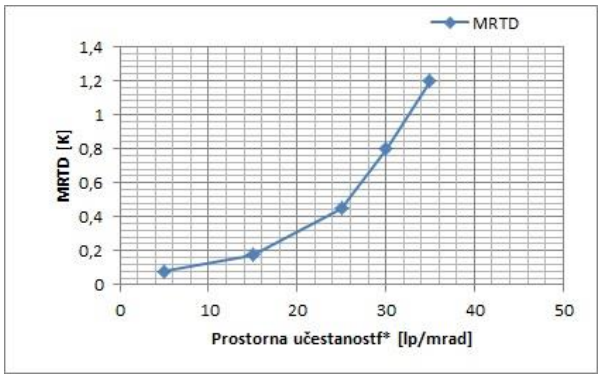

Fig. 5. MRTD measurement results chart

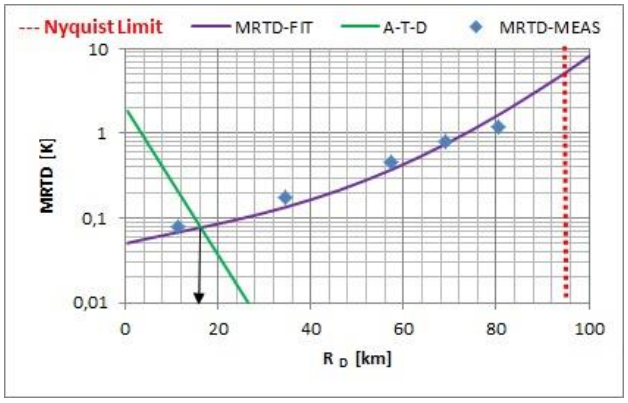

Fig. 6. MRTD Chart with target apparent temperature used for range prediction in case of Detection - D

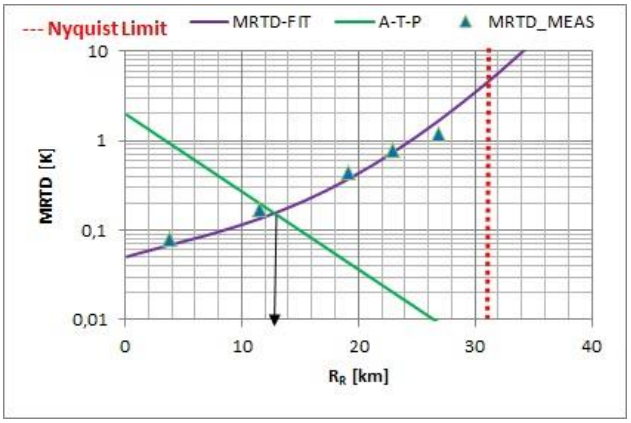

Fig. 7. MRTD Chart with target apparent temperature used for range prediction in case of Recognition - R

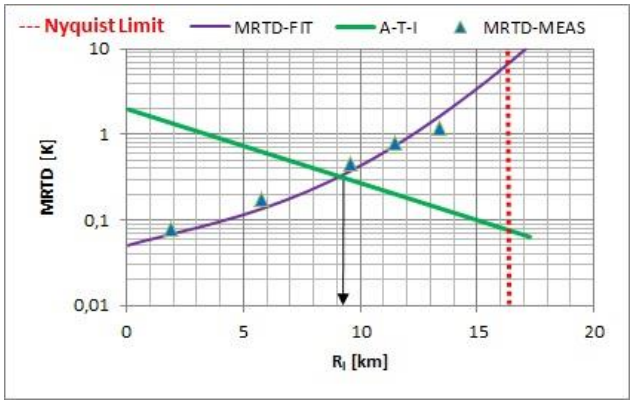

Fig. 8. MRTD Chart with target apparent temperature used for range prediction in case of Identification - I

VII. CONCLUSION

MRTD is complex parameter that combines thermal imager response, image transformation and sensitivity limit, providing possibility for imager range prediction. Because of that it is one of the most important thermal imager parameters. MRTD is imagers figure of merit that measure end-to-end sensor performance including the human observer.

Subjective measurement methods use predefined test patterns and human observer is involved in the measurement. Subjective MRTD measurements are time consuming and costly but provides reliable and reasonably repeatable measurement results

MRTD laboratory test is used for several purposes: (i) to verify if a sensor is working properly; (ii) to compare competing sensor systems; (iii) to verify if a new type of sensor meets the expectations based on its design – compare measurement results with model predictions, and (iv) to predict field performance (target acquisition task performance as a function of distance).

Objective MRTD measurements methods are still being developed and main issue is to criteria definition for human observer perception of the displayed information.

TOD methodology main advantage is that it is applicable without limitation to all the sensor types.

The standard MRTD methodology is successfully realized and applied in Vlatacom EO laboratory for quality assessment of the thermal imager channel in our long range surveillance systems. Our next goal is to extend standard MRTD methodology for evaluation of the SWIR and visible imaging channels.

FPGA Implementation of Selective Pseudo Coloring of Thermal Image

Petar Marin, Igor Beracka, Nikola Latinović, *Member, IEEE*, Miloš Pavlović, *Member, IEEE*, Miroslav Perić, *Member, IEEE*

***Abstract*—In this paper we describe Field Programmable Gate Array (FPGA) implementation of a new method for selective pseudo coloring of thermal image. Pseudo coloring is a digital image processing method of coloring gray scale images, imparting a visual appeal and highlighting specific features in the image. Our selective pseudo coloring method colors only features with thermal emissivity in certain range that is controlled within thresholds. Since pseudo coloring is memory intensive task for many embedded video processing platforms our method of pure FPGA implementation has the advantage in execution speed and reduction of processing delay. Experimental results on selected scene have shown improvement in operator ability to spot objects of interest on image when using our pseudo coloring method.**

***Index Terms*— FPGA, pseudo coloring, video, thermal imaging, digital image processing, embedded**

I. Introduction

Thermal imaging is a technique of acquisition and image processing of thermal radiation emitted by hot objects [1]. Any objects at a temperature higher than absolute zero (i.e. T>0K) emits electromagnetic radiation [2]. The Stefan–Boltzmann law describes the power radiated from a black body in terms of its temperature. Human body temperature has peak of thermal radiation at infrared part of electromagnetic spectrum. The human eye cannot see this type of radiation therefore infrared measuring devices are required to acquire and process this information [3].

There are several types of detectors of medium wave infrared radiation. The most basic one is pyrometer which has single detector capable of detecting temperature of a single spot. Most advanced devices include an array of sensors to produce a detailed infrared image of the scene.

The main advantage of thermal over optical imaging is that illumination of objects is not needed because of emissive nature of hot objects in infrared part of electromagnetic spectrum.

Pseudo coloring, also known as false coloring, is a method of artificially coloring an image in effort to reveal otherwise hidden details and textures from original grayscale image. Various pseudo coloring methods and color palettes are developed [4].

II. System Description

System consist of thermal imaging camera, our frame grabber implemented on Xilinx Kintex 7™ [5] series FPGA and NVIDIA Jetson TX2™ [6] ARMv8™ based video processing engine with NVIDIA Compute Unified Device Architecture (CUDA™) cores for graphics acceleration, all of which is integrated on Vlatacom Video Signal Processing (vVSP™) platform [7].

Output video format from thermal camera is VGA (640x480) pixels at 60 frames per second. FPGA handles Camera Link™ to HDMI™ [8] interface conversion and real time pseudo coloring of video. One of the two HDMI™ interfaces is connected to NVIDIA Jetson TX2™ and the second one is used for displaying uncompressed video on monitor.

Video is compressed on NVIDIA Jetson TX2 ™ embedded video processing system.

PC grabs compressed network stream via Real Time Streaming Protocol (RTSP) [9] and displays compressed video footage on monitor.

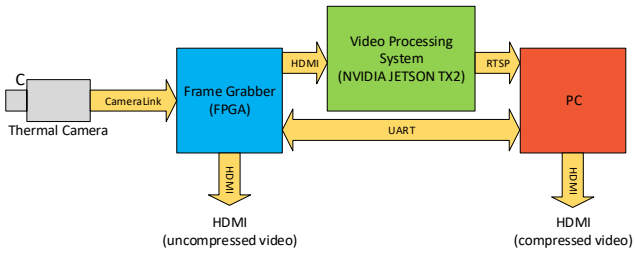

Fig. 1. Functional block diagram of system used for real time selective pseudo coloring of video frame from thermal imaging camera.

III. Selective Pseudo Coloring With Thresholds

Selective pseudo coloring is our approach to emphasize objects with thermal emissivity by choosing two thresholds. Process of forming Look-up Table (LUT) is shown in figure 2. There are two thresholds that user can choose manually. Grayscale LUT is described with equation (1). *R(i),G(i), B(i)* are values of red, green and blue color channel respectively. Parameter "*i*" is intensity of pixel from thermal camera.

$$R_a(i) = G_a(i) = B_a(i) = i,\ i \in [0{,}255] \in N_0 \quad (1)$$

All described LUT palettes from figure 2. are derived from "Image J" [10], an open source project for scientific image analysis. It is possible to use all of defined pseudo

coloring palettes for described selective pseudo coloring method.

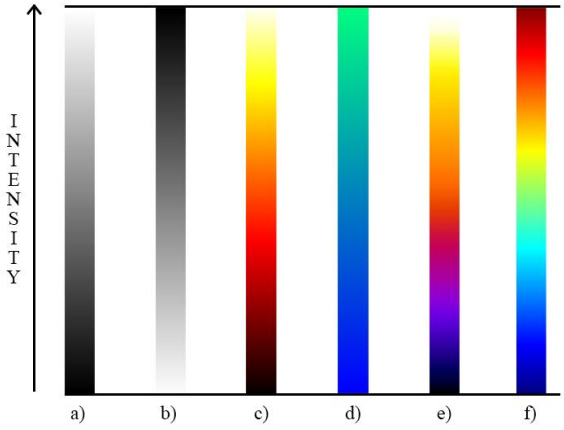

Fig. 2. Graphical representation of all available pseudo color palettes for selective pseudo coloring. a) direct LUT palette, b) inverse LUT palette, c) hot LUT palette, d) cold LUT palette, e) inferno LUT palette, f) jet LUT palette

Formally selective pseudo coloring with threshold and non-expanded LUT is described with equations (2), (3) and (4). User chooses functions $R_b(i),\ G_b(i),\ B(i)$ by choosing pseudo color palettes from Graphic User Interface (GUI) on Personal Computer (PC). Those palettes are shown on figure 2.

$$R_c(i) = \begin{cases} i,\ i < th1,\ \ i \in [0,255] \\ R_b(i),\ i \geq th1, i \leq th2\ ,\ \ i \in [0,255] \\ i,\ i > th2,\ \ i \in [0,255] \end{cases} \quad (2)$$

$$G_c(i) = \begin{cases} i,\ i < th1,\ \ i \in [0,255] \\ G_b(i),\ i \geq th1, i \leq th2,\ i \in [0,255] \\ i,\ i > th2,\ \ i \in [0,255] \end{cases} \quad (3)$$

$$B_c(i) = \begin{cases} i,\ i < th1,\ \ i \in [0,255] \\ B_b(i),\ i \geq th1, i \leq th2\ ,\ \ i \in [0,255] \\ i,\ i > th2,\ \ i \in [0,255] \end{cases} \quad (4)$$

Formally selective pseudo coloring with threshold and expanded LUT is described with equations (5), (6), (7) and (8).

$$th_2 - th_1 \neq 0 \quad (5)$$

$$R_d(i) = \begin{cases} i,\ i < th1, i \in [0,255] \\ R_b\left(\left[\frac{255}{th_2 - th_1}\right]\right),\ i \geq th1, i \leq th2\ , i \in [0,255] \\ i,\ i > th2, i \in [0,255] \end{cases} \quad (6)$$

$$G_d(i) = \begin{cases} i,\ i < th1, i \in [0,255] \\ G_b\left(\left[\frac{255}{th_2 - th_1}\right]\right),\ i \geq th1, i \leq th2, i \in [0,255] \\ i,\ i > th2, i \in [0,255] \end{cases} \quad (7)$$

$$B_d(i) = \begin{cases} i,\ i < th1, i \in [0,255] \\ B_b\left(\left[\frac{255}{th_2 - th_1}\right]\right),\ i \geq th1, i \leq th2, i \in [0,255] \\ i,\ i > th2, i \in [0,255] \end{cases} \quad (8)$$

IV. Practical Implementation

FPGA frame grabber is used for grabbing frames from Camera Link™ interface and processing of captured frame. Frame grabber consist of video preprocessor module, video buffer, pseudo coloring module, HDMI™ driver module and MicroBlaze™ microcontroller implemented on FPGA. Video preprocessor module consists of multiplexers for choosing bit-width of input stream from Camera Link™ interface and RGB to Y converter. Possible configurations are: 8, 10, 12, 14 and 16 bits.

Purpose of video buffer is to synchronize input and output frame rates from different interfaces i.e. clock domains. It can store one whole frame.

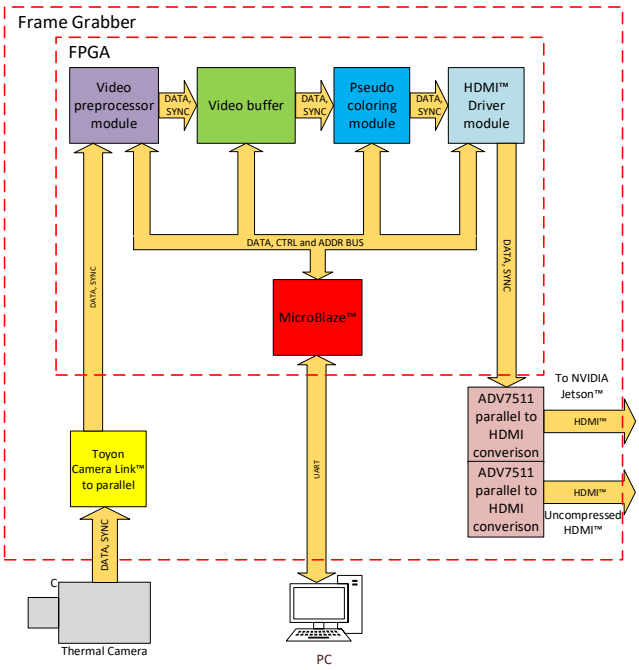

Fig. 4. Simplified block diagram of FPGA frame grabber

Pseudo coloring module is part of a frame grabber implemented on FPGA platform. This is most relevant module in this paper so it will be thoroughly described. Grayscale data is 8 bit wide signal that carries information from pixel that currently draws on HDMI™ interface. It is registered to reduce fan-out of logic that drives this signal because it's used for several other modules. Registered grayscale signal goes to read address input of Dual-ported RAM (DPRAM) and output data is used as output from LUT. Write port of DPRAM is used for loading LUT from MicroBlaze™ microcontroller. It's not possible to read content of this LUT from MicroBlaze™. In this configuration DPRAM act as a configurable LUT. Multiplexer after DPRAM is used for bypassing LUT when DPRAM is not initialized e.g. after system reset. There are three DPRAMs for each color channel. DPRAM has depth of 256x8bit words. Output from multiplexers are registered for reducing fan-out of multiplexer logic.

Output delay from this module is described with equation (12).

$$\tau_{delay} = \tau_{reg} + \tau_{DPRAM} + \tau_{reg} \cong 3T_{CLK} \qquad (12)$$

Frame valid, data valid and line valid signals are synchronization signals needed for generating HDMI™ output signals. Synchronization signals must be delayed for τ_{delay} to be in synchronization with output data from pseudo coloring module.

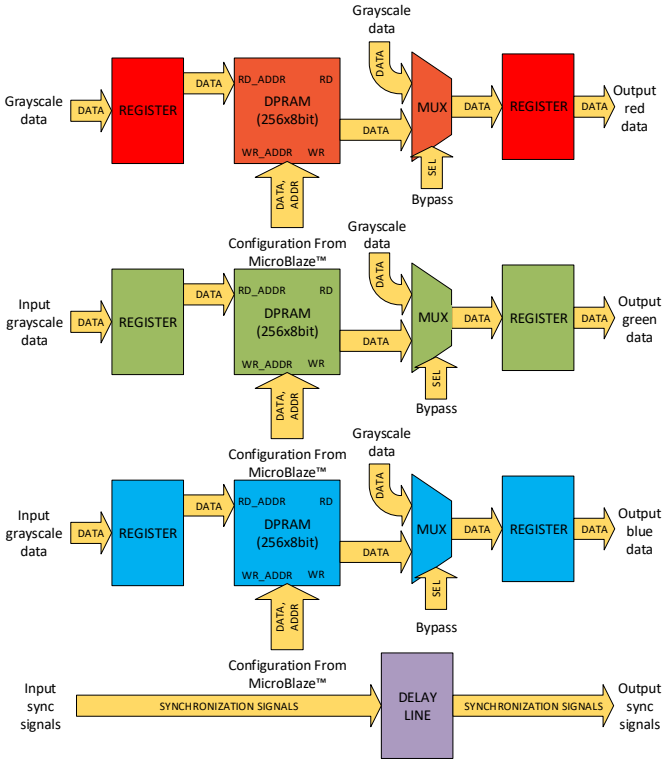

Fig. 5. Block diagram of implemented pseudo coloring module on FPGA platform.

HDMI™ driver module generates address signals for reading from video buffer and synchronization signals for driving external parallel to HDMI™ conversion Integrated Circuit (IC). HDMI™ driver module can be configured with MicroBlaze™ to change resolution and framerate of HDMI™ interface.

MicroBlaze™ is a Soft Intelectual Property (IP) core microcontroller used to control mentioned modules. It uses 64 KB of internal block RAM implemented in logic fabric of FPGA for storing UART terminal application which receives commands from MATLAB™ GUI application. LUTs are created in GUI on PC and loaded in pseudo coloring module via UART interface on MicroBlaze™.

V. Experimental Results

Experimental system consist of thermal imaging camera RP Optics C330™ [11] with electronically controlled optics from PC, Vlatacom vVSP module and two UART connections on PC. One is used for configuring camera and the other one is for communication with MicroBlaze™ microcontroller on Vlatacom vVSP module. Ethernet connection is used for watching video stream via RTSP on local PC.

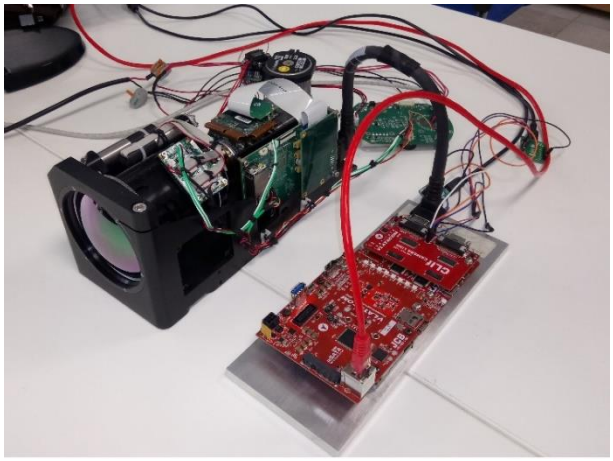

Fig. 6. Setup used for capturing images for examples. RP Optics C330 thermal imaging camera is on the left side of the picture and Vlatacom VSP module is on the right side of picture (red PCB).

On figure 7. scene is observed in visible part of electromagnetic spectrum. There are several objects of interest of this picture like hot cup of water, bottle of cold water and a subject holding a hot soldering iron.

Fig.7. Observed scene captured in visible part of electromagnetic spectrum

Frame in figure 8. is captured with thermal imaging camera. In this picture it is clearly visible that cup of water and soldering iron are indeed hot. Reflection of soldering iron on a glass wall is clearly visible in this picture.

Fig. 8. Grayscale frame with resolution 640x480 pixels from thermal camera.

After the pseudo coloring is applied for a specified thresholds subject, hot cup of water, and a soldering iron are emphasized in figure 9.

Fig. 9. Selective pseudo coloring of frame from thermal camera with th1=0 and th2=87 without LUT expansion. LUT palette is on the right side of the picture.

Contrast of objects of interest are further increased when LUT expansion is applied in figure 10.

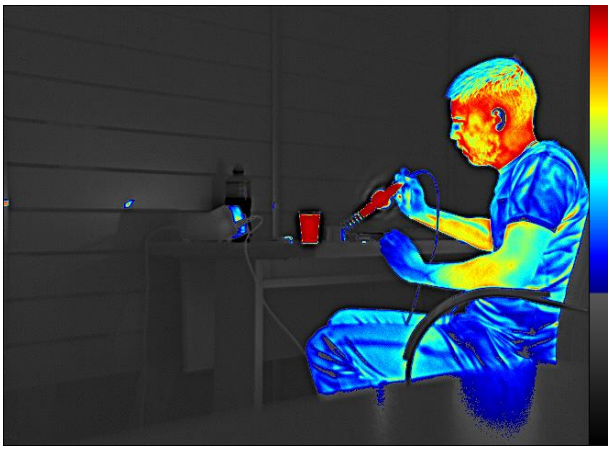

Fig. 10. Selective pseudo coloring of frame from thermal camera with th1=0 and th2=87 with LUT expanded. LUT color palette is on the right.

It is also possible to isolate cold background for empirically derived threshold levels as it was shown on figure 11.

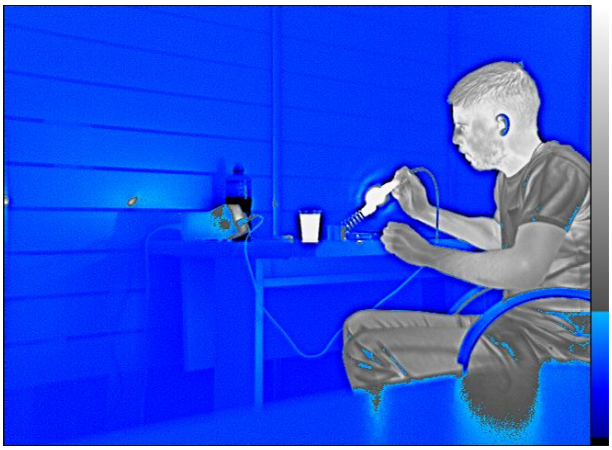

Fig. 11. Selective pseudo coloring of frame for parameters th1=5 and th2=79. LUT color palette is on the right side of the picture.

VI. Conclusion

Implementation has proven that acceleration of pseudo coloring process is indeed possible with the use of FPGA. Selective pseudo coloring gave good results as visibility of object of interest in image is greatly increased. Visibility of halo effect from sharpening filter of camera internal video processing engine is also increased.

Increasing captured frame dynamic range and bit depth of pseudo coloring module is expected to give even better results.

***Abstract*— Video enhancement techniques are very important part of long-range multi-sensor surveillance systems. Infrared sensors are typically affected by nonresponsive pixels, or "dead pixels." These dead pixels can severely degrade the quality of images and often have to be replaced before subsequent image processing and display of the imagery data. Conventional dead pixel replacement methods (methods for 'salt' noise reduction) take a lot of processor time and cannot be employed in real-time applications. This paper proposes a real-time infrared imaging dead pixels removal algorithm, applicable to SWIR sensor. Dead pixels reduction is based on *Inverse Distance Weighting* algorithm applied only on positions of dead pixels. Also, paper provides comparison of *Inverse Distance Weighting* algorithm with the most commonly used techniques in literature - median filtering. All the techniques are tested on experimental data.**

***Index Terms*— Dead pixels, Real - Time, IDW, Median filtering, Thermal imaging.**

I. Introduction

Infrared (IR) thermal cameras have been used in military and civil applications for many years. An IR thermal camera provides a picture of the electromagnetic energy radiated from an object in the IR spectral band. The IR spectrum consists of the reflected band which is dependent upon material reflectivity and thermal IR band, which is dependent upon the temperature and emissivity of the material. A number of sensor technologies have been designed and optimized for imaging in the IR spectral band, each posing unique design challenges. In various atmospheric conditions that make visible light sensors partially or completely "blind", infrared sensors provide ability of effective view.

The IR band is further divided into four bandwidths: Near IR (NIR) - 0.74-1.4μm wavelength range, Short-Wave IR (SWIR - 1.4-3μm), Medium-Wave IR (MWIR - 3-8μm) and Long-Wave infrared (LWIR - 8-14μm) [1]. The main advantage of thermal sensors is that they are nearly invariant to changes in illumination conditions and provide visual information in low visibility environments and conditions. Emitted thermal energy is less affected by scattering and the absorption by smoke, fog or dust [2].

Despite these advantages and robustness to illumination variations, infrared sensors also suffer from disturbances - most commonly from blur and noise originating from sensors and their environment, sensor dead pixels, … [1], [3].

All thermal sensors are affected by the common problem of unresponsive pixels - termed dead pixels [4], [5]. Dead pixels affect the quality of both, the visual image and the elementary data. True scene that is being measured and dead pixels measurement do not have any correlation, and in that way, dead pixels intensely degrade the quality of measured images. Dead pixels measurements need to be replaced with more appropriate values to improve image quality to an acceptable level.

In situations when servicing and calibration of thermal cameras is not possible or takes too much time, image processing algorithm for the repair of dead pixels must be implemented.

Problem of dead pixels in image is a type of 'salt' noise problem. Standard approaches to salt noise removal from literature are mostly based on nearest-neighbor or median filtering [6], [7], [8]. In applications for surveillance, monitoring, especially for ultra-long-range target detection, recognition and identification in full zoom, applying filtering on whole image reduces the noise from the image very successfully, but with the cost of blurring edges. This effect greatly degrades the image quality. Also, applying filtering on the whole image with other video processing algorithms such as digital video stabilization, enhancement and tracking is very time-consuming, especially for real-time applications, such as 25-30 fps and high image resolution. So first, it is necessary to find the positions of dead pixels and then replace their values with appropriate values. It is important to note that determining whether the pixel is dead or not is a significant topic in itself.

This paper proposes a real-time infrared image enhancement pipeline, based on dead pixels reduction (edge preserving smoothing), independent of type of scene content. Dead pixels position detection is based on calculating average pixels value using set of frames while dead pixels reduction is based on Inverse Distance Weighting (IDW) [9] algorithm applied only on positions of dead pixels. provides comparison of processing time per frame for median filtering applied on positions of dead pixels and on the whole image (as the most commonly used technique in literature) and IDW algorithm.

The paper is organized as follows. Section II describes the dead pixels detection algorithm. Section III proposes algorithms for dead pixels replacement – Median filtering and IDW. Section IV describes the experimental work including the experimental setup, results and discussion. Section V lists conclusions and indicates directions for future work in this research area.

II. Dead Pixels Detection

An attempt to find dead pixels as pixels that do not change their value through frames is not possible. Although dead pixels shown in image are actually sensor's dead pixels, the dead pixel intensity on raw images is not constant on all video frames. Dead pixels change values from frame to frame, depending on the scene, as a result of histogram equalization that is performed on the sensor. Also, dead pixels do not have either maximum or minimum intensity value, so their intensities only cannot be indicator of dead pixels positions.

An image contains a number of distinct gray levels of the pixels with difference compared to their neighborhood pixels. If the gray levels of the pixels in an image and their neighbors are mapped in such a way that the difference in the gray levels of the neighbor with the pixel is noticeable, then dead pixels can be detected and mapped by estimating average pixel value for each pixel using set of frames contaminated with dead pixels – Eq. (1).

$$I(i,j) = \frac{1}{N_{frames}} \sum_{k=1}^{N_{frames}} F_k(i,j) \qquad (1)$$

Fig. 1 presents average pixel values obtained using Eq. (1).

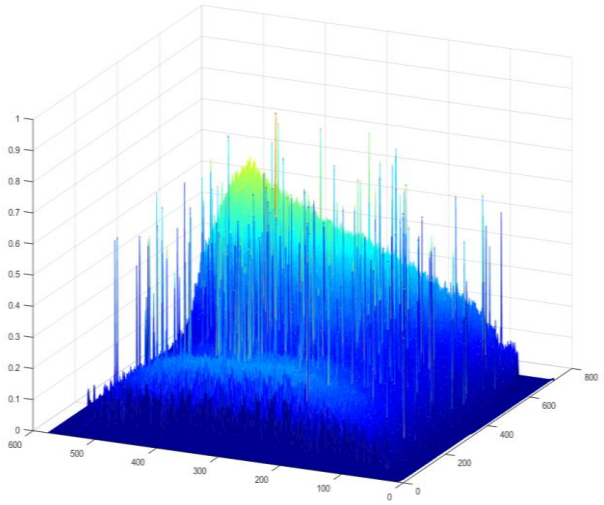

Fig. 1 Average pixel values

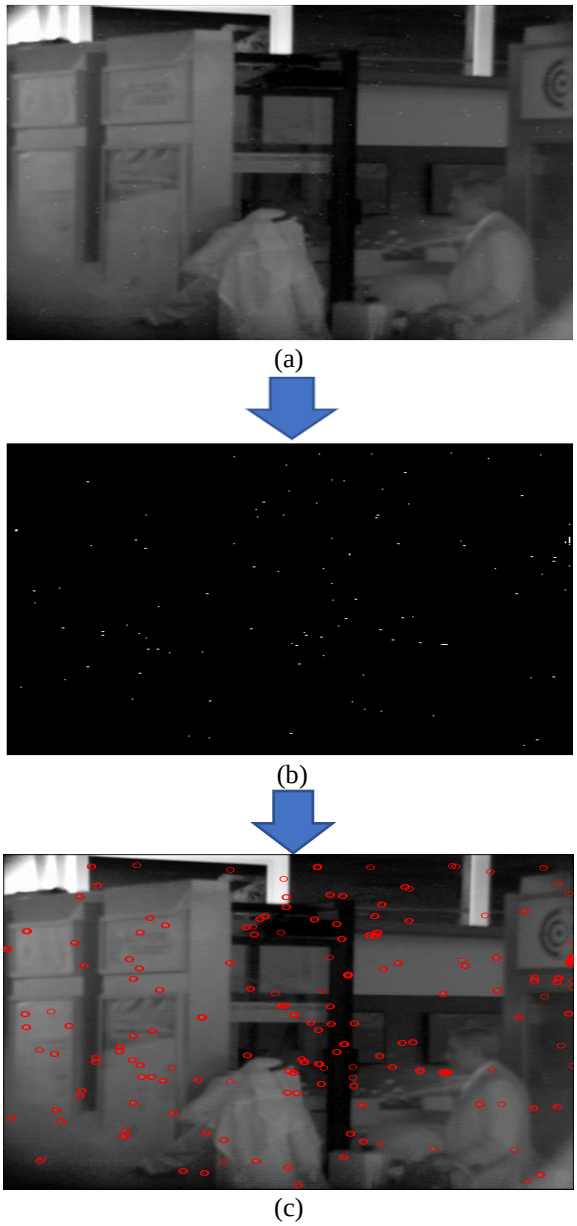
Existing image pixel values are mapped to new values. By mapping, pixel values in the image are more or less equal or rather uniform, except for the dead pixels. Mapping of the pixels by estimating the average value for each pixel results in similar pixel values within the correct image pixels and augments the obviousness of dead pixels. Dead pixels are detected as those whose average value is higher than defined threshold. For better detection, image is divided in cells, and estimating average value for pixels in different cells is calculated using different sets of frames and thresholds.

Fig. 2 presents an image contaminated with dead pixels and map of detected dead pixels.



(a)

(b)

(c)

Fig. 2 Image contaminated with dead pixels (a), map of detected dead pixels(b), original image with detected dead pixels(c)

In Fig. 2, there are a significant number of dead pixels that are observed. Also, it can be observed that in the SWIR camera, the visibility of dead pixels depends on the scene

structure, object temperature, as well as the object surface properties. For the purposes of dead pixel replacement, a binary image of the same dimensions as the original image is obtained, such that a dead pixel is indicated with 1 and a properly functioning pixel is indicated with 0 – Fig. 2 (b). This binary image is called the dead pixel map and it is assumed that this map already exists in replacement strategies discussions in Section III.

III. Proposed Algorithms

Image filtering is one of the most fundamental techniques for modifying or enhancing an image. Image is filtered to emphasize certain features or remove other features. Image processing operations implemented with filtering include smoothing, sharpening, and edge enhancement. Filtering is a neighborhood operation - the value of any given pixel in the filtered image is determined by applying some algorithm to the values of the pixels in the neighborhood of the corresponding input pixel. A pixel's neighborhood is set of pixels, defined by their locations relative to that pixel.

A. Median Filtering

Median filtering [7], [10] is a non-linear method used to remove noise from images. It is widely used in digital image processing as it is very effective at removing noise while preserving edges. Particularly, it is effective at removing 'salt and pepper' type noise.

The main idea of the median filtering is moving through the image pixel by pixel, replacing each value with the median value of neighboring pixels. The pattern of neighbors is called the "window", which slides, pixel by pixel over the entire image. First, all the pixel values from the window are sorted into numerical order. The window usually has an odd number of pixels, so value of the central window pixel is simply replaced with the middle (median) pixel value. In processing the boundary values, there are other approaches that have different properties (shown in Fig. 3):

- Avoid processing the boundaries (with or without cropping the image boundary afterwards).
- It is possible to select entries from a far horizontal or vertical boundary.
- Changing the window size near the boundaries, so that every window is full.

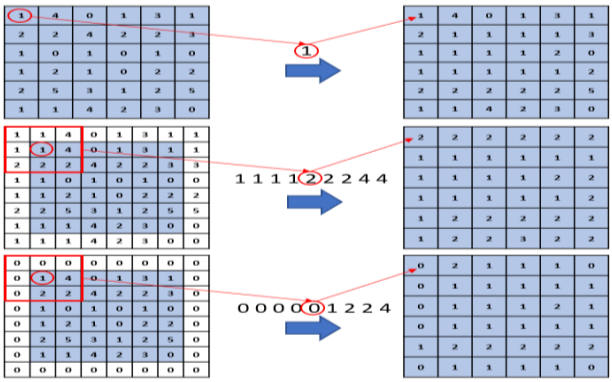


Fig. 3 Processing the boundary values in median filtering

B. Inverse Distance Weighting (IDW)

Inverse Distance Weighting - IDW algorithm is one of the simplest interpolation algorithms. IDW algorithm is widely used in many applications such as [9], [11], [12] and is operated as the spatial interpolation method. In this paper IDW is applied to remove dead pixels.

The interpolation of new value for each dead pixel can be calculated using the uncorrupted surrounding pixels. For the interpolation pixels, a window of the eight nearest pixels surrounding the current dead pixel is used. The new value of the dead pixel is obtained as:

$$Y_{DP} = \frac{\sum_{i=1}^{8} DPM_i \cdot \frac{1}{d_i} \cdot Y_i}{\sum_{i=1}^{8} DPM_i \cdot \frac{1}{d_i}} \qquad (2)$$

In Eq. (2):
Y_{DP} - pixel value at the DP position
Y_i - neighbor pixel value at the position i
DPM_i - dead pixel indicator used for interpolation (1 – correct, 0 – dead pixel)
d_i- Euclidian distance from the DP to the interpolation pixel

In case that none of the given eight pixels is correct, the wider field is searched, but only by width and height until the first correct pixel is reached or it does not reach the image boundary. In that case, the new value of the dead pixel is obtained as:

$$Y_{DP} = \frac{\sum_{i=1}^{4} DPM_i \cdot \frac{1}{d_i} \cdot Y_i}{\sum_{i=1}^{4} DPM_i \cdot \frac{1}{d_i}} \qquad (3)$$

If there is no correct pixel, the Y_{DP} value is 0.5.

IV. Experimental Work and Results

The system setup used in this paper is based on vMSIS (Vlatacom Multi-Sensor Imaging System) [13]. Integrating visible and infrared imaging sensors and providing ultra-long-range target detection, recognition and identification, vMSIS is a state-of-the-art monitoring and surveillance system.

The algorithm pipeline is implemented for real-time performance for SWIR sensor, with 500mm continous zoom lens, image resolution 576×720 pixels, and 25 fps frame rate, using specialized GPU based hardware, C++ and OpenCV and CUDA libraries.

Detection of dead pixels is implemented offline, and based on map of dead pixels, further dead pixels replacement is implemented in real time.

A. Image Database

For the purpose of the proposed algorithm pipeline evaluation of three SWIR video footages containing 750 frames each are used. The frame's resolution is 576×720 pixels. All video footages are obtained with Vlatacom Multi-Sensor Imaging System.

B. Results and Discussion

Median filtering applied on whole image is a method independent on positions of dead pixels. However, some image texture could be lost, which results in small objects disappearing from an image, which is not allowed, especially in applications for ultra-long range monitoring in full zoom. Namely, image pixels which define small objects in the image can be replaced by the median value of surrounding pixel values during the filtering process. Because of that, filtering must be applied only on pixels detected as dead pixels. Another limiting factor is the processing time, since dead pixels removal is a preprocesing method for other video processing algorithms, such as digital video stabilization or object tracking that are very time-consuming. In order to reach frequency of 25 fps, processing time needed for dead pixels removal has to be as short as possible. Table I presents processing time per frame measured for three methods: median filtering (full image), median filtering (based on dead pixels position) and IDW (based on dead pixels position). Based on these results, IDW algorithm applied on dead pixels only is the best solution, in terms of processing time per frame. Average filtering technique applied to dead pixels' position gives same effect as IDW algorithm, but only in situation when none of the local neighborhood of 3x3 pixels is correct. For calculating the new value of the dead pixel using the uncorrupted pixels from longer distance form observed dead pixel, it is important to take into account the distance of those pixel pixels from the dead pixel.

TABLE I
PERFORMANCE MEASURE – TIME

Algorithm	Time [s]
Median (full image)	0.003446
Median	0.001807
IDW	0.000913

Visual results for subjective quality assessment (original frames contaminated with dead pixels and corresponding filtered frames) for SWIR video sequences and IDW algorithm are presented in Fig. 4. The conclusion from the observer stand point is that image clarity is better, and that the quality is enhanced, without deteriorating image quality on other pixel's positions.

V. CONCLUSION

The real-time enhancement algorithm pipeline for infrared imaging in multi-sensor imaging systems proposed in this paper is designed for solving SWIR camera imaging problem – dead pixels presence. The algorithm is designed for detection and replacement of dead pixels. Also, this method is applicable to LWIR and MWIR sensor types. The proposed method is implemented in a real-time environment.

The given results of SWIR sensor testing indicate that the proposed IDW method gives satisfying performance in terms of processing time per frame, without dropping frame rate. Image quality is subjectively better without replacing values of any other image pixel except dead pixels.

Except of dead pixels problem, thermal images have very different nature of noise. In outdoor applications, IR imaging is sensitive to changes in environment's temperature and especially at long distance, the object temperature can be drastically reduced by atmospheric loss. Thermal image noise analysis and enhancement techniques applied to thermal images are certainly planned to be part of the future research to provide better quality of thermal images, more convenient for information extraction.

A Novel Approach for Pan/tilt Drift Detection in Gyro Stabilized Systems Using IMU Sensors

Petar Milanović, Marko Nerandžić, Medhat Abdelrahman Mohamed Mostafa, Ilija Popadić, *Member, IEEE*, Miroslav Perić, *Member, IEEE*

***Abstract*—It is known that drift occurs when the pan/tilt gyro stabilization is turned on. On multi-sensor camera systems, drift is the reason why after a while the observed object is no longer in the centre of the screen and it has a tendency to disappear from the screen. The conclusion is that gyro stabilization is unusable when the field of view is narrow. In this paper, a method for pan/tilt drift detection and its measurement is developed. IMU sensor, which consists of a 3-axis MEMS gyroscope and a 3-axis MEMS accelerometer is used for measuring the system's angular position. Kalman filter is implemented to compensate for the MEMS inertial sensor flaws by combining a gyroscope and accelerometer data.**

***Index Terms* — Pan/tilt, Drift, Gyro stabilization, IMU, Gyroscope, Accelerometer, Kalman filter.**

I. Introduction

Pan/tilt positioner is a servo-driven two-axis device which is designed for long-distance video surveillance systems. Pan/tilt can carry heavy long range electro-optical surveillance sensors that require azimuth and elevation rotation with very high accuracy and angular velocity. The range of movements of pan/tilt that is used is n x 360° per azimuth and ±40° per elevation, and the rotation speed goes from 0.005°/s to 120°/s per azimuth and up to 100° per elevation.

Fig. 1. Pan/tilt with 2 cameras

Stabilization is essential for most long-range multi-sensor camera systems with pan/tilt, because the effect of system shake is more pronounced when using larger focal lengths or narrower field of view – FOV [1]. For that purpose, fibre optic gyroscope or MEMS gyroscope, which measures each movement of the system is engaged. When the gyroscope detects a movement, the command is sent to the pan/tilt engines, so they can resist disturbances. Gyro stabilization performance depends on the gyroscope accuracy, system delays and pan/tilt engine accuracy and speed.

After the stabilization has been turned on, the user gets a stable image, but as a negative effect the system drift occurs. After a while the observed object is no longer in the centre of the screen and it has a tendency to disappear from the screen. The time after which the drift is observed depends on the FOV. If the FOV is narrower, the drift is more pronounced. For narrow FOV, gyro stabilization is unacceptable and after just a few seconds user don't observe the same scene. Because of this, it is very important to detect the drift, to measure its value and to send the command to pan/tilt engine for its compensation.

The pan/tilt drift appears because gyro stabilization does not take into the account the angular position of the system. Fitness function does not take into the account its angular position per azimuth and elevation. In systems that are used, drift is significantly more pronounced per elevation than per azimuth, so in this paper the drift detection will be done only per elevation. This is due to the pan/tilt construction and the position and weight of the cameras placed on it. The cameras can be positioned so the system is not perfectly balanced and the centre of gravity does not match ideally with the pan/tilt centre. Also, pan/tilt manufacturers probably ignore errors that are less than 0.1° per minute, which is very important when observing an image with narrow FOV.

For the purpose of drift detection in this paper, IMU sensor which consists of tri-axis gyroscope and tri-axis accelerometer is used. Both MEMS sensors, the gyroscope and the accelerometer, have flaws [2]. The angle that is calculated by gyroscope measurement drifts. Bias drift estimation is explained in [3]. The accelerometer is too sensitive on disturbances and its signal has a lot of noise. Sensors and algorithm for signal fusion is used in order to achieve reliable estimate about the angular position. A Kalman filter is implemented to yield the reliable information. By monitoring the movement of the system when the gyro stabilization is activated, drift can be detected and measured.

II. IMU SENSORS – FUNCTIONAL DESCRIPTION AND SIGNAL ACQUISITION

The system is composed of a tri-axis MEMS gyroscope and a tri-axis MEMS accelerometer. The sampling rate is 10 samples per second. The gyroscope resolution is 16 bits and the sensitivity is 7.8125 mdps/LSB. The accelerometer resolution is 14 bits and the sensitivity is 0.244mg/LSB.

The gyroscope measures the angular velocity, and the rotation angle can be computed by time-integrating of gyroscope output. Trapezoidal integration method is used.

$$\int_a^b f(x)dx = (b-a)f(a) + \frac{1}{2}(b-a)[f(b) - f(a)] \quad (1)$$

The computed result drifts over time and after approximately 300 seconds it drifts about 5 degrees (Fig. 2). The explanation for this is that integration accumulates the noise over time and turns noise into the drift, which yields unacceptable results. The problem is unpredictable bias due to temperature effect, calibration errors, flicker noise and random walk due to thermo-mechanical white noise [4].

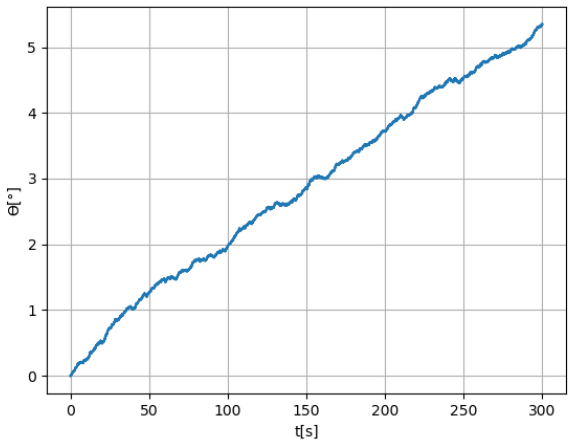

Fig. 2. Gyroscope output, sensor is still

Accelerometers are sensitive to both linear acceleration and local gravity field. In the absence of linear acceleration, which is the case here, the accelerometer output is rotational gravity field vector and it can be used to determine pitch and roll orientations:

$$roll = arctan\left(\frac{G_{py}}{G_{pz}}\right) \quad (2)$$

$$pitch = arctan\left(\frac{-G_{px}}{\sqrt{{G_{py}}^2 + {G_{pz}}^2}}\right) \quad (3)$$

where: G_{px}, G_{py}, G_{pz} are measurement of acceleration along *x*, *y*, *z* axis, respectively [5].

The great advantage of such output from the accelerometer is that integration isn't performed in order to get a position.

III. ALGORITHM FOR SYSTEM POSITION ESTIMATION

In order to get better estimation of system angular position, a combination of measurement from both sensors is used. In this paper Kalman filter is implemented as a sensor fusion algorithm in order to compensate for the weakness of each sensor by utilizing other sensors.

The system should be described in a state space form:

$$x[k+1] = Ax[k] + Bu[k] + w[k], \quad (4)$$

$$y[k] = Cx[k] + v[k], \quad (5)$$

where: *x* is the state vector, *A* is the state transition matrix, *B* is matrix which is called the control-input model, *w*is state transition noise which is Gaussian distributed with a zero mean and with covariance *Q*, *y* is measurement, *C* is the observation matrix and *v* is the measurement noise with a zero mean and *R* as covariance.

The Kalman filter is a recursive state *x(k)* estimator based on the known model, parameters *A*, *B* and *C* and measurement *y(k)*, which is optimal in terms of minimization of variance of the estimation error [6]. The estimation of the state is obtained only on the previously estimated values *x(k-i),i>0* and the last measurement. Kalman filter is theoretically ideal for fusion of the noisy data [7].

In our system, the states are angle Θ and gyro bias $\dot{\Theta}_b$.

$$x_k = \begin{bmatrix} \Theta \\ \dot{\Theta}_b \end{bmatrix}_k \quad (6)$$

Matrices *A*, *B*, *C* are defined as follows:

$$A = \begin{bmatrix} 1 & -\Delta t \\ 0 & 1 \end{bmatrix} \quad (7)$$

$$B = \begin{bmatrix} \Delta t \\ 0 \end{bmatrix} \quad (8)$$

$$C = [1\ 0] \quad (9)$$

Control input *u* is the gyroscope $\dot{\Theta}_k$ measurement in degrees per second. Covariance matrices *Q* and *R* should be calculated before implementing the algorithm.

Algorithm:

1. Set initial values,
   $P_0 = 0$, $\hat{x}_0 = 0$ (10)
2. State prediction
   $\hat{x}_{k|k-1} = A\hat{x}_{k-1|k-1} + B\,u_k$ (11)
3. Calculating error covariance matrix prediction
   $P_{k|k-1} = AP_{k-1|k-1}A^T + Q_k$ (12)
4. Kalman gain computation
   $K_k = P_{k|k-1}C^T(CP_{k|k-1}C^T + R)^{-1}$ (13)
5. State estimation
   $\hat{x}_{k|k} = \hat{x}_{k|k-1} + K_k(y_k - C\hat{x}_{k|k-1})$ (14)
6. Error covariance matrix computation
   $P_{k|k} = (I - K_kC)P_{k|k-1}$ (15)
7. Loop to step 2.

IV. IMPLEMENTATION IN THE REAL SYSTEM

Communication scheme for data acquisition is shown in Fig. 3. Control communication between host machine (PC) and embedded machine Nvidia Jetson TX2 is established using ssh protocol. Jetson TX2 reads data form sensor periodically using I2C serial communication. Sampling period is 100ms. Data is processed on Jetson TX2 in order to get the system angular position information. Position estimation is sent to PC using UART in order to be graphically displayed.

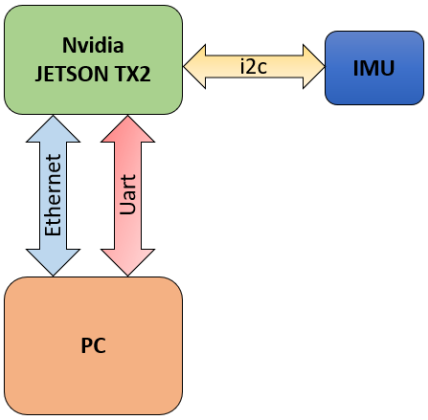

Fig. 3. Communication scheme

A schematic view of the complete procedure for determining the angular position of the system is shown in Fig. 4

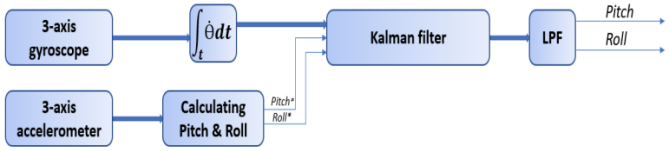

Fig. 4. A complete data processing scheme

As a first step, the initial testing of Kalman filter is done. The sensors were moved from the initial position by 90 degree to one side, then returned and moved by 90 degree to another side and returned to the initial position again. After that sensors were exposed to disturbances. Result is shown in Fig. 5.

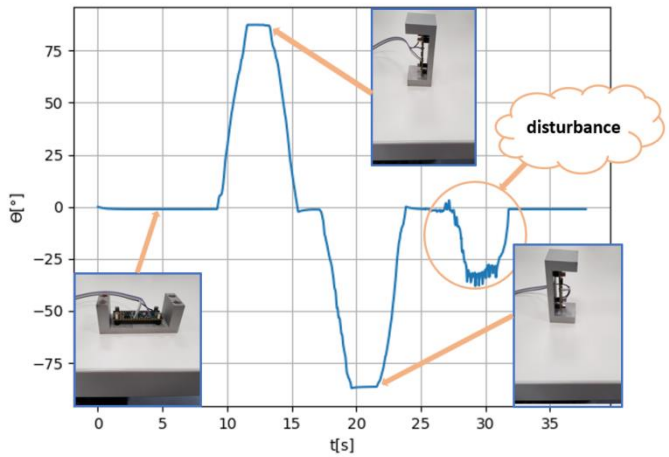

Fig. 5. Estimated system angular position (elevation), initial test

Multi-sensor camera systems with pan/tilt are placed on the shaker. Jetson TX2, sensors and laser are placed on camera sunshield. The laser is directed towards grid paper. Jetson TX2, IMU and host machine are connected as shown in Fig. 3. The described system is shown in Fig. 6 and Fig. 7.

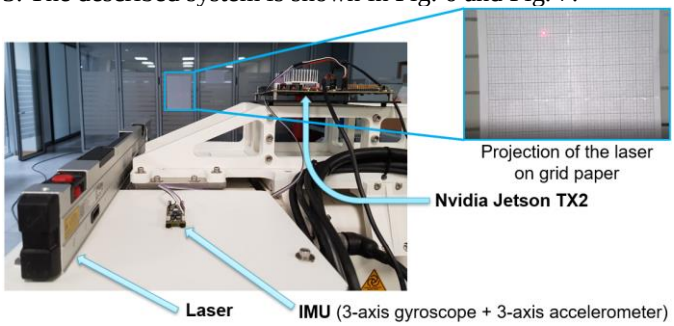

Fig. 6. Measuring equipment

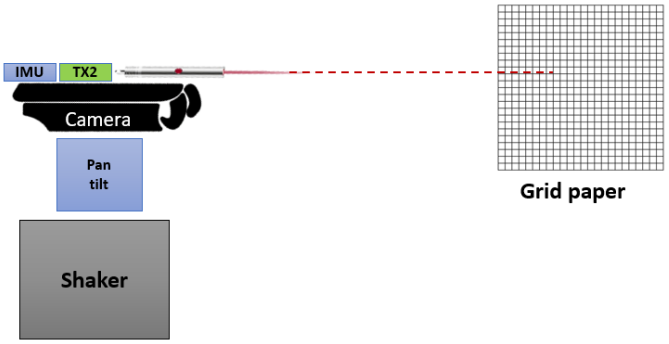

Fig. 7. Scheme of the testing procedure

The shaker is running and the camera is recording movement of laser on grid paper. The shaker oscillates with frequency of 0.25 Hz and brings disturbances per elevation. The disturbances per azimuth are negligible. The purpose of the shaker is to simulate wind-related disturbances. Peak-peak amplitude of laser movement by elevation is around 12cm which translated to degrees is around 1 degree. After starting gyro stabilization, peak-peak amplitude is decreased to approximately 1.2cm (0.1 degree), but drift appears. This drift is very small and projection of laser moves only 2.5cm (0.21 degrees) per elevation after 275s. That does not seem much, but in case where this is observed under narrow FOV (which is 1 degree on some cameras), movement would be significant.

First 25 seconds system works without gyro stabilization. After that gyro stabilization turns on for 275 seconds. Based on video of movement of laser projection on grid paper it is calculated that after 275 seconds drift is 0.21 degree.

Information whether the gyro stabilization is turned on or turned off is known in advance. The assumption is that the system is still during the gyro stabilization, meaning that commands for moving pan/tilt per azimuth and per elevation are not set. System movement should be monitored after the gyro stabilization is turned on.

In Fig. 8, system movement by elevation calculated by gyroscope and accelerometer is shown. Accelerometer measurements have a lot of noise. Gyroscope has accumulated drift due to its uncompensated bias and due to pan/tilt gyro stabilization.

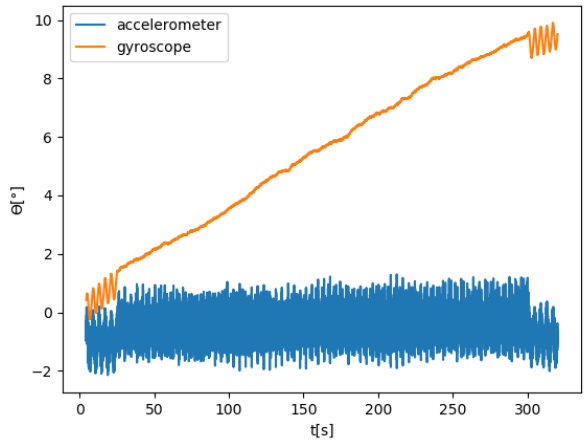

Fig. 8. Gyroscope and accelerometer measurement

System movement per elevation, obtained after the whole procedure of data processing, and the detected drift are depicted in Fig. 9.

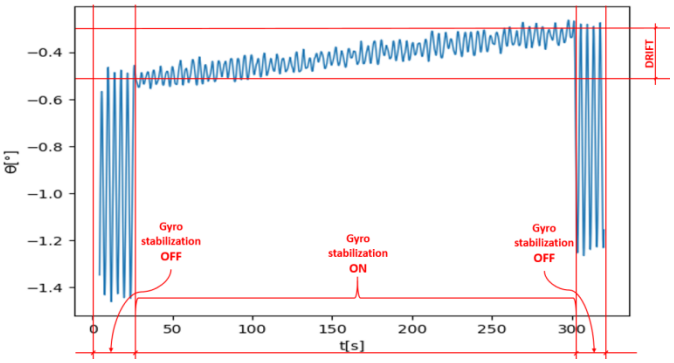

Fig. 9. Detected drift

To eliminate the remaining oscillations in order to determine the exact value of the drift, averaging with window function with length N has been done, as depicted on the image below (Fig. 10).

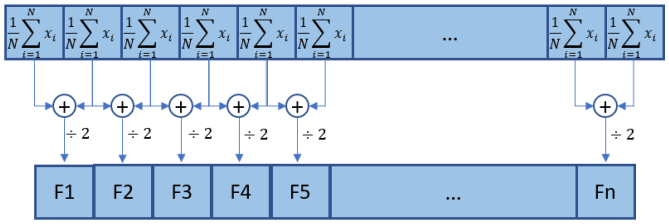

Fig. 10. Extraction drift

x_i in Fig. 10 is data after Kalman filter, and F_i is the final result. Based on the obtained result, it is possible to detect drift of 0.01 degree.

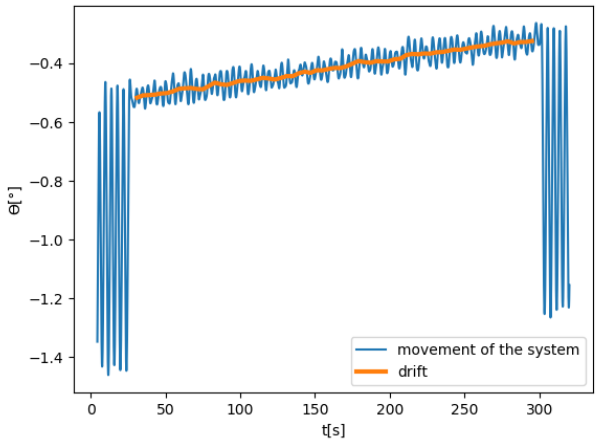

Fig. 11. Signal of system movement and drift

V. CONCLUSION

This paper presents results of the pan/tilt drift detection obtained on the basis of measurements with 2 MEMS sensors, gyroscope and accelerometer. Kalman's filter has been implemented with the aim to get the best out of both sensors and compensate for the flaws which the sensors have when they are used independently. It should be mentioned that some of the existing solutions for the needs of surveillance applicationdo not have the mentioned detection, therefore it is not possible to perform the drift compensation, which leads to the unusable gyro stabilization when the FOV is narrow. It has been shown that it is possible to detect drift of only 0.01 allowing for its almost unnoticeable compensation even in case of the narrow FOV.

Further improvements could be achieved by introducing magnetometer in the system. Using the magnetometer measurements a reliable estimation of the system position per azimuth could be calculated [7].

Requirements Analysis for ADAS Perception in Bad Visibility Conditions

Nedeljko Padjen, Nikola Latinović, Dragana Perić, *Member, IEEE*,
Milan Milosavljević, *Member, IEEE*

***Abstract*— In this paper we elaborate on requirements that are imposed on the vision system that should be used for ADAS (Advanced Driver-Assistance Systems) perception. In order to fulfill its task of perception under all visibility conditions, we are taken into consideration bad visibility scenarios that can be met due to fog, rain, snow etc. We analyze the range and the resolution issues of solution based on sensor fusion of different type of sensors like LWIR, SWIR imagers, SWIR LIDARs supported by MIMO Radar. The goal of this analysis is to set the guidelines for selection of appropriate system components.**

***Index Terms*—ADAS perception, sensor fusion, gated SWIR**

I. Introduction

One of the major concerns and challenges in car industry in the last few decades was to increase safety of the passengers. Introduction of seatbelts, airbags and crumple-zones, as a form of passive safety systems, has reduced the severity of injuries, but it was clear they are not sufficient to make a bigger impact on the safety aspect [1]. The overall safety was further improved with the introduction of active safety systems, which were rapidly implemented in the vehicles, following the general technology progress, reflected on decrease size and price of different type of elements implemented in cars. As the name suggests, active systems are actively involved in preventing the accidents, instead of only reducing the severity of accident outcomes.

ADAS, as an electronic system consisted of different sensors, represents one form of the vehicle active safety systems, offering different levels of support to the driver. This support can go from the basic level of only informing the driver on some events ahead of him, to the level where ADAS can take the full control of the vehicle, in order to avoid some imminent danger [2]. The SAE automation level 5 is vehicle with a completely automated navigation system, while SAE level 0 are the vehicle without any ADAS system [3]. Regardless of the level of the control, these driver assistance systems share the same goal – to prevent the accident by giving proper and timely information to the driver/system, or at least to reduce the consequences of it [4]. In other words, their goal is to decrease driver decision time, but also detection time [5].

Nikola Latinović is with the Vlatacom Institute of High Technologies, 5 Milutina Milankovića Blvd.,11070 Belgrade, Serbia (e-mail: nikola.latinovic@vlatacom.com).

Dragana Perić is with the Vlatacom Institute of High Technologies, 5 Milutina Milankovića Blvd.,11070 Belgrade, Serbia (e-mail: dragana.peric@vlatacom.com).

Milan Milosavljevic is with the Singidunum university, 32 Danijelova Str., 11000 Belgrade, Serbia (e-mail: univerzitet@singidunum.ac.rs).

Selection of the appropriate sensors for ADAS system which can bring a substantial benefit to the driver safety is a complex task, requiring many different inputs and analysis. The system should be designed having in mind the drivers real needs and requirements, but also his/hers attitude, that depend significantly on the region of the world where he comes from [6]. Some of the inputs are controversial; such is one study in Greece which has shown the decreased number of accidents during the rain, while the most of the other studies show the opposite [5].

At the end, the deployment of the sensors and level of introduced automatism should be carefully taught, since they can result in negative tendencies – due to increased safety equipment, the driver can decrease his/hers overall awareness and compliance with traffic regulations, resulting in a higher driving speed. This can result in fatal outcomes since vehicles, regardless on the number and quality of the installed active safety systems, still obeys the laws of the physics, where the car stoppage time is inversely dependent on its speed.

Within this variety of the aspects influencing the design of the ADAS, we have chosen to analyze the effects of the adverse weather condition on the driver and try to define the requirement for the adequate choice of the sensor equipment.

Chapter two of this paper will list the sensors which can be used in one ADAS, pointing out their advantages/disadvantages. Chapter three will give the system requirements in terms of sensor range, and field of view (FOV). Chapter four will present the current equipment available on the market. In chapter five we will discuss the process of integration of the different sensors to a functional system. As this paper is one of the steps in designing, but also assembling and testing of a real system, chapter 6 will give an overview of the potential tests for real performance analysis (laboratory, controlled environment, field test in real scenario). Conclusion on the raised topics and directions for further research will finally be given in chapter 7.

II. Sensor Types

Adverse weather conditions, as the most analysis has shown, have negative affect on the driver's safety. Fatalities (deaths caused by accidents) represent 10-15% of the total number of accidents [5]. While the ADAS for the good weather condition would be mostly based on some color camera(s), the weather such as fog, mist, dust, dark, rain and snow requires the introduction of different type of sensors, which will contribute in the collection of information from the road. Some technologies will assist in detecting the

pedestrians at night; some others will give best results in detection of the other vehicles [7]. It is important to underline that there is no single sensor to perfectly fit all needs, but their fusion, with the usage of appropriate algorithms, can hide their downsides and combine their advantages. The following lines will list the most promising type of sensors that can enhance the perception of ADAS in adverse weather conditions [8]:

- RADAR (RAdio Detection And Ranging) – The well-known concept can be used for detection, but also direction and speed of several targets, using the arrays of micro-antennas installed in the vehicle bumpers. These Millimeter Micro Wave (MMW) radars are generally performing well in all weather conditions, and as such, they are good for detecting the close targets. The downsides are the reduced Field of View (FOV) and low precision.
- LiDAR (Light Detection And Ranging) – Using the same principle as radar, the distance to the object is measured by the equation:

$$d = \frac{c}{2} \times ToF \tag{1}$$

where c is the velocity of the light and ToF is the time of the return trip of the light emitted by lidar.

Solid state lidars, consisting of the arrays of photodiodes, can obtain the 3D object map, thus they are very useful for object identification and avoidance. Downside of this sensor is that its performance is degraded in the bad weather conditions, where the light beams are diffracted on the rain, snow or dust drops and particles.

- Visible (VIS) camera – Capturing the wavelengths in visible spectrum (400 nm to 780 nm), the resulted high-resolution images are the major source of information in good weather conditions. Using more than one camera avails stereoscopy vision, which is additionally giving depth to the pictures. Unfortunately, this type of camera is highly affected by the weather conditions, leading to complete degradation of the performance, for example, during the cloudy nights.
- Longwave Infrared Camera LWIR – Sensitive to emitted thermal radiation in spectral range from 8 µm to 12 µm. For this application we are referring to uncooled micro-bolometer cameras, operating in mentioned spectral range. LWIR cameras provide night vision, and also perform better than visible cameras in case of fog, Sun glare, sudden illumination variations (tunnel entering, headlights from cars in the opposite lane etc.). Object identification range of thermal cameras is not related to illumination level, therefore it can be much larger than visibility range of VIS cameras.
- Shortwave Infrared Camera SWIR– Sensitive to reflected light in spectral range from 0.9 µm to 1.7 µm. Due to different reflectivity of the materials in this spectral range, SWIR offers imagery richer in details than visible camera. SWIR camera can be used as passive imager and as active imager, with laser illuminator. Active, range gated SWIR cameras can provide very good identification capability in all lighting conditions (complete darkness, fog, smoke, etc.). By choosing the delay of the gate impulse, the depth of the scene is regulated.

The following table summarizes the advantages and disadvantages of the listed sensors, grading them to four different levels, being 0 the worst and 3 the best ranked [7]

TABLE I
SENSOR CHARACTERISTICS

FEATURE	RADAR	LIDAR	VIS	GATED SWIR	LWIR
FOV	2	2	3	3	3
RANGE	3	3	2	2	3
ACCURACY	2	3	3	3	2
FRAME RATE	2	2	2	2	3
RESOLUTION	1	2	3	2	1
COLOR PERCEPTION	0	2	3	1	1
WEATHER AFFECTION	3	2	1	2	3

The same results are also presented on the following charts:

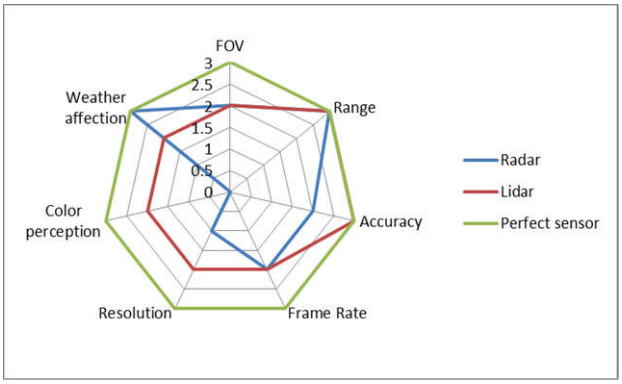

Fig. 1. Main characteristics of radar and lidar sensors

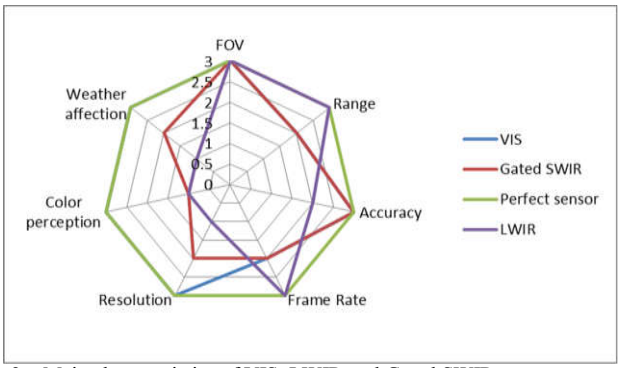

Fig. 2. Main characteristics of VIS, LWIR and Gated SWIR cameras

III. SYSTEM REQUIREMENTS

Triangle concept of the road safety recognizes three major "stakeholders": human, environment and vehicle, with bidirectional relations between them during the course of driving [9]. Any analysis of the concepts that can improve overall safety on the roads must include all three aspects into consideration. In line with that, the reaction of the driver-vehicle system can be divided in three components:

- Decision time (td) – Time from the recognition of some situation, to the moment the driver's brain indicates something should be done. This time is longer in adverse weather condition.

- Initiation time (ti) – Time from "should be done", to doing it. The weather does not affect this time length.
- Action time (ta) – Time from the driver acts, to the moment vehicle has stopped (either safely, or by crashing to the obstacle). Adverse weather is decreasing the vehicle-road adhesion and, as a result, increasing the action time.

Thus, the total vehicle stopping distance is the sum of distances travelled during these three time components, and it is given by the following equation:

$$s = v_0 \times t_r + d_b = v_0 \times t_d + v_0 \times t_i + \frac{v_0^2}{2 \times g \times (f + G)} \quad (2)$$

where:
s - Vehicle stopping distance (m)
v_0 – Vehicle initial speed (m/s)
d_b – Breaking distance (m)
g – Gravity acceleration (m/s^2)
f – Coefficient of deceleration (m/s^2)
G – Gradient (slope of the road)

Based on this equation, we can calculate the residual speed distance at the distance x from the point of detection:

$$\begin{aligned} v(x) &= \sqrt{v_0^2 - 2gf(x - v_0 \times t_r)} && x_d + x_i < x \le s \\ v(x) &= v_0 && \text{, if } x \le x_d + x_i \\ v(x) &= 0 && x \ge s \end{aligned} \quad (3)$$

Where:
x_d – distance driven during decision time,
x_i – distance driven during initiation time,

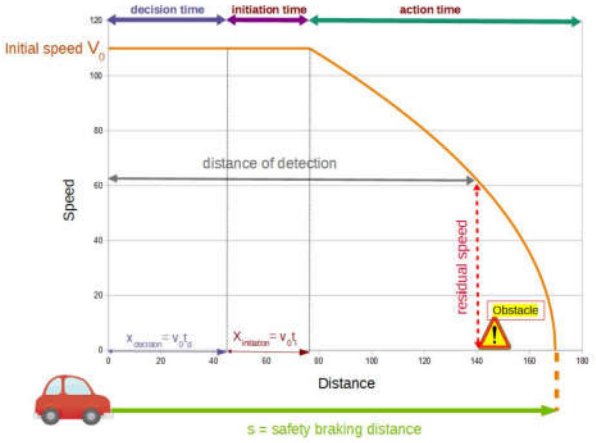

Fig. 3. Decomposition of the total breaking distance [5]

Based on these equations, one European study [5] has calculated the residual speeds, based on initial speed and different weather conditions on the road. The following tables are giving the results of the calculations:

TABLE II
SAFETY BREAKING DISTANCES BREAK-DOWN

		Equation (2) input parameters				
	Unit	Clear weather	Rain		Fog	Snow
Initial speed	km/h	130	130	110	90	67
Decision time distance	m	43.3	57.8	48.9	55	/
Initiation time distance	m	10.8	10.8	9.2	7.5	/
Braking distance	m	93.1	163	116.7	78.1	/
Safety braking distance	m	147.2	231.6	174.8	140.6	<140

TABLE III
RESIDUAL SPEED FOR DIFFERENT WEATHER CONDITIONS

Distance of detection	Residual speed in km/h at detection distance				
	Clear weather	Rain		Fog	Snow
50	130	130	110	90	67
140	36	97	60	8	0
145	20	95	56	0	0
150	0	92	51	0	0
175	0	77	0	0	0
200	0	57	0	0	0

Taking into account some other studies which are showing that residual speed higher than 70 km/h are usually ending with fatality, it is safe to say that we should target the sensor which can detect the obstacle on at least 200 meters.

Beside the sensor range, the important sensor parameter is the field of view (FOV), i.e the angle of camera view. The Horizontal FOV (HFOV) can be expressed as the function of the visible field (D, expressed in meters), on different distances from the camera (s, in meters), by the following equation:

$$FOV = 2 \times \arctan \frac{D/2}{s} \quad (4)$$

If our requirement is that our system should have D=10meters (approximately 3 lanes of the road), we are getting the following table:

TABLE IV
CAMERA FOV AT DIFFERENT DISTANCES, FOR D = 10M

Distance from camera **s** (meters)	Required visible field **D** (meters)	Camera **FOV** (degrees)
5	10	90.000
10	10	53.130
25	10	22.620
100	10	5.724
200	10	2.864
250	10	2.292

The following chapter will analyze some of the cameras on the market to verify if they conform with these requirements.

IV. Equipment Available on the Market

As previous analysis has shown, ADAS system that would fulfill requirements for vision enhancement in adverse weather conditions should contain LWIR and SWIR imagers because of their favorable features. In this work we will focus on part of the system that combines these two sources of information and analyze the currently available

equipment available on the market that can be used in order to realize the subsystem.

A. LWIR camera

When selecting LWIR camera, we choose its parameters with following objectives:

- Detection range – distance at which the camera will spot an object
- Field of view – Width and height of the scene in front of the vehicle that camera will observe.

According to previous analysis, requirements for detection range should be selected to provide sufficient time to the driver to stop the vehicle. Previous analysis show that 200 m is the minimum distance for braking, so we shall select the camera detection range accordingly. Camera's field of view should be wide enough to provide good covering of the road. For this parameter selection we will refer to requirements given in Table IV.

In Table V we presented parameters of two LWIR cameras suitable for this application.

Calculated ranges of pedestrian and car detection, recognition and identification are given for each camera. Performances of thermal cameras are expressed in detection, recognition and identification (DRI) ranges that are calculated following STANAG 4347 procedure [10]. DRI ranges are given for a pedestrian (1.8m x 0.5m) and for a car (2.3m x 2.3m). These three numbers give the information of the level of object perception (detection is defined as 1 lp/object size, recognition is defined as 3 lp/object size and identification is defined as 6 lp/object size).

TABLE V
LWIR CAMERAS PARAMETERS

	Camera 1			Camera 2		
Spectral range	7.5 µm – 13.5 µm			8.0 to 14.0 µm		
Pixel size	12 µm			17 µm		
Resolution	640 x 512			640 x 480		
Frame rate	60 Hz			50 Hz		
Thermal sensitivity	<50 mK			<50 mK		
Lens focal length	4.9 mm			10 mm		
Horizontal FOV	76 º			57 º		
Vertical FOV	64 º			44 º		
Pedestrian DRI	204m	51m	25m	294m	73m	36m
Car DRI*	626m	156m	58m	901m	225m	112m

*DRI – detection, recognition, identification

B. SWIR camera

SWIR cameras can be used either in passive or in active mode. First we will give the characteristics of two types of SWIR cameras in passive mode and then additional details regarding active SWIR will be given.

As in the case of LWIR camera, also for SWIR camera we have to make a compromise with selection of detection range and wide field of view. To select optimum lens focal length, we use geometrical calculation. Field of view should be close to the one already defined in LWIR camera case, in order to provide better alignment of two cameras that will observe the same scene.

In Table VI we present parameters of two SWIR cameras suitable for this application.

TABLE VI
SWIR CAMERAS PARAMETERS

	Camera 1	Camera 2
Spectral range	0.9 µm – 1.7 µm	0.9 µm – 1.7 µm
Pixel size	15 µm	20 µm
Resolution	640 x 512	640 x 512
Frame rate	up to 230 Hz	max 100 Hz
Integration time	10 µs to 10 ms	1 µs - 40 ms
Noise high gain	50 e^-	60 e^-
Noise low gain	270 e^-	400 e^-
Lens focal length	8 mm	8 mm
Horizontal FOV	61 º	77 º
Vertical FOV	51 º	65 º

Active, gated imaging provides the ability to image a specific depth slice of a scene. Applications are in observations through obscurants (severe weather conditions), estimation of distance and localization of obstacles. Imaging devices must be fast enough to cope with the reflected light.

According to the technical specifications of the Camera 1, it is stated that this camera can be used also in gating mode with exposure time from 100ns to 9µs. To provide complete gated vision system, SWIR camera should be coupled with pulsed laser source that will illuminate the scene. Camera gating should be synchronized with laser pulses. More details of the gated system realization can be found in [11].

C. Displaying the images to the driver

We propose the presentation of collected imagery from the ADAS to the driver.

First solution would combine videos from both cameras simultaneously and present them on the same screen, on left and right halves. The driver can switch passive SWIR to active gated SWIR if suspected object appears on LWIR image.

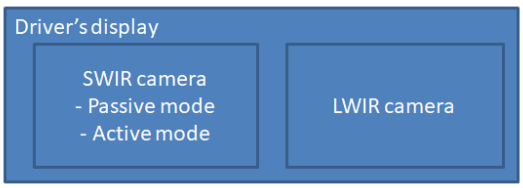

Fig. 4. Driver's display with two images

Second solution would require additional image processing and forming of a single image using both cameras as inputs. In that case image blending or image fusion should be performed. This solution would require minimum execution time of image processing algorithms, as ADAS require no-latency imagery to be presented to the driver, which is a key in providing the with real situational awareness. Advantage of this approach would be in unique screen from which the driver would follow the information.

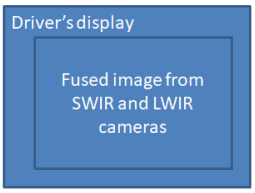

Fig. 5. Driver's display with fused image

V. CAMERAS SIGNAL PROCESSING

As described in the previous chapter, the proposed solution combines the imaging of two cameras on the same presentation medium (display). This will require the complex process of synchronized signal processing, which will not be described in details in this paper. Instead, we will list the main challenges of this process and give the main directions for the design.

The proposed cameras for the integration in the ADAS system are originating from different manufacturers, with different characteristics and parameters (camera interfaces, frame rate, resolution). In order to achieve the equalization of the frame rates and image resolution adoption, but also the advanced image processing such as image stabilization & enhancement, target tracking, or image fusion, the signals from all cameras should be converted to the same format [12].

Our approach will be to develop a dedicated hardware platform which will house the main elements of this signal processing unit:

- Interface board, which will collect the signals from both cameras and forward it to FPGA
- FPGA processing unit, for converting camera input interfaces to common HDMI signal [13]. Unlike most of applications where a single FPGA is processing signal from only one camera, in this realization both camera signals will be processed by the same FPGA. The signals will be forwarded to the main processor board
- Nvidia Jetson TX2, as a main digital signal processing (DSP) unit. This powerful hardware structure will provide the output to vehicle display, by means of Ethernet cable.

Although the previous experience with the proposed design and equipment is indicating the smooth work of the system, the detailed tests must be performed, including the measurements of the overall signal processing delay, which must be taken into calculations for system detection time.

VI. PERFORMANCE TEST ENVIRONMENT

As any other system with the ambition to be recognized as ADAS system, the series of rigorous testing must be performed. We are proposing three-level system testing:

A. Laboratory tests

The initial test will be performed in electro-optical laboratory equipped with collimator test-station [14], with the appropriate radiation sources and different test targets. The test results should give a clear picture of the real system (camera) characteristics and performance, which is a prerequisite for the further testing.

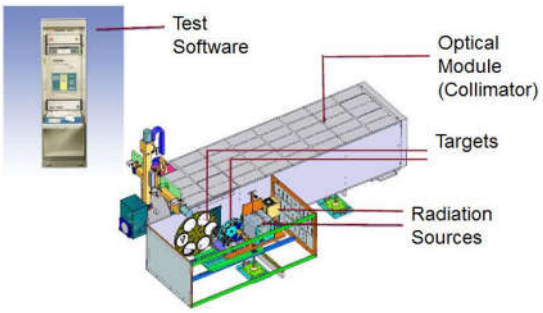

Figure 6. Electro-optical modular test station [14]

B. Tests in the controlled conditions

These tests should verify the system performance under controlled adverse weather condition. Although it would be ideal to test the system behavior in all weather conditions (fog, mist, snow, rain, etc..), our focus will be only on rain and low visibility conditions, since the rain is identified as the biggest challenge for safety breaking (Table 2, Ch. 2).

Fig. 6. Example of tunnel and sprinkle system [7]

As per the world's best practices [7], we will establish a form of tunnel 250 meters long, 10 meter in width (to match the requirements from the Chapter 3 of this paper) and. The rain should be produced by sprinkles with different size of nozzles (for producing different raindrop size), that can produce different rain intensity. The required height of the tunnel will be defined together with sprinkle selection, so the rain distribution on the camera level (around 1 meter from the ground) is even.

C. Real environment testing

At the end, the equipment should be tested in the real environmental conditions. This testing will last for several months where, ideally, the equipment will be tested on several locations known for higher probability of some adverse weather condition. The test location will also be equipped with a small meteorological station, which should be equipped with luxmeter (for measuring ambient light), rain gauge, and temperature and humidity sensors [15].

VII. CONCLUSION

Advanced driver-assistance systems are the group of sensors which main purpose is to decrease the chance of the road accidents. In this paper we have listed the types of sensors suitable for deployment in ADAS, with the focus on adverse weather condition. We have identified two major requirements for these systems, being the detection range and field of view, and confirmed that SWIR and LWIR cameras are in-line with these requirements. Since the key of this system is in providing the timely information to the driver, we have also suggested the components for the signal

processing unit which should introduce the minimal delay. All this information gave us the major guidelines for the future work, which will be to assemble a real system with some of the proposed cameras, and test it in various laboratories, controlled and real environmental conditions. The results of these tests will surely give us new inputs directions in further development of a reliable ADAS system.

Adaptive Kalman Filtering Using M-robust Dynamic Stochastic Approximation Combined with Robust Median Estimation

Zoran Banjac, Željko Đurović, Branko Kovačević, *Senior Member, IEEE*

***Abstract*—One of the most significant achievement of the linear estimation theory is the Kalman filtering. In this paper, the problem of robustifying the Kalman filter in the presence of unknown noise statistics has been considered starting from the equivalence between the linear estimation problem and a specific form of dynamic stochastic approximation, M-robust statistical approach is used to robustifying the Kalman filter. The proposed approach includes the modified M-robust performance index based on the mean square optimal prediction of the expected changes in the system states, together with the given output measurements. The M-robust dynamic stochastic approximation algorithm is derived from step-by-step minimization of the adopted criterion. In order to improve the convergence rate, the gain matrix of the algorithm is derived from step-by-step minimization of the prespecified mean square error criterion. In addition, robust median estimations are derived for adaptive estimation of the unknown state and observation noise statistics, simultaneously with the system states. A real life examples of maneuvering target tracking is presented to demonstrate the practical robustness of the proposed adaptive robustifying Kalman filter.**

***Index Terms*—Adaptive filtering, impulsive noise, Kalman filtering, non-Gaussian noise, nonlinear filters, robust estimation**

I. Introduction

AN optimal estimate of a random vector, or a random vector process, from noise-corrupted data, is one which minimizes an appropriate functional of the estimation error. Examples of such criteria are the maximum likelihood, least squares, mean-square error, minimum variance, etc. [1-4]. However, optimal estimation criteria often depend upon assumptions about the statistical characteristics of the random variable which has to be estimated and its associated random data. Particularly, one of the most significant achievements in the linear estimation is the Kalman filtering. Except of the theoretical interest, it is also important from the practical applications, [3, 4]. However, if the system dynamics and its observations are dominated by nonlinear effects that cannot be accurately approximated by linearization, or if the noise processes are non-Gaussian, the corresponding optimal estimation algorithm is often too complex to mechanize. In such circumstances, it is sometimes possible, through the use of a class of time-varying stochastic approximation methods, to obtain a sequence of estimates that possess a statistically bounded error [5]. Thus, a dynamic stochastic approximation algorithm offers a reasonable alternative to optimal estimation techniques in many applications, such as the problems in estimation, optimization and pattern classification [6-8].

Unfortunately, in many practical applications the real noise distribution differs from the supposed normal one by heavier tails. This, in turn, generates the spiky noise realizations named outliers [9]. Since the Kalman filter is a linear function of observations, it is susceptible to outliers. Therefore, it is of great practical interest to designing robustified Kalman filtering techniques that are able to cope with impulsive noise or outliers. In such circumstances, robust statistical methods provide suitable tools to spot bad data points and suppress their effects [9-11]. Particularly, the M-robust statistical approach is widely used in practice, since it represents an approximation of maximum likelihood estimation that is easy to implement, [10]. In recent literature, there exist a number of articles devoted to robustifying the Kalman filter using the M-robust approach [12-19]. Moreover, the solution proposed in [17, 18] is based on the similarity between the Kalman filter and a weighted least squares parameter estimation, as well as the application of M-robust approach to solving the parameter estimation problem robustly. However, the so obtain solution requires complex computations.

The proposed solution in [19] has the predictor-corrector structure, as the original Kalman filter, but the M-robust dynamic stochastic approximation algorithm is used for the measurement update, instead of the original Kalman filtering relations. In addition, M-approach is conservative, and it not only has a lower efficiency in Gaussian noise, but also may degrade otherwise [17, 18]. Therefore, some kind of adaptation to the underlying noise condition is necessary. An approach to overcome this difficulty based on a weighted least-squares approximation of the M-robust estimates, as well as the M-robust estimation of the unknown noise statistics, simultaneously with the system states, has been proposed in [18]. An alternative approach based on M-robust dynamic stochastic approximation with the parallel adaptation of unknown noise statistics using robust median estimation, has been considered in this paper.

II. Problem Formulation

Let us assume that an abstract linear discrete stochastic system is given by the state-space model

$$x(k+1) = F(k)x(k) + G(k)w(k) \quad (1)$$

$$y(k) = H(k)x(k) + v(k) \quad (2)$$

Here $x(k)$ is the random state vector, $y(k)$ is the observation or measurement vector, $w(k)$ is the state noise or disturbance, and $v(k)$ is the additive measurement noise, at the discrete time indexed by k. Furthermore, $w(k)$ and $v(k)$ are zero-mean noises that are uncorrelated by itself and mutually, satisfying

$$E\left\{\begin{bmatrix} w(j) \\ v(j) \end{bmatrix}\begin{bmatrix} w^T(k) \\ v^T(k) \end{bmatrix}^T\right\} = diag\left\{Q(k)\delta_{kj}, R(k)\delta_{kj}\right\} \quad (3)$$

with $E\{\cdot\}$ being the mathematical expectation, δ_{kj} denotes the Kronecker's delta symbol ($\delta_{kj} = 0$ if $k \neq j$ and $\delta_{kk} = 1$), and $diag\{\cdot,\cdot\}$ represents the block-diagonal matrix. In addition, $F(k)$ is the state-transition matrix, $G(k)$ is the state-noise or disturbance matrix, and $H(k)$ is the measurement or observation matrix. If $\hat{x}(k|l)$, $l = k-1, k$, is the linear least squares type estimate of $x(k)$ when the measurements $\{y(j), j \le l\}$ are given, while $P(k|l)$ denotes the underlying estimation error covariance matrices, then the classical Kalman filter equations are the following, [1-4]

Time update (prediction stage):

$$\hat{x}(k+1|k) = F(k)\hat{x}(k|k) \quad (4)$$

$$P(k+1|k) = F(k)P(k|k)F^T(k) + G(k)Q(k)G^T(k) \quad (5)$$

Measurement update (estimation or correction stage):

$$\varepsilon(k) = y(k) - H(k)\hat{x}(k|k-1) \quad (6)$$

$$K(k) = \frac{P(k|k-1)H^T(k)}{\left[H(k)P(k|k-1)H^T(k) + R(k)\right]} \quad (7)$$

$$\hat{x}(k|k) = \hat{x}(k|k-1) + K(k)\varepsilon(k) \quad (8)$$

$$P(k|k) = \left[I - K(k)H(k)\right]P(k|k-1) \quad (9)$$

with I being the identity matrix. The measurement residual or innovation, $\varepsilon(k)$, represents the zero-mean, uncorrelated random sequence with covariance matrix $S(k)$, [3, 4]

$$S(k) = H(k)P(k|k-1)H^T(k) + R(k) \quad (10)$$

In most applications the elements of the observation vector, $y(k)$, are independent, so that they may be analysed one at a time. This means that $y(k)$ and $\varepsilon(k)$ are zero-mean scalar real random variables, having the variances $R(k)$ and $S(k)$, respectively. The state disturbance, $w(k)$, is also taken to be zero-mean scalar real random variable having the variance $Q(k)$, [1-4].

Unfortunately, if the noise statistics are non-Gaussian or undefined, the underlying optimal estimate may be indeterminate [18, 20-22]. Thus, the Kalman estimator is susceptible to departures of the noise statistics from the adopted Gaussian distribution, or it is not robust [12-18]. Formal mathematical definitions of robustness are given in the statistical literature [9-11], but these are inconvenient for practical workers. In this sense, simple intuitive and data-oriented practical definitions are more suitable. Particularly, the two types of such definitions are popular in practice, the so-called resistant and efficiency robustness. Thus, an estimation procedure is robust in the resistant sense if it stays finite when some of the observations become too large in positive or negative direction. On the other hand, an estimator is efficiency robust if it possesses a high efficiency under the assumed Gaussian distribution of observation data, but it also remains acceptably high efficiency when the real distribution differs from the Gaussian one by heavier tails. This, in turn, generates the outlying data points contaminating the normally distributed observations. Thus, a practically robust estimator has to satisfy the resistant property, together with the efficiency one. A possible approach for designing a simple but practically robust version of the standard Kalman filtering technique has been proposed in [19]. The brief review of this approach is presented in the next chapter.

III. Brief Review of Kalman Filtering based on M-robust Dynamic Stochastic Approximation

Most robust statistical procedures represent a nonlinear problem of estimating a set of constant parameters arranged in a vector satisfying a scalar linear measurement [8-11]. This approach can be extended to the time-varying vector variables, with the observations that are linearly dependent upon the variable to be estimated, [8-11]. Particularly, for the discrete time state vector estimation in question, the posed problem reduces to the step-by-step minimization of the modified M-robust performance index, [10]

$$J_k(\bar{x}_k) = E\left\{\rho\left[\varepsilon_k(\bar{x}_k)\right] \middle| \bar{x}_k, Y^k\right\};\ \varepsilon_k = y_k - H_k\bar{x}_k \quad (11)$$

where $E\{\cdot|\cdot\}$ denotes the conditional mathematical expectation of the nonlinearly transformed measurements residuals, $\varepsilon_k(\cdot)$, given the predicted state vector, $\bar{x}_k$, of the unknown systems state vector, x_k, at the discrete time, k, together with the measurement sequence $Y^k = \{y_1, y_2, ..., y_k\}$. Moreover, $\rho(\cdot)$ is a robust score, or loss, function that has to suppress the influence of outliers. Because it is frequently supposed that the measurement noise is confined to the normal distribution, a high efficiency at the normal noise is

also required. This is the feature of efficiency robustness. Thus, $\rho(x)$ should be look like the quadratic function, x^2, for small and moderate values of the argument, x. Furthermore, as a rule, the measurements data contain 5 to 10 percentage of outliers, [9]. For this reason, it is desirable that the first derivative, $\psi(\cdot)=\rho'(\cdot)$, called the influence function, has the bounded and continuous characteristics, [10, 11]. Bounded feature obeys the requirement that a particular outlier may not have a significant influence on estimates. On the other hand, continuity feature ensures that grouped, or patchy, outliers will not produce for large impact. This is the requirement for resistant robustness. The both requirements correspond to the saturation type nonlinearity, the so-called Huber's score function [10]. The corresponding influence function is the first derivate of the Huber's function, that is

$$\psi(x)=\min\left(|x|,\Delta\right)\operatorname{sgn}(x);\ \Delta=1.5 \tag{13}$$

Furthermore, the dynamic stochastic approximation algorithm can be applied for step-by-step minimization of the M-robust criterion (11), where the standard Kalman filter time-update recursions, (4), (5), are used to predict the system states at each stage k, yielding

$$\hat{x}_k=\bar{x}_k-\Gamma_k\nabla_{\bar{x}}J_k(\bar{x}_k);\ \nabla J_k\sim\frac{1}{d_k}\psi\left(\frac{\varepsilon_k}{d_k}\right)\Gamma_k H_k^T \tag{14}$$

with Γ_k being the matrix gain sequence, where the unknown gradient vector in (14) is replaced by the simple sample realization. In addition, the scale factor, d_k, represents some estimate of the standard deviation of measurement residual, ε_k, in (11), and a natural choice is to use the standard Kalman filtering relation (10) for its calculation. Finally, the gain matrix, Γ_k, in (14) represents a free quantity that influence the convergence property of the proposed robust estimator. Starting from the desired fast-tracking performances, Γ_k may be obtained by the minimization of an additional criterion

$$J_1(\Gamma_k)=TraceP_k;\ P_k=E\left\{(x_k-\hat{x}_k)(x_k-\hat{x}_k)^T\right\} \tag{15}$$

where *Trace* denotes the trace operation on the matrix. The derivation of the recursive relation for Γ_k requires convenient approximations, due to both the dynamic, multivariable, time-varying nature of the system and a nonlinear character of the robust state estimator by itself. The approximate optimal solution is given by, [19]

$$\Gamma_k=M_k=E\left\{(x_k-\bar{x}_k)(x_k-\bar{x}_k)^T\right\} \tag{16}$$

Thus, the proposed M-robust Kalman filter obeys the recursive predictor-corrector structure of the standard Kalman filtering. However, the prediction stage is defined by the standard Kalman filtering time-update recursions, (4), (5), while the correction stage is given by the M-robustified dynamic stochastic approximation algorithm, (10), (11)-(16). The corresponding recursions are given by, [19]

Time update, (4), (5):

$$\bar{x}_k=F_{k-1}\hat{x}_{k-1}+m_w(k);\ m_w(k)=E\{w(k)\} \tag{17}$$

$$M_k=F_{k-1}P_{k-1}F_{k-1}^T+G_{k-1}Q_{k-1}G_{k-1}^T \tag{18}$$

Measurement update, (10), (11)-(16):

$$\varepsilon_k=y_k-H_k\bar{x}_k+m_v(k);\ m_v(k)=E\{v(k)\} \tag{19}$$

$$d_k=S_k^{1/2};\ S_k=H_kM_kH_k^T+R_k \tag{20}$$

$$\omega_k=\begin{cases}\dfrac{\Psi\left(\frac{\varepsilon_k}{d_k}\right)}{\frac{\varepsilon_k}{d_k}} & \text{for } \varepsilon_k\neq 0 \text{ and } d_k\neq 0\\ 1 & \text{for } \varepsilon_k=0 \text{ and/or } d_k=0\end{cases} \tag{21}$$

$$K_k=\omega_kM_kH_k^TS_k^{-1} \tag{22}$$

$$\hat{x}_k=\bar{x}_k+K_k\varepsilon_k \tag{23}$$

$$P_k=(I-K_kH_k)M_k \tag{24}$$

As mentioned before, the M-robust approach is conservative and requires further adaptation to the underlying noise statistics.

IV. Adaptive Robustifying Estimation of Noise Statistics Using M-robust Approach Combined with Robust Median Filtering

Starting from the observation model (2), the measurement noise, v_k, can be estimated as

$$r_k=y_k-H_k\hat{x}_k \tag{25}$$

here $\hat{x}_k$ is the M-robust estimate (17)-(24). Taking into the account the assumptions in (3), together with the assumption of adequate initialization of the robust filter, resulting in the unbiased state estimates, one obtains from (2) and (25)

$$m_r(k)=E\{r(k)\};\ m_v(k)=E\{v(k)\};\ m_r(k)=m_v(k) \tag{26}$$

Additionally, the variance of the random varijable, r_k, is given by

$$V_r(k)=E\left\{\left[r(k)-m_r(k)\right]^2\right\}=H_kP_kH_k^T+R_k \tag{27}$$

where P_k is generated by (24). Furthermore, if the first and second order statistics, $m_r(k)$ and $V_r(k)$, are somehow estimated, say by $\hat{m}_r(k)$ and $\hat{V}_r(k)$, one can estimate further the unknown measurement noise statistics, $m_v(k)$ and R_k, from (26) and (27). In this way one obtains the following estimates

$$\hat{m}_v(k) = \hat{m}_r(k);\ \hat{R}_k = \hat{V}_r(k) - H_k P_k H_k^T \tag{28}$$

Similarly, the state noise sample, w_k, can be estimated from the state equation (1), where the unknown states, x_{k+1} and x_k are replaced by the two successive M-robust estimates, $\hat{x}_{k+1}$ and $\hat{x}_k$. A such obtained state noise estimate represents a scalar real random variable

$$q_k = T_k(\hat{x}_{k+1} - F_k\hat{x}_k);\ T_k = \left(G_k^T G_k\right)^{-1} G_k^T \tag{29}$$

The mean value of their random variable is given by

$$m_q(k) = E\{q_k\} = m_w(k);\ m_w(k) = E\{w_k\} \tag{30}$$

while its variable is defined by the relation

$$\begin{aligned} V_q(k) &= E\left\{\left[q_k - m_q(k)\right]^2\right\} \\ &= T_k\left(-P_{k+1} + F_k P_k F_k^T\right)T_k^T + Q_k \end{aligned} \tag{31}$$

with Q_k being the variance of the state noise sample, w_k. In deriving the expressions (30) and (31) are used the assumptions (3), under which the measurement noise, $\{v_k\}$, and the state noise, $\{w_k\}$, are uncorrelated stochastic sequences, that are mutually uncorrelated and are also uncorrelated with the random initial state, x_0. In addition, it is supposed that the adequate robust Kalman filter initialization produce the unbiased state estimates, $\{x_k\}$. Thus, if $\hat{m}_q(k)$ and $\hat{V}_q(k)$ denote some known estimates of $m_q(k)$ and $V_q(k)$, one can estimate the unknown statistics of the state noise, w_k, using relations (30) and (31). In this way, ones obtains the following estimates

$$\hat{m}_w(k) = \hat{m}_q(k);\hat{Q}_k = \hat{V}_q(k) - T_k\left(-P_{k+1} + F_k P_k F_k^T\right)T_k^T \tag{32}$$

The practical applications of the noise statistics estimations in (28) and (32) requires that the first and second order statistics, (26), (27), (30) and (31), of the random variables r_k and q_k, in (25) and (29), respectively, are estimated in advance. There are at least three approaches to perform this task. The first one is to use conventional sample mean and sample variance estimates, which generate the unbiased and consistent estimates of the mean value and variance under the condition that the random samples, r_k and q_k, are produced by the normal distribution, [3, 4]. However the sample mean and the sample variance lack robustness towards the outliers, [9-11]. A better robust solution is to use M-estimate of the location parameter of the unknown probability distribution, from which the data samples are generated, as an alternative to the sample mean. Moreover, an alternative to the sample variance should be based on the asymptotic formula for the variance of M-robust location parameter estimate, [10]. In this paper, we suggest the third approach based on the median estimators of the mean value and the variance of the unknown probability distribution to which the data samples are confined. Although ad hoc, these estimators are commonly used in engineering practice, due to their simplicity and efficiency, [9]. Thus, if $\{s_i,\ i = 1,...,L\}$, denotes the sample of the size L, from the underlying probability distribution, then the sample median represents the central sample within the rearranged data sequence in increasing order, if the sample size, L, is odd positive integer. On the other hand, if L is an even positive number, the median is given by the arithmetic mean of the two central samples within the sorted data sequence. Under the assumption that the underlying probability distribution function is symmetrical, the corresponding mean value, m, can be estimated by sample median, $\hat{m}(L)$, that is, [9-11]

$$\hat{m}(L) = median\{s_i,\ i = 1,...,L\} \tag{33}$$

In addition, the variance, V, of the distribution in question, can be estimated by $\hat{V}(L)$, representing the median of the absolute median deviations, or MAD estimator, [9, 10]

$$\hat{V}(L) = \left(\frac{median\{s_i - \hat{m}(L);\ i = 1,...,L\}}{0.6745}\right)^2 \tag{34}$$

The factor 0.6745 in (34) is used, because if the sample size, L, tends to infinity, and the data are generated by Gaussian distribution, then the statistics (34) converges towards the real unknown variance of the underlying normal distribution, [9, 10]. In this way, the robust median filters, (29), (34), can be applied for estimation of the unknown quantities, $m_r(k)$ and $V_r(k)$, in (26) and (27), using the sliding data frame, $\{r_i, i = k, k-1,...,k-L+1\}$, where the samples, r_i, are generated by (25). Then, the unknown measurement noise statistics, $m_v(k)$ and R_k, can be estimated by (28). In addition, the unknown quantities, $m_q(k)$ and $V_q(k)$, in (30) and (31), can be estimated by the median estimators (33) and (34), respectively, using the sliding data window,

$\{q_i, i = k, k-1, ..., k-L+1\}$, with q_i being generated from (29). Then, the unknown state noise statistics are calculated from (32).

In summary, the estimators for the first and second-order moments of the measurement and state noises are based upon the last L of the state, q_k, and observation, r_k, noise statistics at discrete time, k, generated by the M-robust Kalman filter (17)-(24). The process requires some extra storage, as well as sorting and shifting operations on the noise samples. However, since a common choice in practice is $L \in [3,10]$, there are no significant additional requirements on the computer time and memory storage. On the other hand, the second approach based on the M-robust estimation of location parameter of the underlying probability distribution entails much more work at each step, but usually not through to preclude the consideration, [17, 18]. Moreover, the noise variance estimators may become negative in numerical applications, especially at the beginning steps, and these quantities have to be reset to the absolute values of their estimates. Additionally, the noise samples (25) and (29) are poor indicators of the noise environment during the robust Kalman filter, (17)-(24), initialization. This difficulty, may be overcome by using the fading memory approach in which the successive noise samples are multiplied by a growing weighting factor

$$g_k = (k-1)(k-2)...(k-\gamma)/k^{\gamma};\ k = 1,2,... \tag{35}$$

In this way, the invalid noise samples are delayed for the first γ-stages, and g_k tends to 1 when k tends to infinity, [18].

V. Experimental Results

The proposed noise-adaptive M-robustified Kalman filter has been derived on the basis of heuristic reasoning, requiring further practical verifications. The figure of merit of the so obtained adaptive robust state estimator is presented by simulations. In the following characteristics examples, using the three-state track model with only position measurement is presented. Due to simplicity, the one-dimensional radar tracking problem, where the target is moving in the x-direction with the constant accelerator, is considered. The system dynamics is given by the kinematic equations of motion, [23].

$$\begin{aligned} s_t &= s_k + z_k(t-t_k) + a_k(t-t_k)^2/2 \\ z_t &= z_k + a_k(t-t_k) \\ a_t &= a_k \end{aligned} \tag{36}$$

where, s_k, z_k and a_k indicate the target position, velocity, and acceleration at discrete time, $t_k = kT$, $k = 0,1,2,...$, with T being the sample period ($T = 4s$), and $t_k \le t \le t_{k+1}$.

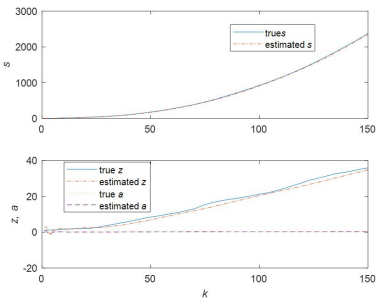

Fig. 1. True and estimated state obtained by the algorithm A1

Since by assumption only the target position is measured, the observations are produced by the equation

$$y_k = x_k + v_k \tag{37}$$

where the additive measurement noise, v_k, is generated from the heavy-tailed Gaussian pdf

$$\begin{aligned} &f(v) = (1-\varepsilon)N(v|0,1) + \varepsilon N(v|0,\sigma_0^2) \\ &0 < \varepsilon < 1;\ \sigma_0^2 \gg 1 \end{aligned} \tag{38}$$

with $N(\cdot|a,b)$ being Gaussian pdf with mean a and variance b. In monopulse radars this heavy-tailed behavior is presented because of the target glint, [23]. By using $t_k = t_{k+1}$ in (36), together with (37), the filter equations are given by

$$x_{k+1} = \begin{bmatrix} 1 & T & T^2/2 \\ 0 & 1 & T \\ 0 & 0 & 1 \end{bmatrix} x_k + \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} w_k = Fx_k + Gw_k \tag{39}$$

$$y_k = [1 \quad 0 \quad 0]x_k + v_k = H_k x_k + v_k \tag{40}$$

where $x_k = [s_k, z_k, a_k]^T$ is the state vector and w_k is the disturbance input (state or process noise), which compensates for unmodelled system dynamics in (36). Namely, in the presence of target maneuver the state model (36) is inadequate, and a such model error is compensated by zero-mean white Gaussian noise term with unit variance, $Q = 1$. The performance of the adaptive robustified Kalman filter, denoted as A1, are compared with the standard Kalman filter, denoted as A2. Simulation results are compared in terms of the estimated noise statistics and the cumulative estimation error (CEE) criterion

$$CEE(k) = \frac{1}{k}\sum_{i=1}^{k}\frac{\|\hat{x}_i - x_i\|}{\|x_i\|} \tag{41}$$

where $\|\cdot\|$ is the Euclidean norm. Figure 1 depicts the true, x, and the estimated, $\hat{x}$, states obtained by the algorithm A1.

The comparison of the algorithms A1 and A2 through the *CEE* simulation results for different noise statistics are presented in Fig. 2.

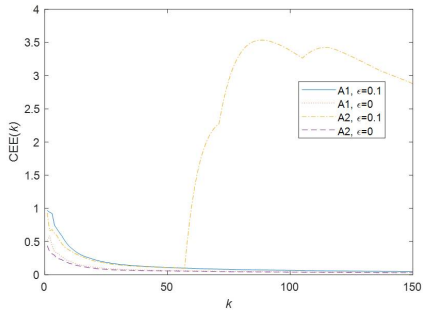

Fig. 2. Cumulative estimation error (*CEE*) of algorithms Alg1 and Alg2 for different noise statistics

Estimated noise statistics are given in Fig. 3. The simulation results have shown that proposed adaptive robustified Kalman filter algorithm, A1, can improve the state estimation performance of the standard Kalman filter, A2, when a priory statistics of the measurement noise are erroneous and there exist a significant dynamic model error, i.e. disturbance input or state noise, owing to the target maneuver.

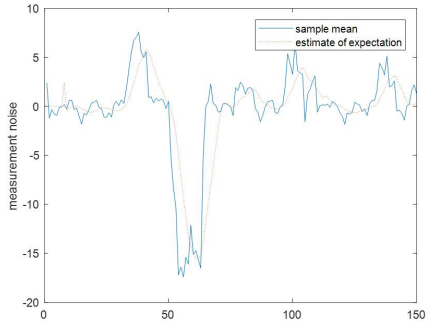

Fig. 3. Estimated noise statistics

VI. Conclusion

In this paper, a feasible Kalman filer modification that performs quite well in the presence of disturbance uncertainty and unmodeled system dynamics has been considered. It has been shown in a realistic simulation task of tracking maneuvering target that the proposed noise-adaptive robustified Kalman filter, based on M-robust dynamic stochastic approximation state estimation combined with robust median estimation of noise-statistics, simultaneously with the system states, can improve the state estimation performance in the presence of erroneous a priory noise statistics and significant dynamic model errors. The proposed adaptive robustified estimator may offer a desirable alternative to other adaptive approaches, particularly those that include state vector estimator of the unknown noise distribution. Finally, the emphasized adaptive robustified procedure in the one that, with some modifications, can be used whenever the least-squares or Kalman filter are used.

Design, Analysis, Validation, and Reporting of Continuous-Time Systems Using CAS

Miroslav Lutovac, *Senior Member, IEEE*, Maja Lutovac-Banduka, and Aleksandra Pavlović

***Abstract*—The automated symbolic manipulations are presented according to user preferences in such a way that all representations (mathematical, graphical, as net-list, software code, or time-domain and frequency domain responses) are obtained from the same visual system description using computer algebra system (CAS) as add-ons for extending software environment. The paper is devoted to researchers and scientist using basic electrical engineering tasks, so that time-consuming tasks are automated in software and the properties of the systems can be discovered, and optional conditions or discovered properties can be used for synthesis, verifications, simulations, and optimization with real parameters. All derived properties are available as closed-form relations, which can help the faster design of robust systems.**

***Index Terms* — Computer algebra systems, electrical engineering, graphical user interface, symbolic processing.**

I. Introduction

IN the process of designing contemporary electric systems usually we start with system specification and deal with system modeling, analysis, software and hardware synthesis and implementations, simulation, verification, tolerance centering, fault detections, design space optimization, and user interface (more details are available in [1] and [2]). We can use numeric or symbolic software environments to design and implement electronic systems. The symbolic software environment as CAS (Computer Algebra System) [3] is the best initial step because expressions from textbooks or published papers can be simply redrawn or rewritten in CAS environment. The programed functions appear in the same traditional forms as in textbooks. Also, the system represented by formulas can be transformed into realizable program or hardware chips, the hardware realization can be transformed into programs and expressions. It is easily to go between hardware descriptions, software implementations, and traditional mathematical expressions. Optimization, verification, and testing the accuracy are available at each design step between the system specification and implementation.

The unified hardware/software approach is using symbolic processing for more than a decade for the design, analysis, verification, and synthesis ([1], [4], and [5]). In spite of the superiority of the symbolic processing, the prevalent software for the design, analysis, verification, and synthesis is still numeric processing.

The purpose of this paper is to exemplify the benefits of symbolic approach. This paper is the third paper in series on this topic: the first part [6] is presenting the development process of GUI (Graphical User Interface) in Mathematica using modern trends in visual programing and some new functions of Mathematica, following the main features of Wolfram language; the second paper [7] is presenting derivation of mathematical representations from schematic description in a form of frequency responses, or as a set of equations and software for the system synthesis. Instead of using textual description of the system, the visual programming technique is used.

This paper starts with derived expressions in [7] and explains analysis and optimization steps.

It should be noticed that the usage of some of the popular graphical programming packages for teaching electrical engineering was presented in [8]. The importance of the visualization of programing in robotics was explained in [9].

II. GUI in CAS environment

GUI in CAS environment is used for visual programing in such a way that the system specification is generated as lists of element specifications by clicking the appropriate buttons. New element can be added into the lists as new function that has all drawing command for all possible node positions. One, two, and three port elements can be added into schematic by clicking only one or two points on the drawing table (see Figures 1, 2, and 3 in [6]). The distinctive feature of the GUI is that the third node is automatically added assuming the most frequently used element position. The default scale is automatically chosen so that element looks as in the most textbooks. The connection lines between the element and the circuit nodes are the minimal. Tooltip function displays label as a tooltip while the mouse pointer is in the area where the element is drawn; label contains element name and coordinates of all ports.

It is possible to draw smaller elements by specifying the element scale property, but not larger than that allowed by element node positions. For testing all positions of the multi-port elements, a special test-code was used with all possible positions in the drawing table.

For different irregular element positions, when mouse is

Miroslav Lutovac is with The School of Electrical and Computer Engineering of Applied Studies Belgrade, 283 Vojvode Stepe, 11000 Belgrade, Serbia, (e-mail: mlutovac@viser.edu.rs).

Maja Lutovac-Banduka is with RT-RK Institute for Computer Based Systems, Novi Sad, Serbia (e-mail: majalutovac@yahoo.com).

Aleksandra Pavlović is with The School of Electrical and Computer Engineering of Applied Studies Belgrade, 283 Vojvode Stepe, 11000 Belgrade, Serbia, (e-mail: aleksandrap@viser.edu.rs).

over that element in the drawing table, the corresponding tooltip shows what is wrong.

III. Transformation of Schematics with Multi-Port Elements into Schematic with Basic Elements

In [7], it is demonstrate the transformation of multi-port elements into a combination of connected two-port elements, and automated generation of system of equations that can be solved using the basic Ohm's law and Kirchhoff's current and voltage laws. As an example schematic is used the schematic that is successfully implemented in many applications as robust solution; that is the general-purpose second order KHN filter section (Kerwin-Huelsman-Newcomb). The well-known schematic is modified so that a new opamp is added for implementing transfer function zero. The new properties of the modified filter section are not documented in the textbooks, and the designer should solve the system. The GUI is used for visual programing (actually for drawing the schematic), the multi-port elements are replaced with standard two-port elements, and the system of equation is automatically derived for setting up circuit equations.

The derivation of the transfer function, of filter section presented in Figure 1, can be a serious problem even for experienced designers when the amplification A is of finite value or given as an expression. The whole procedure is explained in [7]. A part of the example schematic specification is as follows:

```
mySchematic = {
   {"VoltageSource",{{3,7},{3,9}},vin,""},...
   {"Resistor",{{14,11},{17,11}},r5,""}, ...

Fig. 2. Derived coefficients of modified KHN filters section.

After transformation of the schematic elements into two-port elements, we can use the basic Ohm's law and Kirchhoff's current and voltage laws for setting up circuit equations. For each resistor or capacitor element we can use generalized Ohm's law. For each node that is a connection to at least two elements, we can setup equations using Kirchhoff's current law. For the voltage sources between two nodes we can use Kirchhoff's voltage law. The system of equations consists of 27 equations with 27 variables. The final results cannot be presented in viewable format. The transfer function coefficients are presented in Figure 2.

Assuming that amplification of the amplifiers is infinitive, A→∞, the simplified transfer function of the second-order function is obtained using limiting value of the expression when *A* approaches ∞. The simplified transfer function can be used for the filter synthesis. In Figure 3 we have used the traditional type of displaying the derived result.

$$\frac{R_3\,R_4\,(R_1+R_9)\,R_{10}\left(C_6\,C_8\,R_5\,R_7\,s^2\,R_L+R_H\right)}{R_H\,R_L\left(C_6\,C_8\,R_2\,R_3\,R_5\,R_7\,R_9\,s^2+C_8\,R_1\,R_3\,R_4\,R_7\,s+R_2\,R_4\,R_9\right)}$$

Fig. 3. The derived transfer function of KHN filter section for A→∞.

IV. Determining Design Constrains

In this section we have demonstrated how the initial schematic and the automated deriving of the transfer functions help us to choose the most preferred values for implementation.

For known transfer function and the circuit that has to implement it, we can prepare synthesis procedure. In this case the transfer function that we have to implement can be low-pass H_{LP} or low-pass-notch H_{LPN} with four symbolic parameters K_0, ω_z, ω_p, Q_p:

$$H_{LP}=K_0\frac{s^2}{s^2+\frac{\omega_p}{Q_p}++\omega_p^2} \tag{1}$$

$$H_{LPN}=K_0\frac{s^2+\omega_z^2}{s^2+\frac{\omega_p}{Q_p}++\omega_p^2} \tag{2}$$

For the 6th order filter, on disposal are 12 values that we have to determine to implement the filter section with the transfer function. Most values can be arbitrary chosen. As the first attempt, let us choose R_3, R_4, R_9, and R_H as variables that we can determine from the filter transfer function. All other values we would like to specify arbitrary. From the schematic we can determine relations between four parameters K_0, ω_z, ω_p, Q_p and four resistances. For example,

$$R_3=R_2\frac{-1+C_8Q_pR_7\omega_p}{C_8Q_pR_7\omega_p} \tag{3}$$

The value of the resistance R_3 can be negative in the case when *Q* factor is too low:

$$C_8Q_pR_7\omega_p<1 \tag{4}$$

The lowest *Q* factor for elliptic-type filters is 0.5. Therefore we can determine constrains for the resistor R_7:

$$R_7>\frac{2}{C_8\omega_p} \tag{5}$$

The design procedure is as follows assuming that R_x and C_x are from the set of the most preferred values for the implementation:

$$\begin{aligned}&R_x>\frac{2}{C_x\omega_p}\\&R_1=R_2=R_5=R_7=R_{10}=R_L=R_x\\&C_6=C_8=C_x\end{aligned} \tag{6}$$

The next step is to determine the design procedure. The design procedure means that we have to automatically derive a code for computing all filter values. Again, comparing the transfer function in terms of filter parameters (K_0, ω_z, ω_p, Q_p) and the transfer function in terms of resistances and capacitance, we can obtain all implementation values as a code in the Wolfram language [1].

V. Design of Higher-Order Filters Using Known Schematic

Once the circuit is well analyzed and design procedure is available, we can use as embedded solution in higher order systems.

Suppose we have to implement low-pass filter that satisfies the following conditions: the passband edge frequency F_p=3000 Hz, the stopband edge frequency F_s=4500 Hz, the maximal passband variation A_p=0.2 dB, the minimal stopband attenuation A_s=40 dB.

The minimal filter order of the most efficient elliptic filter is 5. Since we are planning to use the same second-order filter section, we will choose the sixth order approximation. Thera are many solutions from the design space [1]. We choose the minimal Q factor elliptic filter [1] with the selectivity factor 1.635, and the frequency normalization 1.1 (move the passband edge to the transition region). This approximation was robust as digital filters [1], and we are expecting that the analog filter can be also robust to many parasitic effects and imperfections.

The filter parameters are for three sections:

	H_3	H_2	H_1
ω_p^2	$4.8016\ 10^8$	$4.8016\ 10^8$	$4.8016\ 10^8$
Q_p	4.24831	1.13453	0.557171
ω_z^2	$9.48906\ 10^9$	$1.40637\ 10^9$	$8.29491\ 10^8$

Since all ω_p are the same, we can choose the referent capacitance C_x=10 nF. The minimal value from design constrains is $R_{x,min}$= 9127 Ω: we chose the large value R_x=10 kΩ. All three sections have the same value for resistances R_1=R_2 =R_5=R_7=R_{10}=R_L =10 kΩ and capacitances C_6= C_8=10 nF. Other resistances are computed using design procedure for known filter parameters:

	H_3	H_2	H_1
R_3 [Ω]	8930	5980	1810
R_4 [Ω]	42900	28700	8690
R_9 [Ω]	83500	14900	2210
R_H [Ω]	82900	141000	949000

In this section we have demonstrated how the initial schematic, the automated deriving of the transfer functions from the schematic description, and derived design procedure, can be used to design higher order filter as cascaded connection of initial second-order filter sections.

VI. Verification of the Magnitude Response of Designed Circuit

In the verification step, we would like to obtain the same magnitude response with computed resistances and capacitances as the taken approximation. In the derived transfer function in terms of resistances and capacitances we are replacing computed values that are within 0.1% tolerances. The magnitude responses of the theoretical and implemented filter are presented in the Figures 4 and 5.

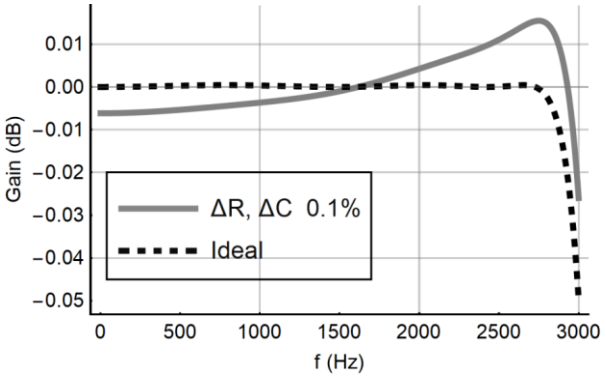

Fig. 4. Pass-band magnitude response of theoretical and implemented filter.

The pass-band variation is within required specification and significantly smaller than 0.2 dB. The minimum stopband attenuation is approximately 40 dB.

VII. Study of Imperfection

The purpose of the study of imperfection is to identify the critical components that can harm the specification and regular operation. In this section we will consider the finite gain of the amplifier as an example. The magnitude responses of the theoretical and implemented filter are presented in the Figures 6 and 7.

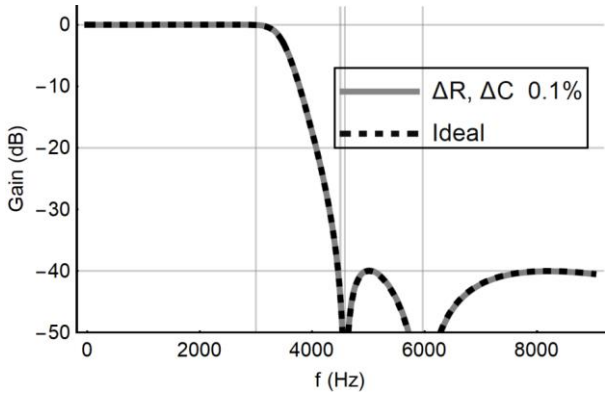

Fig. 5. Stop-band magnitude response of theoretical and implemented filter

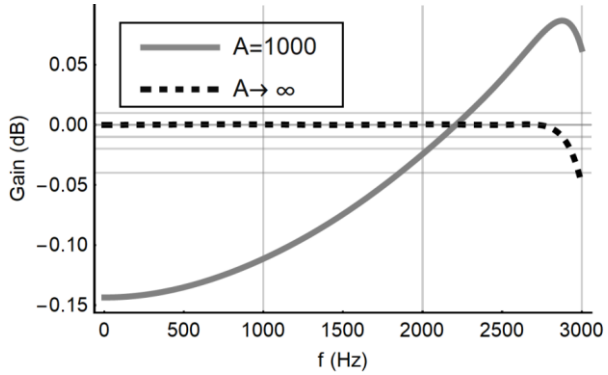

Fig. 6. Pass-band magnitude response of theoretical and implemented filter for A=1000.

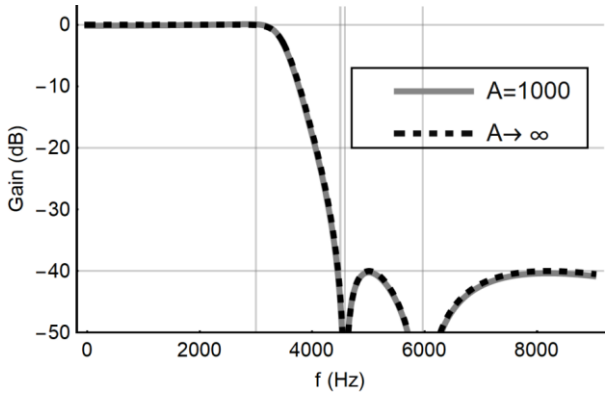

Fig. 7. Stop-band magnitude response of theoretical and implemented filter for A=1000.

The pass-band variation is slightly larger than the required specification 0.2 dB. The minimum stopband attenuation is approximately 40 dB. This implies that for implementation is required the opamp with larger gain then 1000.

VIII. Optimization and tuning procedure

The purpose of the optimization step is to optimize some values for the optimal values using different approaches. One possibility is to find referent resistance R_x for minimal gain-sensitivity product. Since all expressions are available as closed-form relations, it is simple to derive all sensitivity functions and to find the minimal value using procedures from [1]. In practice, many elements can be modeled using manufacturer instructions, and that models can be used to replace ideal values. For example, the gain of the amplifier can be modeled as single pole function that is frequency dependence. Replacing this model into derived transfer function will lead to increasing the order of the transfer function. This is not serious problem when we are using CAS, because all substitutions are in closed form and in the overall response we can identify the expression of the second-order section. From that expression we can discover the influence of R_3, R_4, R_9, and R_H as variables on four parameters K_0, ω_z, ω_p, Q_p.

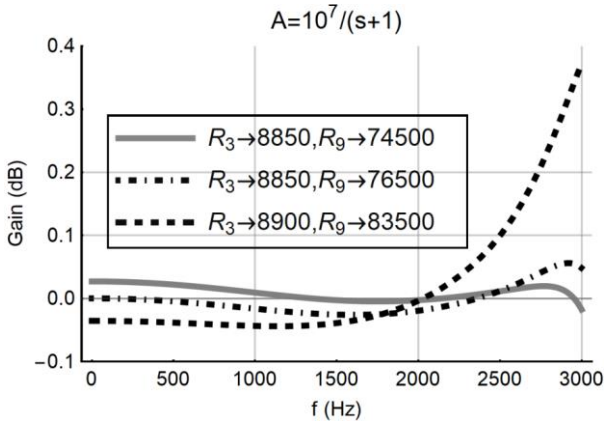

Fig. 8. Pass-band magnitude response of implemented filter for different values of R_3 and R_9.

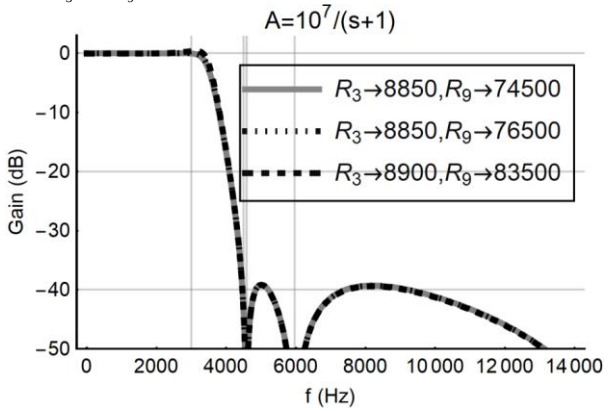

Fig. 9. Stop-band magnitude response of implemented filter for different values of R_3 and R_9.

Those resistances can be used for discovering tuning procedure. As an example, the magnitude responses of the implemented filters for several values of R_3 and R_9 are presented in the Figures 8 and 9.

After tuning R_3 and R_9, the pass-band variation is within required specification 0.2 dB. The minimum stopband attenuation is slightly smaller than 40 dB. This implies that the optimization or tuning procedure is possible by computing the new values of several resistances (for example, R_3 and R_9).

IX. Conclusion

In this paper, we have developed an environment and graphical user interface (GUI) so that the system description can be generated with the small number of tasks. The software is not like usual canned applications and it is possible to combine system description with many other specific user targets such as manipulate with symbolic expressions and analyze complex non-ideal element and system models.

Implementation of IIR Digital Filters with Variable Characteristics in GNU Octave

Darko Đ. Vračar

***Abstract*—Implementation of IIR digital filters with variable characteristics in GNU Octave software is presented. The goal is to demonstrate efficient usage of free open-source software instead of the commercial ones. The method for tuning the cut-off frequency with one parameter is based on series expansion of the low-pass-low-pass frequency transformation. The filter structure is a parallel connection of real or complex all-pass sections. The simulation results are matched with results in the references. In addition, simulation of the example elliptic filters in time domain is shown which verifies their design.**

***Index Terms*— All-pass, IIR, free software, GNU Octave implementation, recursive digital filters, variable characteristics.**

I. Introduction

MAIN function of electric filters is to adjust signal spectrum. In many cases such adjustment of signal spectrum comes down to allowing signal to pass in some frequency range (i.e. band-pass) and attenuation of signals that are outside of that range (i.e. band-stop) [1].

In many applications it is desirable to change frequency characteristics of a digital filter during its operation. This is subject of research in last several decades [2]-[6]. For example, filters with variable characteristics are used in: telecommunications, digital audio equipment, medical electronics, radar, sonar and control systems, adaptive and tracking systems, spectrum and vibration analyses, and in laboratory instruments [5].

There are many methods how to change filter frequency characteristics. A good review and systematization of such methods is given in [5]. Method used in this paper is based on Taylor series expansion of the low-pass-low-pass (LP→LP) frequency transformation [2]. The filter structure is a parallel connection of real or complex all-pass sections.

The recursive digital filter is a discrete system that is, in transformation domain, described with equation [1]

$$\mathrm{H(z)}=\frac{\mathrm{Y(z)}}{\mathrm{X(z)}}=\frac{\sum_{k=0}^{M} b_k \cdot z^{-k}}{1+\sum_{k=1}^{N} a_k \cdot z^{-k}}. \qquad (1)$$

The (1) is valid for linear time-invariant discrete systems. Note that the IIR (infinite impulse response) filter is often called a recursive one [2]-[4]. One has to keep in mind that these two terms are not synonyms although IIR filters are always realized as recursive ones [1].

In this paper, implementation of IIR digital filters with variable characteristics in free open-source software *GNU Octave* [7] is presented. In addition, for signal processing tasks, one had to use its package named *Signal* [7]. The similar results one could also get by using commercial software like *Matlab*™ and its *Signal Processing Toolbox*™. The goal of this paper is to demonstrate efficient usage of the free open-source software for such applications thus avoiding going for the commercial ones. Author's wish is to encourage audience to use more free software so the filter drawings are done by using free software as well [8].

This topic about tunable digital filters with relevant, although old, references was chosen as appropriate for such a demonstration. The task was to simulate all four transformations: low-pass-low-pass (LP→LP), low-pass-high-pass (LP→HP), low-pass-band-pass (LP→BP) and low-pass-band-stop (LP→BS) of a starting LP filter.

II. Theoretical Background

In this section only minimum theoretical background is given that was used for the software implementation. For more details the reader shall refer to [2]-[4]. One shall note that majority of the sentences in this chapter are either paraphrased or directly copied from [2]-[4]. Similar is valid for formulas as well.

If we mark transfer function of a digital filter as *H(z)*, adjustment of its frequency response can be made by using transformation of Constantinides [2], [5]-[6]

$$z^{-1} \rightarrow T(z) \qquad (2)$$

which gives us a new transfer function

$$H'(z) = H(z)\big|_{z^{-1}=T(z)} \qquad (3)$$

whose frequency response $H'(e^{j\omega})$ is appropriate transformed version of the original frequency response $H(e^{j\omega})$.

Let us have a look at the transfer function of recursive filter of N^{th} order given with (1). For LP→LP transformation, the *T(z)* function is an all-pass one of the 1^{st} order, and is given as [2]

$$T_1(z) = \frac{z^{-1}-\beta}{1-\beta \cdot z^{-1}} \qquad (4)$$

where

Author, at the time when similar results were initially obtained, was with the School of Electrical Engineering, University of Belgrade, Serbia. Author is now with Huawei Technologies Duesseldorf GmbH, Riesstr. 25, 80992 Munich, Germany; (e-mail: vracard@eunet.rs).

$$\beta = \sin\left(\frac{\Theta_P - \omega_P}{2}\right) \Big/ \sin\left(\frac{\Theta_P + \omega_P}{2}\right). \qquad (5)$$

Here Θ_P is cut-off frequency of the initial filter (i.e. prototype filter), and ω_P is the desired cut-off frequency. If $\beta=0$, then (4) reduces to delay operation. This transformation is not linear regarding ω.

Modified frequency transformation of the LP→BP type for recursive filter has form of a 2nd order all-pass function

$$T_2(z) = -z^{-1}\left(\frac{z^{-1} - \alpha}{1 - \alpha \cdot z^{-1}}\right) \qquad (6)$$

where

$$\alpha = -\cos(\Theta_C). \qquad (7)$$

Here Θ_C is the desired central frequency of the BP (BS) filter. It is calculated as a difference between upper and lower band-pass (band-stop) boundaries divided by 2.

The general form of these frequency transformations in discrete domain is [1]

$$T(z) = e^{j \cdot n \cdot \pi} \prod_{i=1}^{m} \frac{z^{-1} - a_i^*}{1 - a_i z^{-1}} \qquad (8)$$

where n and m are integers, whereas a and a^* are conjugate-complex constants. One can see that in (4) $m=1$, and in (6) $m=2$. This transformation does not have influence on stability of the transfer function.

The reader shall notice that (6) differs from *(23)* in [2] in sense that, in this paper, differences in nominator and denominator were used (i.e. not the sum as in [2]). This is what worked in software implementation and it is in accordance with (8) as well as with *(33)* in [5]. That was probably just a typo in [2].

This method uses, as basic structure, parallel connection of all-pass filter sections [2]. By introducing standard LP→LP transformation in these sections and with decomposition into Taylor series on control variable, one gets filter structure that is possible to realize. With only one parameter it is possible to control cut-off frequency.

A. Structures for Filter Realizations

The all-pass transfer function of N^{th} order with complex coefficients is given as

$$\varepsilon_N(z) = \frac{z^{-N} + a_{N-1} z^{-N+1} + \ldots + a_1 z^{-1} + a_0}{1 + a_{N-1}^* z^{-1} + \ldots + a_1^* z^{-N+1} + a_0^* z^{-N}} \qquad (9)$$

and for all-pass transfer function with real coefficients the $A_N(z)$ coefficients $\{a_i\}$ are the real ones. In [2] is shown that a big class of transfer functions with real coefficients can be realized as parallel connection of all-pass filters with real or complex coefficients as shown in Fig. 1 [2].

This type of structure has low sensitivity in band-pass and requires only N multipliers for N^{th} order filter. All standard low-pass filters of odd order (e.g. Butterworth, Chebyshev, elliptic, etc.) can be realized in this form [2].

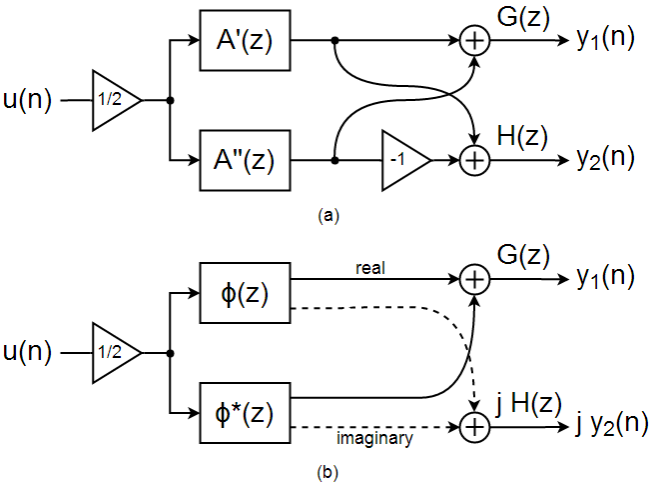

Fig. 1. Realization of a double-complementary filter pair. (a) Filters derived from LP transfer function of odd order have form of two, parallel connected, real all-pass sections. (b) Filters based on LP transfer function of even order are implemented as parallel connected complex all-pass sections.

1) Realization of Odd-Order Filters

At Fig. 1 one can see that at outputs one has complementary filter pairs. It is possible to show that, for LP-HP pair of N^{th} order, all-pass sections $A'(z)$ and $A''(z)$ are of "$<N/2$" and "$>N/2$" order, respectively; where "<" and ">" denote first lower and first bigger integer than $N/2$.

There are many structures for implementation of all-pass sections of 1st and 2nd order. At Fig. 2 two examples are shown that require only one and two multipliers per 1st and 2nd order sections, respectively [2]. They are used in this paper for software implementation of odd-order filter.

Derivation of $A'(z)$ and $A''(z)$ is given in [3] and I will repeat it here in short form for sake of paper completeness. Let us have a look at the N^{th} order transfer function of IIR filter

$$G(z) = \frac{P(z)}{D(z)} = \frac{p_0 + p_1 z^{-1} + \ldots + p_N z^{-N}}{1 + d_1 z^{-1} + \ldots + d_N z^{-N}} \qquad (10)$$

where coefficients p_i and d_i are real ones. Now let us assume that the structure is such that, despite real values of multipliers m_i, the absolute value $|G(e^{j\omega})|$ is bounded above by a fixed constant, e.g. 1:

$$|G(e^{j \cdot \omega})| \le 1 \quad \text{for all } \omega. \qquad (11)$$

The stable function $G(z)$, with real coefficients, that satisfies (11) is called bounded real function. If expression (11) is valid, with equal sign, for every ω then the $G(z)$ is called bounded real transfer function without losses. It is more known as stable all-pass function.

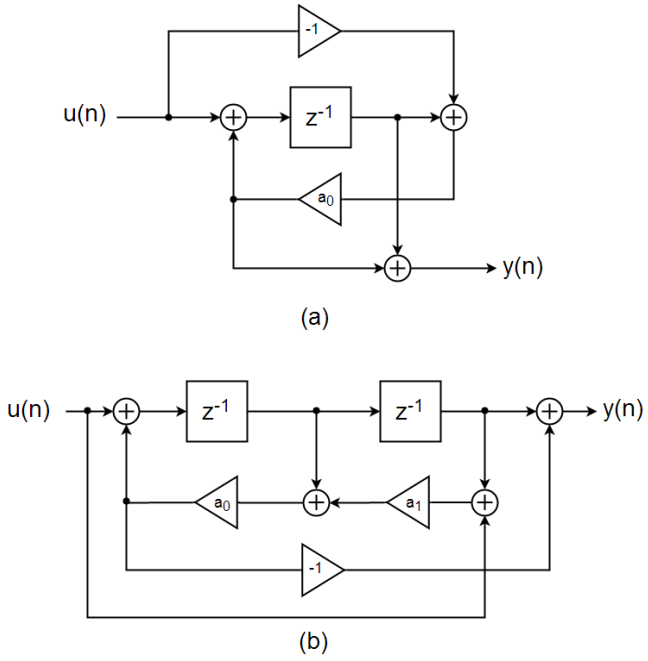

Fig. 2. All-pass structures (blocks): (a) 1st order, (b) 2nd order.

Let us consider typical bounded real LP transfer function of N^{th} order like in (11). Let us assume that $P(z)$ has linear phase. This is typical for majority of transfer functions of digital filters (because zeroes are usually located at unity circle) and, therefore, this is just mild boundedness. In order to be more precise, let $P(z)$ be symmetrical, i.e. $p_k=p_{N-k}$. Let us now look at another transfer function $H(z)$ given as

$$H(z)=\frac{Q(z)}{D(z)}=\frac{q_0+q_1z^{-1}+\ldots+q_Nz^{-N}}{1+d_1z^{-1}+\ldots+d_Nz^{-N}} \tag{12}$$

where $H(z)$ is defined so that applies

$$|H(e^{j\omega})|^2=1-|G(e^{j\omega})|^2. \tag{13}$$

In another words, the $H(z)$ is complementary to $G(z)$. From this, regarding z variable, we have following expression

$$P(z^{-1})\cdot P(z)+Q(z^{-1})\cdot Q(z)=D(z^{-1})\cdot D(z). \tag{14}$$

Let us now make a non-trivial assumption: $G(z)$ is such so that $Q(z)$, which satisfies (14), is anti-symmetric, i.e. $q_k=-q_{N-k}$. After several mathematical transformations we are coming to the expression for $A'(z)$ and $A''(z)$:

$$A'(z)=\prod_{k=r+1}^{N}\left(\frac{z^{-1}-z_k^{-1}}{1-z^{-1}\cdot z_k^{-1}}\right)$$
$$A''(z)=\prod_{k=1}^{r}\left(\frac{z^{-1}-z_k}{1-z^{-1}\cdot z_k}\right) \tag{15}$$

where r is number of zeros of the polynomial $P(z)+Q(z)$ that are located within unity circle. The calculation of $Q(z)$ is given in [3]. At the end we are coming to the expression for $G(z)$ and $H(z)$:

$$G(z)=\frac{1}{2}[A'(z)+A''(z)] \tag{16}$$

$$H(z)=\frac{1}{2}[A'(z)-A''(z)]. \tag{17}$$

This brings implementation of $G(z)$ and $H(z)$ as parallel combination of stable all-pass functions. If, e.g., $G(z)$ is a LP function then $H(z)$ is the HP one. Following is valid as well:

$$\begin{aligned}G(z)+H(z)&=A'(z)\\G(z)-H(z)&=A''(z)\end{aligned}. \tag{18}$$

If functions G(z) and H(z) are fulfilling (13) and (18) then one can say that they are double complementary.

2) Realization of Even-Order Filters

Let $G(z)$ and $H(z)$ be given as in (10) and (12), respectively, and let they form a double-complementary pair. It is shown in [2] that, when we are working with real input signals, we can use more efficient structure for realization of the even-order filter, and not the structure from Fig. 1(b). Such a structure is given on Fig. 3 [2].

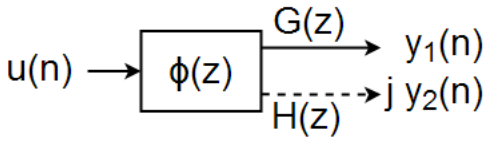

Fig. 3. A structure for implementation of even-order filter that uses one complex all-pass section.

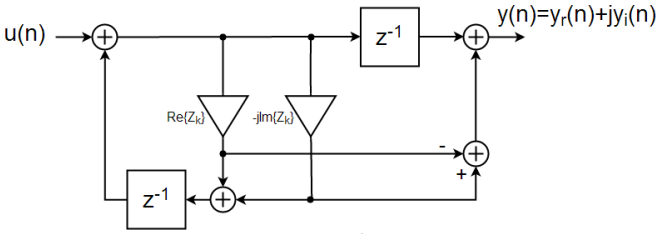

Fig. 4. The all-pass complex section of 1st order.

For the implementation of the complex all-pass section of 1st order the structure from Fig. 4 was used [4].

B. Control of Cut-Off and Central Frequency

Let us have a look at complex all-pass filter like in (9). By using LP→LP transformation of (4) type in $\varepsilon_N(z)$ we are coming to transformed all-pass section

$$\varepsilon_N'(z)=\gamma\cdot\frac{z^{-N}+\hat{a}_{N-1}z^{-N+1}+\cdots+\hat{a}_1z^{-1}+\hat{a}_0}{1+\hat{a}_{N-1}^*z^{-1}+\cdots+\hat{a}_1^*z^{-N+1}+\hat{a}_0^*z^{-N}} \tag{21}$$

where

$$\gamma=\frac{1+\sum_{i=0}^{N-1}(-1)^i a_i\beta^{N-i}}{1+\sum_{i=0}^{N-1}(-1)^i a_i^*\beta^{N-i}}. \tag{22}$$

Let us expand in Taylor series the transfer-function coefficients $\hat{a}_i$ and $\hat{a}_i^*$ *(i=0, 1… N-1)* in regard to β. If we assume that β is very small and omit expansion after linear term we are coming to

$$\begin{aligned} \hat{a}_i &\approx a_i + \beta \cdot c_i \\ \hat{a}_i^* &\approx a_i^* + \beta \cdot c_i^* \end{aligned} \tag{23}$$

where c_i and c_i^* are functions of $\varepsilon_N(z)$ coefficients in (9). If we set $\beta=0$ we will get the original transfer function $\varepsilon_N(z)$.

Let us notice that positive values of β are decreasing cut-off frequency whereas negative values are increasing it.

All-pass transfer functions of higher order, with real coefficients, can always be realized as cascade connection of real all-pass sections of 1st and 2nd order. The transfer functions of higher order, with complex coefficients, can be realized as cascade connection of complex all-pass sections of 1st order.

For the real case of 1st order we have

$$c_0 = -1 + a_0^2 \tag{24}$$

where a_0 is the coefficient of structure from Fig. 2(a). Correspondingly, for the real case of 2nd order we have

$$\begin{aligned} c_0 &= a_1(-1 + a_0) \\ c_1 &= -(2 + 2a_0 - a_1^2) \end{aligned} \tag{25}$$

where a_0 and a_1 are coefficients of structure from Fig. 2(b), respectively. The reader shall notice that (24) and (25) differ from *(16b), (18a)* and *(18b)* in [2] in sense that they are inverted and they did not work in software. The (25) is in accordance with *(39)* in [5]. That was probably a typo in [2].

From implementation point of view, equation (23) and its special cases (24)-(25) are allowing two alternatives for adjustments. We can either calculate the coefficients again by using transformation $T_1(z)$ from (4) or we can introduce braches for tuning, with coefficients $\beta \cdot c_i$, parallel to multipliers (which have nominal values a_i). In this paper the second alternative is used and is shown at Fig. 5 [2].

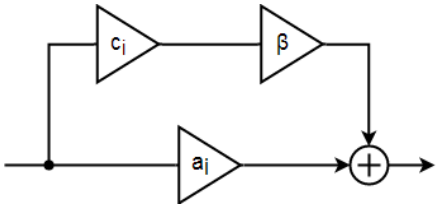

Fig. 5. The tuning branch that is connected in parallel to a nominal value of a coefficient a_i

The variable band-pass (or band-stop) filter one can get by using LP→BP transformation $T_2(z)$ from (6) to variable LP filter. This transformation does not produce loops without delays because it has a form of a delay followed by all-pass section of the 1st order. Therefore, we can control band-pass range and central frequency by using two parameters (one per every characteristic).

III. Implementation Results

As already mentioned, for implementation of such filter structures the *GNU Octave* and its package *Signal* are chosen. The developed m-files comprise around 1000 lines of software code. The *long* number format is used which means that one has 15 digits plus sign.

In [2] is stated that one can get best performance with elliptic filters. That was the reason why it is used in this paper for software implementation. The specifications of elliptic filters are freely chosen and will be stated by the results. Only results related to LP and BP filters will be shown for the sake of simplicity and due to limited number of pages. Showing characteristics of their complementary filter pairs (HP and BS) would be just simple repetition.

For all filter simulations (or processing) in time domain one can notice small signal delay after passing through recursive filter. The delay occurs because it takes some time until all auxiliary variables in 1st or 2nd order sections are initialized. In addition, it is known that IIR filter does not have linear phase characteristics.

A. Odd-Order Filters

Specification of the prototype elliptic filter: 5th order, maximum allowed attenuation in in band-pass area of 1 dB, minimum allowed damping in band-stop area of 35 dB and sampling frequency of 2 kHz.

The change of an amplitude characteristics as well as simulation in time domain of the new filter will be shown.

The LP→LP transformation of the prototype filter is given at Fig. 6. The old cut-off frequency was 400 Hz and new cut-off frequency is 300 Hz.

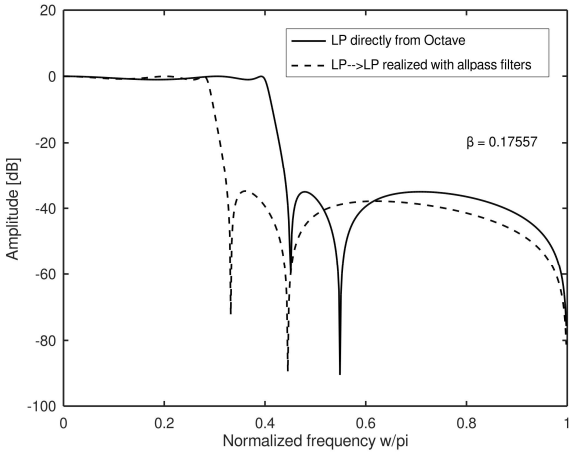

Fig. 6. The LP→LP transformation of 5th order elliptic filter. The old cut-off frequency was 400 Hz (solid line); new cut-off frequency is 300 Hz (dashed line).

The time simulation of the LP→LP transformed filter from Fig. 6 is shown at Fig. 7. Input signal is a discrete sinusoidal with 40 p.u. amplitude and 200 Hz frequency. Work in band-pass area was considered. The new filter worked as expected.

The LP→BP transformation of the prototype filter is given at Fig. 8. The old cut-off frequency was 200 Hz and the new commanded central frequency is 400 Hz.

The time simulation of the LP→BP transformed filter from Fig. 8 is shown at Fig. 9. Input signal is a discrete sinusoidal with 40 p.u. amplitude and 100 Hz frequency.

Work in band-stop area was considered. The new filter worked as expected.

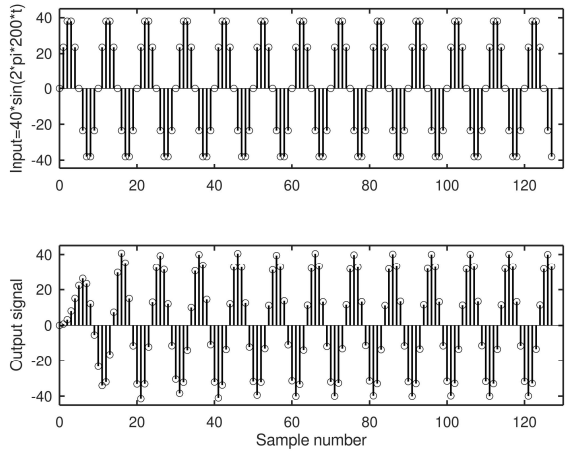

Fig. 7. Time simulation of the LP→LP transformed 5th order elliptic filter from Fig. 6. Input signal (upper trace) is a discrete sinusoidal with 40 p.u. amplitude and 200 Hz frequency. Work in band-pass area was considered.

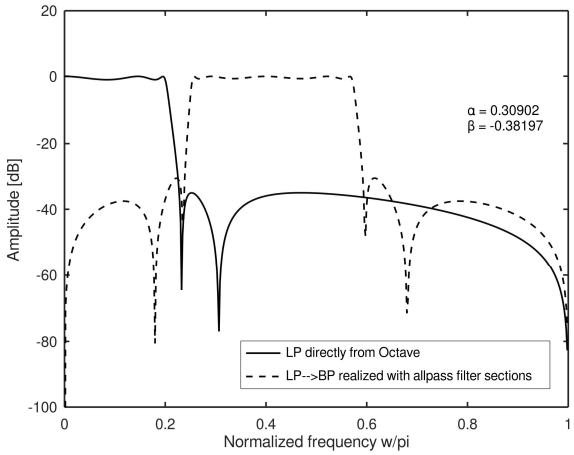

Fig. 8. The LP→BP transformation of 5th order elliptic filter. The old cut-off frequency was 200 Hz (solid line); new commanded central frequency is 400 Hz (dashed line).

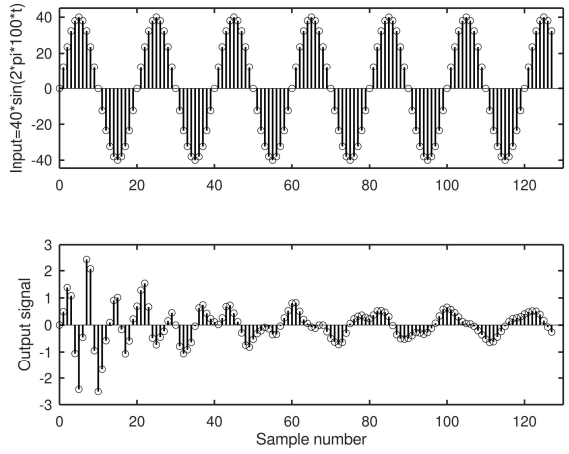

Fig. 9. Time simulation of the LP→BP transformed 5th order elliptic filter from Fig. 8. Input signal (upper trace) is a discrete sinusoidal with 40 p.u. amplitude and 100 Hz frequency. Work in band-stop area was considered.

B. *Even-Order Filters*

Specification of the prototype elliptic filter: 4th order, maximum allowed attenuation in in band-pass area of 1 dB, minimum allowed damping in band-stop area of 35 dB and sampling frequency of 2 kHz.

The change of an amplitude characteristics as well as simulation in time domain of the new filter will be shown. One shall note that structures for even-order filters have narrower allowed tuning range [2].

The LP→LP transformation of the prototype filter is given at Fig. 10. The old cut-off frequency was 200 Hz and new cut-off frequency is 300 Hz. One can notice change (i.e. error) in band-stop attenuation of around 13 dB. In [4] it is mentioned that even-order filters are not low sensitive in band-stop area and band-stop attenuation is also dependent on parameter β (i.e. the same problem is noticeable in the reference - see *Fig. 10* in [2]).

The time simulation of the LP→LP transformed filter from Fig. 10 is shown at Fig. 11. Input signal is a discrete sinusoidal with 40 p.u. amplitude and 150 Hz frequency. Work in band-pass area was considered. The new filter works as expected.

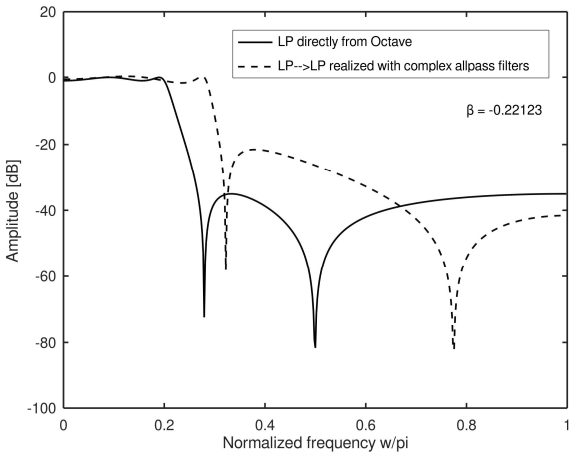

Fig. 10. The LP→LP transformation of 4th order elliptic filter. The old cut-off frequency was 200 Hz (solid line); new cut-off frequency is 300 Hz (dashed line).

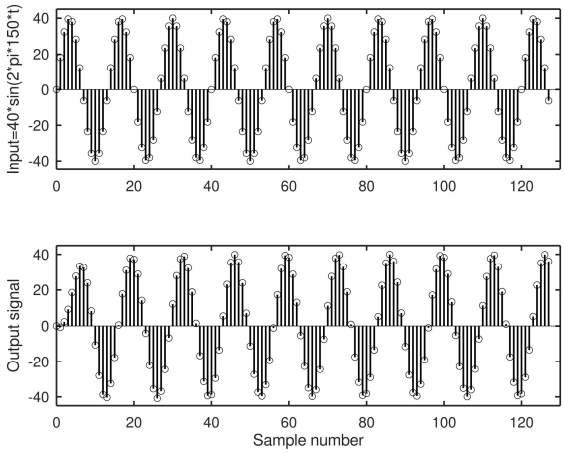

Fig. 11. Time simulation of the LP→LP transformed 4th order elliptic filter from Fig. 10. Input signal (upper trace) is a discrete sinusoidal with 40 p.u. amplitude and 150 Hz frequency. Work in band-pass area was considered.

The LP→BP transformation of the prototype filter is given at Fig. 12. The old cut-off frequency was 200 Hz and the new commanded central frequency is 400 Hz. One can notice change (i.e. error) of more than 10 dB in band-stop attenuation. In addition to comments given for Fig. 10, one can add that in [3] trade-off between errors in pass-band and band-stop areas is analyzed ("*α vs. β*", see *Fig. 10* in [3]). In this paper aim was not to find the perfect combinations of α and β, but to demonstrate that the transformation works in GNU Octave and in accordance with references.

The time simulation of the LP→BP transformed filter from Fig. 12 is shown at Fig. 13. Input signal is a discrete sinusoidal with 40 p.u. amplitude and 100 Hz frequency. Work in band-stop area was considered.

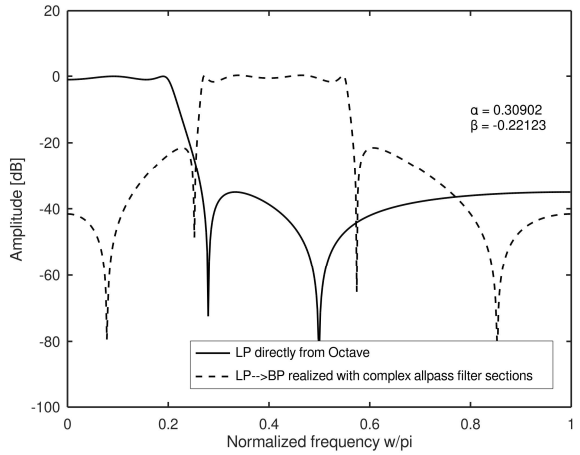

Fig. 12. The LP→BP transformation of 4th order elliptic filter. The old cut-off frequency was 200 Hz (solid line); new commanded central frequency is 400 Hz (dashed line).

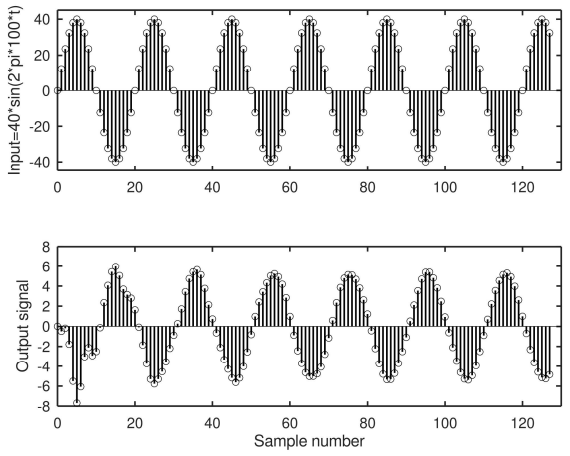

Fig. 13. Time simulation of the LP→BP transformed 4th order elliptic filter from Fig. 12. Input signal is a discrete sinusoidal with 40 p.u. amplitude and 100 Hz frequency. Work in band-stop area was considered.

IV. Conclusion

In this paper the implementation of IIR digital filters with variable characteristics in GNU Octave free open-source software is presented. The goal was to demonstrate efficient usage of such software in tunable digital filters' applications instead of expensive commercial software thus encouraging wider audience to use it.

The new filters, after transformation of their amplitude characteristics, worked as expected. In addition, some small mistakes in formulas in the reference literature [2] are noticed. This is explained and corrected in the paper as well as in the software implementation.

Besides the two aspects mentioned above there were no other new results in this paper compared to the [2]-[4]. The results presented in this paper are in accordance with relevant results in [2]-[4] including errors in band-stop attenuation of even-order filters.

It is worth mentioning that the same code was executed on Octave 4.4 (32-bit) under Windows Vista (32-bit) and Octave 5.1 (64-bit) under Windows 10 (64-bit) and no difference in the filtering results was noticed. No further work is planned on this topic.

Acknowledgment

Author would like to thank Prof. Dr. M. Popović, School of Electrical Engineering, University of Belgrade, for his supervision, advices and tips at the time when initial similar work on this topic was done. This paper is an extension of that work and is not related to author's current job, i.e. affiliation. Author thanks his family and friends for support at that time too. The filter drawings are made in free program *Draw.io* [8].

Multifractal Image Forgery Using Logistic Regression

Natasa Milosavljevic, Aleksandra Pavlovic

***Abstract* – This paper presents multinomial logistic regression (MLR) using multifractal image data for forgery detection. Multifractal analysis gives a much smaller number of parameters which are sufficient to describe the image and which in this paper serve for further analysis in order to better forensics. On the basis of these parameters, a MLR method is proposed that will predict the blocks at which the change occurred in the image.**

Keywords: **multifractal, image forensic, prediction, forgery analysis, multinomial logistic regression, classification.**

I. INTRODUCTION

Supervised classification (and segmentation) of high dimensional data sets such as remotely sensed hyperspectral images is a difficult endeavor [1]. Obstacles, such as the Hughes phenomenon [2], appear as the data dimensionality increases. This is because the number of training samples used for the learning stage of the classifier is generally very limited compared with the number of available spectral bands. In order to circumvent this problem, several feature selection [3] and extraction [4] methods have been combined with machine learning techniques that are able to perform accurately in the presence of limited training sets, including support vector machines (SVMs) [5], [6] or multinomial logistic regression (MLR)-based classifiers [7], [8].

The remainder of this paper is organized as follows. Section II formulates the problem. Section III describes the proposed approach. Section IV reports results based on proposed method. Finally, Section V concludes with some remarks and hints at plausible future research lines.

II. PROBLEM FORMULATION

Digital images are used in everyday life. With development of different software, it has become very easily do change the content of digital image. So, we cannot be sure about originality of the same.

One of the most used methods for image forgery is Copy move forgery detection (CMFD). It means that part of original image is copied and pasted into another part of the same image. The goal of that type of changes is to hide some image's content, or to multiply the content of digital image. The examples of CMFD are shown on the Figures 1 and 2.

Fig. 1. Copy move forgery detection – example 1.

Fig. 2. Copy move forgery detection – example 2.

In the Figure 1, a part of forest is copied and pasted to hide the content of image (the man from the right side). Another example (Figure 2) where the cats are copied and pasted so we have four cats on the image, instead of two.

The aim of this research is to represent how we can use multinomial logistical regression for image forgery detection. For the prediction, we use the parameters obtained by multifractal processing. The benefits of using these parameters are that there are a few of them and it has been shown that it is enough to do a successful prediction forgery detection [17, 18]. There are enough and we will describe the proposed method below in more details.

III. METHODS

Multifractal Analysis parameters

A)

Fractal Dimension.

Fractals are irregular geometric objects that cannot be sufficiently specified using topological dimensions. Fractal objects are self-similar, i.e., if one zooms in or out the fractal set, its geometric shape has a similar appearance. Fractal sets have theoretical dimensions that exceed their topological dimensions and can be noninteger values. The basic idea is to cover a fractal set with measure elements (e.g. box) at different sizes and examine how the number of boxes changes with respect to the size [14, 15]. If $N(a)$ is the number of boxes that are needed to cover a fractal object with the size a, then the box-counting dimension D_B is defined as:

Natasa Milosavljevic is with State university of Novi Pazar, Vuka Karadzica, 36300 Novi Pazar, Serbia (e-mail: natasaglisovic@gmail.com).

Aleksandra Pavlovic is with School of Electrical and Computer Engineering of Applied Studies, Vojvode Stepe 283, 11010 Vozdovac, Belgrade, Serbia (e-mail: sandra.pavlo@gmail.com).

$$D_B = \lim_{a \to 0} \frac{\ln N(a)}{\ln(\frac{1}{a})} \quad (1)$$

The fractal dimension D_B characterizes the average behaviors of the image profiles via the scaling law, and profiles with different levels of roughness may have the same fractal dimension.

B) Multifractal Spectrum.

The multifractal analysis utilizes a spectrum of singularity exponents to provide a detailed local description of complex scaling behaviors. In order to quantify local densities of the fractal set, we estimate the mass probability in the box centered at x_i of the image as

$$P_i(a) = N_i(a)/N \quad (2)$$

where $N_i(a)$ is the number of mass or pixels in the *i*-th box of size a, N is the total mass of the set and x_i is the center of a box with size a. It may be noted that the scaling of mass probability $P_i(a)$ with box size a of a multifractal set also follows the power law. The multifractal spectrum is estimated as

$$f(\alpha) = \lim_{a \to 0} \frac{lnN(\alpha)}{ln\frac{1}{a}} \quad (3)$$

where $\alpha_i = \alpha(x_i) = \lim_{a \to 0^+} \frac{lnP_i(a)}{lna}$, x_i is the center of a box with size a.

Logistical regression

Let $D = \{(x^n, t^n)\}_{n=1}^{l}$ represent the training sample, where $x^n \in X \subset R^d$ is the vector of input features for the i[th] example, and $t^n \in T = \{t \mid t \in \{0,1\}^c, \|t\|_1 = 1\}$ is the corresponding vector of desired outputs, using the usual 1-of-c coding scheme. Multinomial logistic regression constructs a generalized linear model [9] with a softmax inverse link function [10], allowing the outputs to be interpreted as a-posteriori estimates of the probabilities of class membership,

$$p(t_i^n, x^n) = y_i^n = \frac{\exp\{a_i^n\}}{\sum_{j=1}^{c} \exp\{a_j^n\}} \quad (4)$$

where $a_i^n = \sum_{j=1}^{d} w_{ij} x_j^n$.

Assuming that D represents an *i*-th i *d*-th sample from a conditional multinomial distribution, then the negative log-likelihood, used as a measure of the data-misfit, can be written as,

$$E_D = \sum_{n=1}^{l} E_D^n = -\sum_{n=1}^{l} \sum_{i=1}^{c} t_i^n \log\{y_i^n\} \quad (5)$$

The parameters, ω of the multinomial logistic regression model are given by the minimizer of a penalized maximum-likelihood training criterion,

$$L = E_D + \alpha E_\omega \text{ where } E_\omega = \sum_{i=1}^{c} \sum_{j=1}^{d} |\omega_{ij}| \quad (6)$$

and α is a regularization parameter [11] controlling the bias-variance trade-off [12]. A minimum of L, the partial derivatives of L with respect to the model parameters will be uniformly zero, giving

$$\left|\frac{\partial E_D}{\partial \omega_{ij}}\right| = \alpha \text{ if } |\omega_{ij}| > 0 \text{ and } \left|\frac{\partial E_D}{\partial \omega_{ij}}\right| < \alpha \text{ if } |\omega_{ij}| = 0 \quad (7)$$

This implies that if the sensitivity of the negative log-likelihood with respect to a model parameter, ω_{ij} falls below α, then the value of that parameter will be set exactly to zero and the corresponding input feature can be pruned from the model. Details regarding the parameters can be see in [13].

IV. EXPERIMENTAL RESULTS

The implemented method is evaluated by utilizing the images from publicly available CoMoFoD dataset and Image Manipulation Dataset [16]. This research has implemented the block-based copy-move forgery detection approach. Namely, an image of interest is divided into non-overlapping blocks of different size. For each block, a feature vector is calculated, based on the multifractal spectrum and its parameters. Tested images are of 256x256 resolution, and the size of blocks vary from 8x8, 16x16 to 32x32. The tested images are shown on Figures 3-7. The left image represent original image, shown in the right image represents forgered image. Multifractal spectrum of original and modified images are shown on the Figures 8-12.

Fig. 3. The first pair of tested images (images numerated with I in Table 1).

Fig. 4. The second pair of tested images (images numerated with II in Table 1).

Fig. 5. The third pair of tested images (images numerated with III in Table 1).

Fig. 6. The fourth pair of tested images (images numerated with IV in Table 1).

Fig. 7. The fifth pair of tested images (images numerated with V in Table 1).

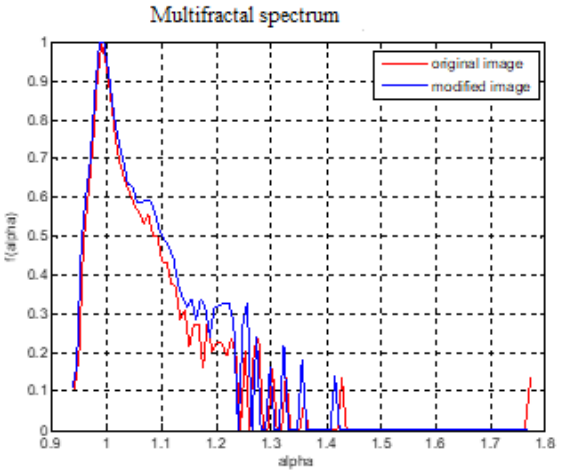

Fig. 8. Multifractal spectrums of original and modified image (image I).

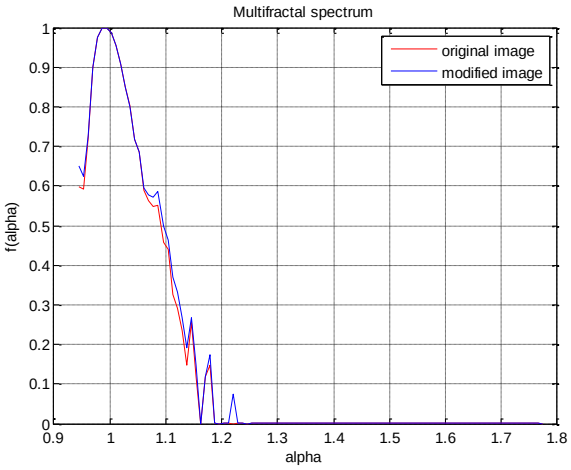

Fig. 9. Multifractal spectrums of original and modified image (image II).

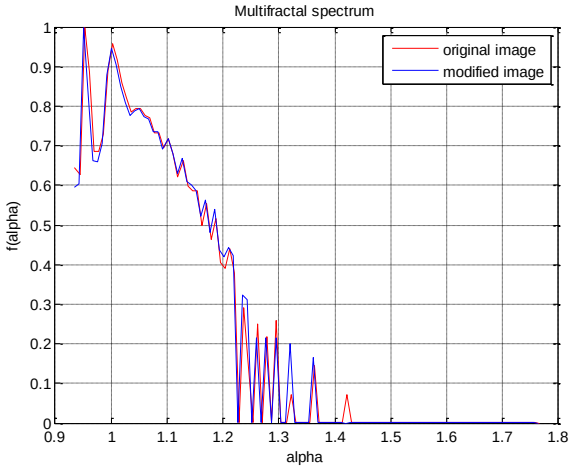

Fig. 10. Multifractal spectrums of original and modified image (image III).

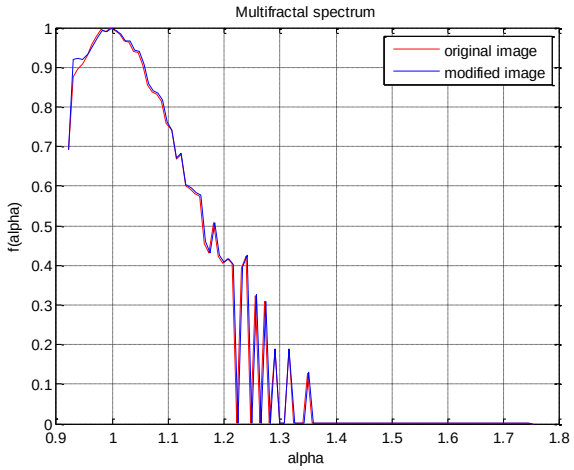

Fig. 11. Multifractal spectrums of original and modified image (image IV).

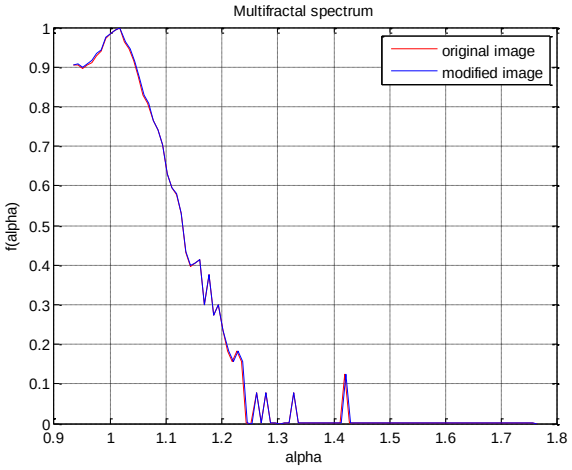

Fig. 12. Multifractal spectrums of original and modified image (image V).

From Figures 8-12, we can see that the spectrum of original and modified images are different. The main differences are in the maximum and minimum value of singularities, the minimum and maximum values of distributions of singularities, the position of the maximum and first zero in multifractal spectrum. So, these parameters are used as elements of characteristic feature vectors of non-overlapping blocks.

After applying the linear multinomial logistic regression, obtained results are shown in Table 1.

TABLE I
EVALUATION OF LINEAR MULTINOMIAL LOGISTIC REGRESSION METHODS OVER A SET OF FIVE BENCHMARK DATASETS (IMAGES)

Benchmark	Error Rate	Cross Entropy	Sparsity
I	0.0213	0.1172	0.0598
II	0.0475	0.2170	0.0691
III	0.1123	0.3661	0.3745
IV	0.2214	0.9412	0.4491
V	0.0142	0.1954	0.0433

Error rate is the error of the prediction model (the smaller it is, the prediction is better). Cross Entropy is the entropy of prediction distribution of outputs and real output. The sparsity is "the scarcity of the model", the scarcity of the model. Namely, in practice, represents how many times when we extend or decrease the test value (which is used to train the regression model). The smaller the value the model is less sensitive.

From Table 1, we can see that the best results are obtained for image I. Namely, as the values of the parameters Error Rate, Cross Entropy and Sparsity are smaller, a minor error of linear regression is achieved. Also, results obtained for other images are very good. The worst results are obtained for image IV (the lower the values of the parameters Error Rate, Cross Entropy and Sparsity, the results are better). The multifractal spectrum of original and modified image IV are very similar (Figure 11), so we get the worst results in parameters of linear regression error.

IV. CONCLUSION

In this paper we have demonstrated that the multifractal approach can be used for multinomial logistic regression. It is interesting to note that the MLR implements a strategy that is exactly the opposite of the relevance vector machine (RVM), in that it integrates over the hyper-parameters and optimizes the weights, rather than marginalizing the model parameters and optimizing the hyper-parameters. In future research we plan to compare this method to other similar method for this problem.

Low cost solution for laboratory class on fundamentals of wireless communication link design

Milutin Nesic[1], Slavica Marinkovic[2], Ivan Pavlovic[3] and Amela Zekovic[4]

***Abstract*—This paper presents inexpensive way for demonstrating concepts and options in wireless link design and deployment for the example of point to point 802.11n link. Students are first introduced to wireless link design by using Radio Mobile software. This simulation is complemented with newly introduced laboratory session that compares results obtained by simulation to results obtained by the link realization in practice with MikroTik wireless device LHG5 with integrated dual polarization grid antenna. During the laboratory sessions students are revising and expanding knowledge on Wi-Fi channels and frequencies, antenna parameters, Wi-Fi modulation and coding schemes, data rates, as well as the impact of wireless channel on the link performance.**

***Index Terms*—Teaching wireless communications; Wi-Fi point to point link; wireless communication link design.**

I. Introduction

The success of 802.11 standard is evident judging by its increasing deployment and applications. This is the widely used family of standards for wireless computer networking used by both commercial and residential users. The most common applications include in-building wireless local area networks, public access hot spots, home networking and wireless bridges. The 802.11 standard denoted by brand name Wi-Fi has evolved quickly and is still under development. The improvement in performance, in terms of data rates and range, has been achieved primarily by employing modern techniques that allow for high spectral efficiency and high data speeds such as the orthogonal frequency division multiplexing (OFDM) and the multiple input multiple output antenna technology (MIMO) [1][2]. This standard is affordable solution to explore and examine principles, concepts as well as certain aspects of practical deployment in wireless communications in general. This would be more complicated in case of licensed microwave links or cellular systems.

In this paper we consider point to point 802.11n link as a wireless link between two buildings that are 3,12 km apart. Wireless point to point link is a cost effective solution easy and fast to deploy in order to connect two locations. The purpose of implementing this link is to complement laboratory sessions on wireless link design and propagation, however the link can be used to send real world traffic between two networks. So far students have been introduced to this topic theoretically and by simulation in Radio Mobile software [3]. The newly introduced demonstration contributes to revising knowledge, expanding it as well as motivating students to learn this subject. This laboratory class is implemented within Mobile Communications course within study program Electronics and Telecommunications at the School of Electrical and Computer Engineering (VISER) in Belgrade. Here we present educational aspects of the use of this link. The choice of equipment, namely MikroTik wireless device LHG5 [4], was motivated by price-performance characteristics. The choice of locations for antennas was also constrained by the position of the VISER School building and the availability of the second site. There is line of sight, however, the environment is dense urban and highly congested.

II. Examining the Radio Link with Radio Mobile Software

In this part of the exercise students first learn how to create Wi-Fi link in the Radio Mobile software. With this software tool it is possible to predict performance of the communication system by using terrain maps (real data) and by defining real characteristics of the elements of the communication system. That is, it is possible to use this program for design and study of the systems implemented in practice. The students are introduced to terminology related to terrain data and then to fundamentals of creating a link such as: defining position of the locations of the communication nodes, defining parameters such as transmitter power, receiver sensitivity, type and height of the antenna and cable losses. They also specify system minimum and maximum operating frequencies. This is done for the example of the implemented point to point Wi-Fi link. Figure 1 shows positions of the transmitting and receiving antennas and the distance in Google maps and Figure 2 shows the same in the Radio Mobile software.

Figure 1. Positions of the transmitting and receiving antennas and the distance in Google maps.

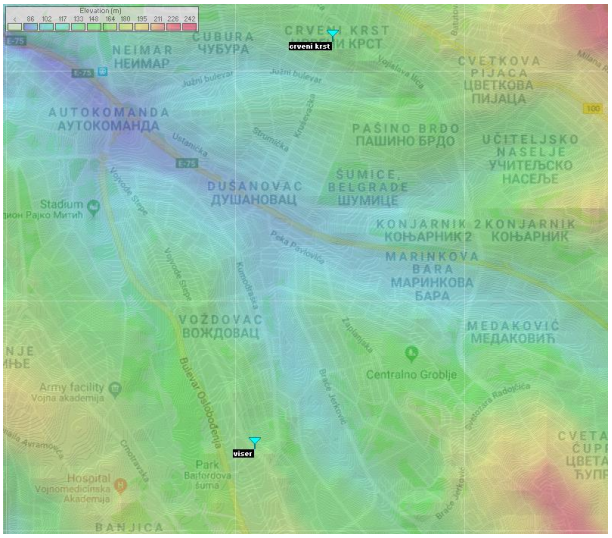

Figure 2. Positions of the transmitting and receiving antennas in Radio Mobile software.

After creating map in Radio Mobile by merging terrain and topographic data and defining positions of transmit and receive antennas, students input into the Radio Mobile program maximum and minimum operating frequencies for the link with band central frequency 5,2 GHz and 20 MHz channel width. Subsequently, they define antenna height. For the next set of parameters students have to consult the datasheet of the MikroTik LHG5 wireless device [4]. They read minimal usable signal level for the modulation and coding scheme (MCS) with binary phase shift keying and convolutional code of rate 1/2, denoted as MCS0, which is −82 dBm. Next required parameter, transmitter output power for MSC0, is taken as the minimum output power which is measured (read) from the antenna and is equal to 22 dBm. Antenna gain is obtained from the manufacturer's documentation and in this case is 24 dBi. Antenna radiation patterns are also downloaded from the manufacturer's website and processed so that the format is matched to one required by the Radio Mobile software. The standard 802.11n allows the use of multiple chains (antennas). MikroTik LHG5 wireless device uses multiple chains on a single dual polarized antenna. This is the way to realize MIMO processing which improves the system performance. The horizontal and vertical radiation pattern for chain 0 that are used in the simulation are shown in Figure 3, and 4 respectively.

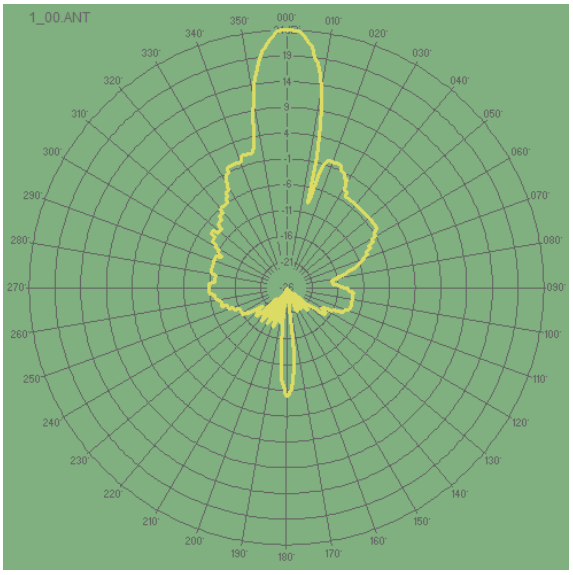

Figure 3. The horizontal radiation pattern for chain 0.

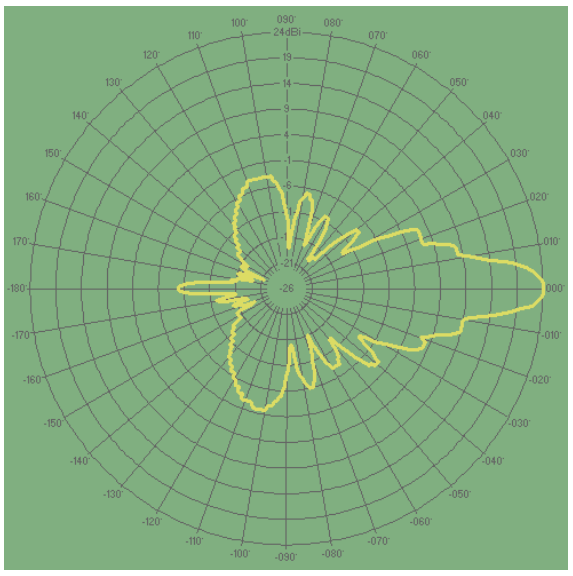

Figure 4. The vertical radiation pattern for chain 0.

The results of the simulation are shown in Figure 5. Radio Mobile uses digital terrain data for automatic extraction of

path profile between a transmitter and a receiver. Students read the predicted path loss and the received signal strength, which are 125,3 dB and −56,3 dBm, respectively. They observe Fresnel zones denoted with white color ellipses with the line of sight denoted in green color in Figure 5. In this simulation we have taken into account only terrain profile, that is only elevation of Earth surface and the default values for the clutter in urban environment and not the detail impact of the ground objects on the RF propagation.

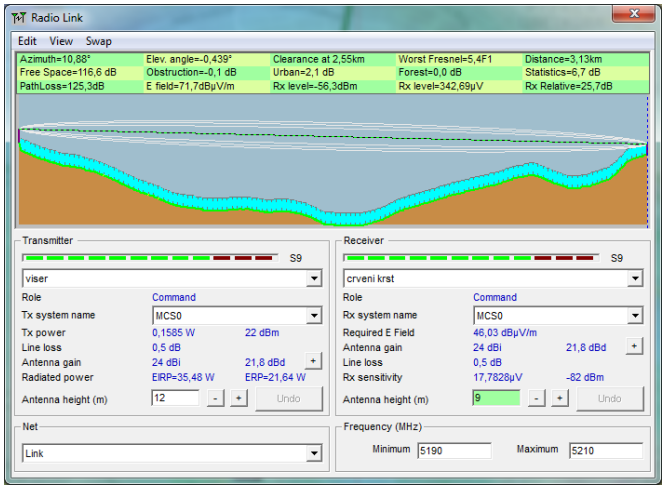

Figure 5. The results of the simulation in Radio Mobile software.

III. EXAMINING THE IMPLEMENTED RADIO LINK REALIZED USING MIKROTIK WIRELESS DEVICE LHG5

In this part of the exercise students get hands-on experience with the realized link in practice.

They observe the antenna mounted on the outer wall of the Electronics and Telecommunications laboratory (Figure 6).

The antenna is in fact compact and light 5 GHz 802.11 a/n wireless device with an integrated dual polarization 24,5 dBi grid antenna. The fact that the antenna element is tightly coupled with compact enclosure of the integrated microwave transmitter/receiver of the equipment means no loss of RF signals on cables [4].

Students further get acquainted with necessary cabling to connect the wireless device and a laptop that contains MikroTik software for configuring link parameters and reading measured parameters from the wireless device. The software tools that are used are Router OS and its GUI version WinBox. The power is supplied by Power over Ethernet (POE) technology that lets network cables carry electrical power.

The initial configuration of the point to point link means that students define central frequency and bandwidth of communication system, as well as wireless protocol and standard wireless network configuration in order to establish the link.

Here we omit initial configuration details of the point to point link and examine just the impact of changing parameters on the performance of the link.

In order to first examine spectral congestion at 5 GHz students first use MikroTik software Dude to perform spectral scan. The spectral scan for the locations of the two antennas are shown in Figure 7 and Figure 8. From the results it can be concluded that the level of interference is high. Several bands with least interference were tested, and 5,2 GHz frequency band was selected. For this part of the exercises the link was not established, because wireless device cannot scan spectrum and maintain link at the particular frequency at the same time.

Figure 6. Antenna mounted on the outer wall of the Electronics and Telecommunications Laboratory.

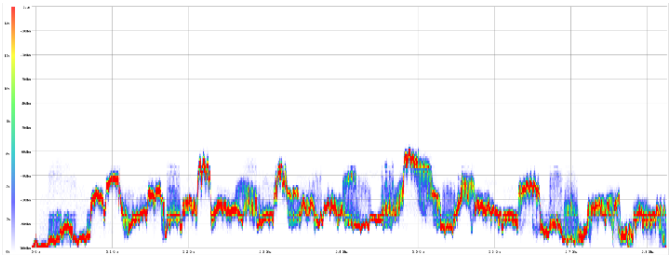

Figure 7. The spectral scan for the location VISER.

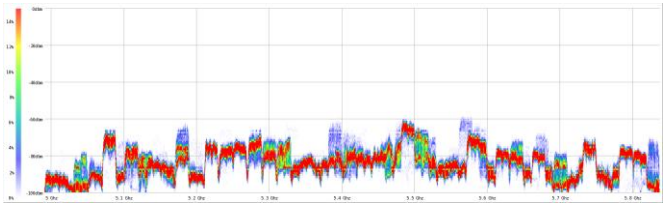

Figure 8. The spectral scan for the location Crveni Krst.

After spectral scan the link is established and students configure wireless device so that modulation and coding scheme MSC0 is active on both chains 0 and 1 and that transmitting power is 22 dBm in each chain. MCS0 is defined in table I. In this part of the exercise the same data is sent on both chains. The results are shown in Figure 9 and Figure 10 .

It can be seen that the received signal strength is −57 dBm. This is comparable with simulation results, although simulation did not consider multiple transmission chains. Students observe that signal strength on individual chains is lower than resulting signal strength, that is the resulting received signal strength is higher due to use of dual chains. They can observe bitrate which is 5,6 Mb/s. The bitrate is measured based on the bandwidth test in the wireless device which uses UDP protocol for estimating bitrate.

The students further change modulation and coding schemes and observe bitrate and received signal strength. The results that are obtained are compared to 802.11n specifications. This is shown in Table I. Table contains information on modulation and coding scheme (MCS) and measured values obtained in our experiment. It is not possible to change MCS completely independently, because wireless device we use dynamically switches to lower modulation scheme in case of change in conditions.

TABLE I
MODULATION AND CODVING SCHEMES AND BITRATE

MSC	Modulation	Coding	Data Rate [Mbps]
0	BPSK	1/2	5,6
1	QPSK	1/2	11,2
2	QPSK	3/4	16,9
3	16-QAM	1/2	22,7
8	BPSK	1/2	10,9
9	QPSK	1/2	22,8
10	QPSK	3/4	33,8
11	16-QAM	1/2	45,4

From the results shown in Table I students can observe that for modulation and coding schemes MSC8 to MSC11 different information is sent on different chains which leads to doubling the bitrate.

Second experiment consists in changing transmit signal power and observing received signal strength, as well as, observing how the modulation and coding scheme changes. The results are shown in Table II.

TABLE II
SIGNAL POWER, RECEIVED SIGNAL STRENGTH, DATA RATE AND MODULATION-CODING SCHEME

Power [dBm]	RSSI [dBm]	Data Rate [Mbps]	MCS
22	-57	22,7	3
10	-70	22,7	3
4	-75	20,7	3
2	-80	10,4	1
1	-81	5,6	0

It can be noted that, as transmit power decreases, the received signal strength decreases. Also the modulation and coding scheme is changed dynamically. It can be observed that dominant MCS is that of lower order modulation and higher rate error control coding scheme for the lower transmit signal powers.

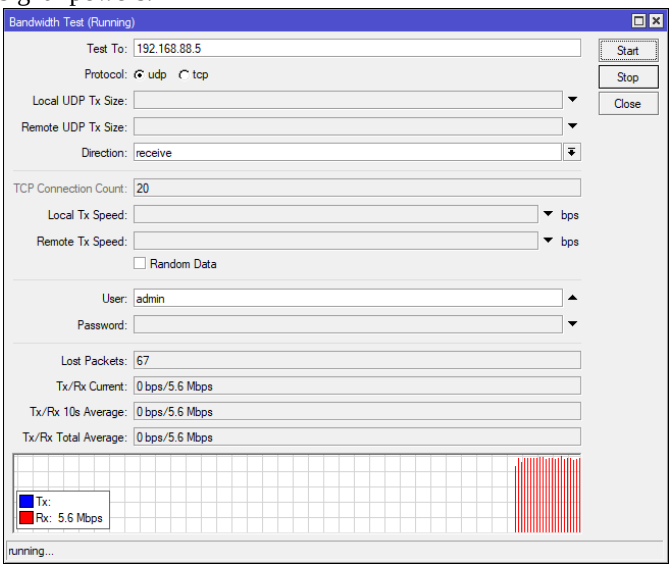

Figure 9. Bitrate obtained by experiment in the field.

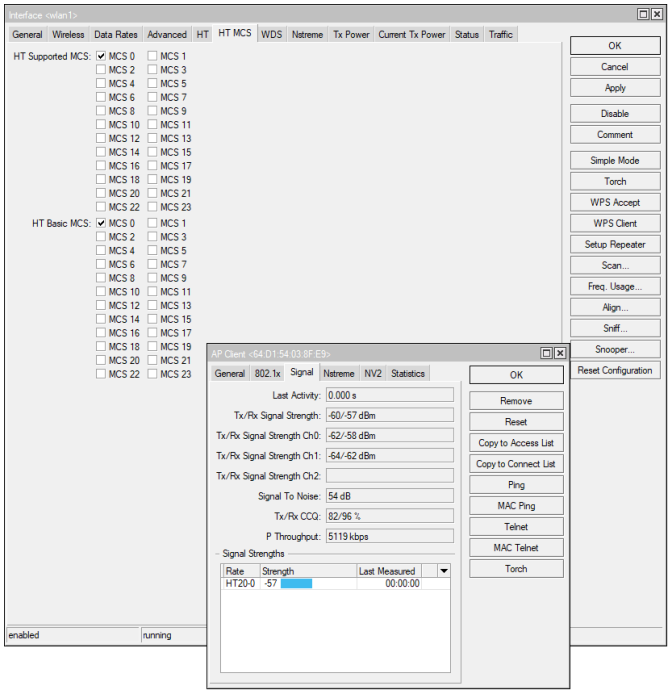

Figure 10. Received signal strength obtained by experiment in the field.

IV. CONCLUSION

The paper presents use of the simple low-cost point to point link for enhancing practical teaching of physical layer aspects of wireless communications. In particular, we have first focused on teaching students about basic elements of wireless system and their parameters such as transmitter and receiver locations, radiated power, frequency, and antenna pattern by simulation in Radio Mobile software. Then we have built on this by teaching students how to set up point to point Wi-Fi link with MikroTik wireless device LHG5. The students had opportunity to examine hardware and software necessary for setting up the link, however, the emphasis was on observing

impact of changing parameters such as modulation and coding scheme on the link performance, as well as demonstrating path loss results obtained by the simulation. The enhancement of teaching and learning process is achieved by engaging students into real world example that apply outside the lab.

Healthcare IoT Monitoring using Photoplethysmography

Milan S. Milivojević, *Student Member, IEEE,* Ana Gavrovska, *Member IEEE,* Irini Reljin, *Senior Member, IEEE* and Branimir Reljin, *SeniorMember, IEEE*

***Abstract*—The Internet of Things (IoT) has offered a variety of different possibilities for healthcare applications and systems. Information and communication technologies (ICT) and high quality micro- and nanoelectronics enable novel solutions based on body area networks for collecting valuable data describing vital signs of humans. In this paper a system for monitoring some vital parameters described by photoplethysmogram (PPG) signals is described. The system is based on low-cost Arduino platform and appropriate sensors. Heart rate is monitored and compared for telemedical and e-health purposes, showing differences between chosen PPG features in physical domain. For this task, a Python based graphical user interface has been developed. Finally, PPG has been compared in counting backwards experiment, where an increase of the selected feature values is obtained due to a cognitive load.**

***Index Terms*— photoplethysmogram, heart rate, internet of things (IoT), cognitive test, graphical user interface.**

I. Introduction

Photoplethysmography (PPG) is an optical measurement technique that can be used to detect blood volume changes in the microvascular bed of tissue [1]. It is widely used in clinical practice with commercial medical devices. The most prominent example is the pulse oximeter used for measurement of the blood saturation by oxygen (SpO2), as well as a heart rate [2]. This technique is used in vascular diagnostics, i.e. estimation of microcirculation. It is also used in digital beat-to-beat devices for blood pressure measurement [3][4].

PPG pulsed current corresponds to alternating component with the fundamental frequency related to the heartbeat of around 1Hz. Pulsating DC (DC-Direct Current) is a consequence of the tissue processes and blood volume changes. The envelope of this quasi-direct component is influenced by processes such as: respiration, vasomotor activity, thermoregulation, etc. The components can be extracted by appropriate signal processing techniques depending on the analyzed phenomenon [5].

The basic architecture of PPG device includes several optoelectronic components: light source used for the tissue (skin surface) illumination, and photodetector for detection of small variations of light rays intensities penetrated in the skin. Variation of the light intensities is a consequence of blood volume change within the tissue (fingertip, earlap/earlobe, etc.). PPG is usually recorded according to non-invasive procedure. Wavelengths used for PPG acquisition correspond to infrared (IR) spectrum part. The most prominent component of the PPG signal is the peripheral pulse synchronized with each heartbeat. Despite the simplicity of the PPG technique, the origin of all of its components is still not known. However, PPG is established as a justified technique for the cardiovascular examinations [6]. Beside commercial applications in medicine, PPG is also used in smart devices, like: fitness smart watches, fitness bracelets or headphones, for providing useful information to professional and recreational athletes during physical activities [7].

Different signals can be monitored using body area network (BAN), where heart rate (HR) is usually of interest. HR is measured by counting the number of heart beats or contractions per minute. PPG can be also used for HR estimation. It represents one of the vital signals and can be measured if appropriate sensor is available. Namely, PPG can be implemented in Internet of Things (IoT) systems for telemedical, i.e. e-health applications [8]. Data is collected from the sensors, and further processed and presented on the Cloud according to physicians' or patient's demands. Information and communication technologies (ICT) in telemedicine enable developing simple, but efficient systems for healthcare

In this paper we present simple system for acquisition of PPG signal using low-cost sensor and Arduino open source platform. We demonstrate PPG acquisition using developed graphical user interface (GUI). The PPG is processed and the HR is estimated. Moreover, we illustrate the influence of the subject cognitive activity on the estimated parameters during the acquisition.

The organization of this paper is as follows. In Section II, typical PPG signal is described. Section III is dedicated to the HR estimation based on PPG signal. Details on data acquisition and the Arduino based system are provided in Section IV. The simulation description is given in Section V, and the obtained experimental results are presented in Section VI. Finally, conclusions are summarized in Section VII.

II. PPG Signal Morphology

Typical photoplethysmogram (PPG) is proportional to the quantity of blood flowing through the blood vessels. It is used to asses blood flow in skin, muscle and bone tissue. It

Milan S. Milivojević is with the School of Electrical Engineering, University of Belgrade, Bulevar kralja Aleksandra 73, 11120 Belgrade, Serbia (e-mail: msmilance@etf.bg.ac.rs).

Ana Gavrovska is with the School of Electrical Engineering, University of Belgrade, Bulevar kralja Aleksandra 73, 11120 Belgrade, Serbia (e-mail: anaga777@etf.bg.ac.rs, anaga777@gmail.com).

Irini Reljin is with the School of Electrical Engineering, University of Belgrade, Bulevar kralja Aleksandra 73, 11120 Belgrade, Serbia (e-mail: irini@etf.bg.ac.rs, irinitms@gmail.com).

Branimir Reljin is with the School of Electrical Engineering, University of Belgrade, Bulevar kralja Aleksandra 73, 11120 Belgrade, Serbia (e-mail: reljinb@etf.bg.ac.rs).

consists of constant-level DC related to the relative tissue vascularization and pulsatile component syncronous with heart pumping. The DC variation occurring is a consequence of cardiac synchronous changes in blood volume in arterial blood vessels. Change is synchronized with heart beats and directly affects the light that falls on the tissue, or the reflected wave. The superposition of direct and reflected waves results in the characteristic morphology of the PPG signal (Fig. 1). The PPG signal has two phases: the anacrotic phase and the catacrotic phase [9].

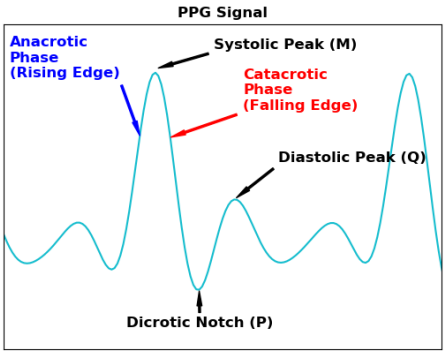

Fig. 1. The PPG signal morphology.

The anacrotic phase corresponds to an increase of the signal amplitude (rising edge) and is associated with a systole (contraction of the heart muscle). Thus, the maximum in this phase is called the systolic peak, and it is denoted by M. The time interval between M peaks defines the MM interval. This interval is strongly correlated with RR intervals in the electrocardiogram signal. Therefore, it is directly related to heart rate variability (HRV) [10][11].

The catacrotic phase is the phase of decreasing the impulse amplitude (falling edge). It is associated with the diastole (relaxation of the heart muscle). Diastolic peak is designated as the Q peak in PPG. Before the diastolic peak occurs, a minimum or dicrotic notch (P point) occurs (P point corresponging to PPG morphology). This point may be missing, and instead of the minimum, it appears as an inflection point.

III. PPG Heart Rate Estimation

PPG signal can be used for HR estimation. Each pair of successive M peaks in PPG defines the MM interval. Within each MM interval, the positions of the P and Q points corresponding to the PPG morphology, are found as the local minimum and maximum, respectively. In this way, both PP or QQ intervals are defined [12]. The HR value in bpm (beats per minute) is defined as the reciprocal value of the MM interval scaled with 60:

$$HR_{MM}\left[bpm\right]=\frac{60}{MM\left[s\right]}. \tag{1}$$

Similarly, it can also be defined as:

$$HR_{PP}\left[bpm\right]=\frac{60}{PP\left[s\right]},\ HR_{QQ}\left[bpm\right]=\frac{60}{QQ\left[s\right]} \tag{2}$$

on the basis of the other two intervals. Since the number of beats per minute is of integer type, HR is rounded up to the nearest integer value. On the basis of these values, dependency diagram of HR in time can be formed.

The values calculated by all three methods ((1)-(2)) are similar so that each approach is valid. In the literature, however, the use of the HR calculation based on the MM interval is common. The reason lies in the fact that M peak is dominant in the morphology of the PPG signal (similarly as in electrocardiogram). Thus, M peak detection is easier to perform [13]. The remaining two points can be more difficult to detect, especially in the case where P is not pointed out. Therefore, HR calculation based on M peak can be taken as a reference. Root mean square error (RMSE) for HR calculated on the PP interval is:

$$\varepsilon_{PP}=\sqrt{\frac{1}{N}\cdot\sum_{i=1}^{N}\left(HR_{PP}-HR_{MM}\right)^2} \tag{3}$$

where N is equal to the length of estimated HR sequence (number of samples). Similarly, estimation error can be performed as:

$$\varepsilon_{QQ}=\sqrt{\frac{1}{N}\cdot\sum_{i=1}^{N}\left(HR_{QQ}-HR_{MM}\right)^2} \tag{4}$$

where QQ interval is observed.

HR values are averaged over a certain number of consecutive values to give accurate estimation results. For this purpose a moving average (MA) filter can be applied:

$$\overline{HR_{MM}}\left[n\right]=\frac{1}{L}\cdot\sum_{k=0}^{L-1}HR_{MM}\left[n-k\right] \tag{5}$$

where L is a length of the window where the averaging is performed.

In the literature, there are many types of features that can be distinguished from the PPG signal. However, they seem not to be completely standardized yet, as is the case with the ECG signal. They can correspond to different domains (time, frequency, etc.). The easiest way to describe the PPG morpohology for HR estimation is to use the original, time domain [14].

IV. IOT SYSTEM AND DATA ACQUSITION

The Arduino based sytem for PPG heart rate estimation is shown in Fig. 2. For the acquisition of pulse waves we used Pulse Sensor Amped [15]. The front of the sensor is the side with the Heart logo. This side contacts the skin. Also, there is a LED (Light Emitting Diode). Under the LED ambient light sensor exists, exactly like the one used in cellphones, tablets or laptops, to adjust the screen brightness in different light conditions. The LED shines light on the skin (the fingertip or earlobe, or other capillary tissue), and sensor measures the light reflection. Since the positions of the light source and the photodetector are on the same side, the reflexive operation mode is used (otherwise transmitting mode can be used) [16].

Sensor has three ports corresponding to: positive potential of +3.3V or 5V (+Vcc), ground (GND), and signal line (S). Sensor is connected to open source Arduino Uno platform. From the sensor, signal is collected on the analog input A0. Analog part also provides power supply of the sensors. Analog-to-digital conversion is conducted with 10 bits. Arduino Uno is connected to PC using USB A/B cable, where digital data is conducted to PC over serial port. The program loaded to Arduino reads the data from the sensor and forwards it to serial port. Data signaling rate is 9600

symbols/s. The time interval between two successive samples is 10ms, and it defines the sampling frequency of 100 Hz. The sensor is positioned on the subject's forefinger of the right hand.

During the acquisition, it is important to avoid abrupt movements and changes of the pressure on the sensor's surface in order to minimize artefacts in the collected data. The room used for acquisition is soundproofed and its temperature is approximately 25°C.

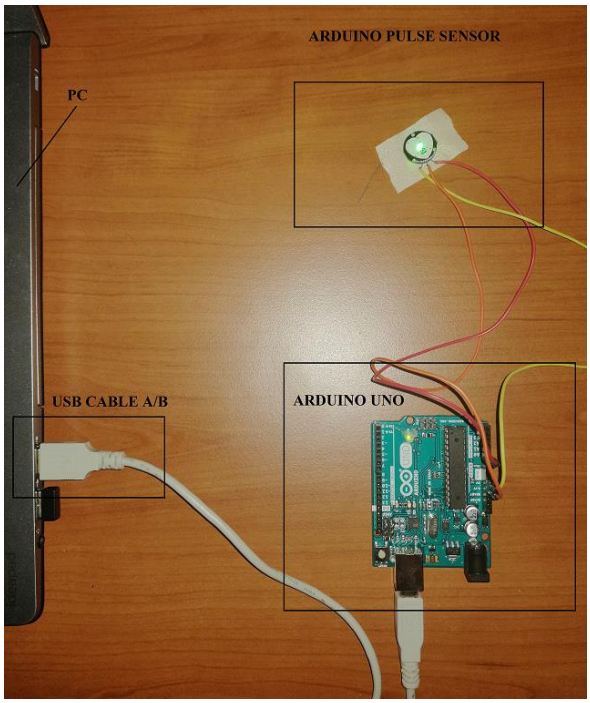

Fig. 2. The Arduino based sytem for PPG heart rate estimation.

V. Simulation

The simulation was performed using the Arduino based system for PPG heart rate estimation. Collected signals are processed within the Python environment. For this purpose, we used libraries for signal processing from the package SciPy.

Raw PPG signal may contain artefacts caused by movements during acquisition or changes of sensor pressures on the skin. In order to deal with artefacts, we used Butterworth bandpass (1-5 Hz) filter of the 4th order for preprocessing. Filtering is conducted forward and backward, therefore the delay can be neglected. This also reduces variation of the base line of the signal, 50 Hz power supply noise, as well as the artefacts caused by movements [17].

Filtered PPG signal is normalized so that the value of the samples belongs to the interval [0,1]. After normalizing the PPG signal, the detection of M peaks is made using methods from publicly available Python libraries. A stepwise form of the display is used so that the duration of each MM interval is appended to the HR value according to the expressions (1)-(5). The error values are calculated for 3 and 5 beats per minute (rounded to the nearest integer).

Continuous depiction of HR is a starting point for applications where HRV analysis is performed, similarly as in the case of ECG signal [18]. For this purpose we realized graphical user interface (GUI) for PPG signal acquisition in program package Python3.6.

An experiment was performed involving a cognitive test. A ninety seconds long recording was acquired, where the central 60s of the signal have been taken for further analysis. Particularly, recording is performed in two iterations, where the first one represents a calm state and the other state is realized during the exercise of mental activity. The subject in both cases is sitting.

Mental exercise involves counting even numbers backwards in a quiet speech manner (counting backwards from one hundred to one). Counting is performed until the recording time expires. The collected signals are filtered and characteristic M peaks are detected. Based on the detected M peaks and determined MM intervals, P and Q points are detected. Then, the amplitudes corresponding to the time positions of M, P and Q are determined. The mutual relations of these amplitudes define two types of features. The amplitude of M peak is taken as a reference for the remaining two amplitudes [19]. The relative amplitude ratio AR_{MP} is defined as:

$$AR_{MP} = \frac{A_P}{A_M} \cdot 100\% \tag{6}$$

where A_P and A_M are minimum values that correspond to the dicrotic notch and the systolic peak, respectively. A relative amplitude relation AR_{MQ} is defined as:

$$AR_{MQ} = \frac{A_Q}{A_M} \cdot 100\% \tag{7}$$

where A_Q corresponds to the diastolic maximum value. These values are calculated for each interval and define one point in the scatter diagram, which is used to present the cognitive load effect.

VI. Experimental Results

A. Heart Rate Estimation results

Fig. 3 shows raw PPG signal acquired from the sensor, as well as PPG signal after filtering. Averaging is carried out at the window of five samples. Larger window lengths lead to greater error in the case of sudden changes in pulse.

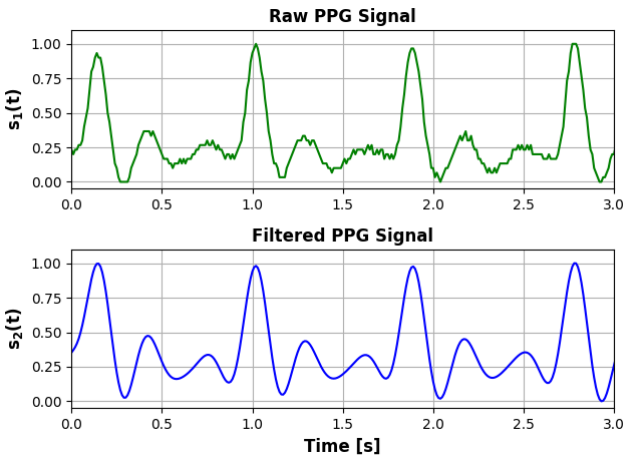

Fig. 3. Raw and preprocessed PPG signal acquired from the sensor.

Characteristic points of PPG signal are detected and presented in Fig. 4. The corresponding amplitudes are used for HR estimation.

A continuous presentation of the HR change in time is given in Fig. 5. Namely, Fig. 5 shows HR calculations based on MM, PP and QQ intervals, respectively. This leads to obtaining the instantaneous heart rate (IHR). Moreover, Fig. 5 shows the original HR and HR after filtering for the case when the assessment is performed based on the MM interval.

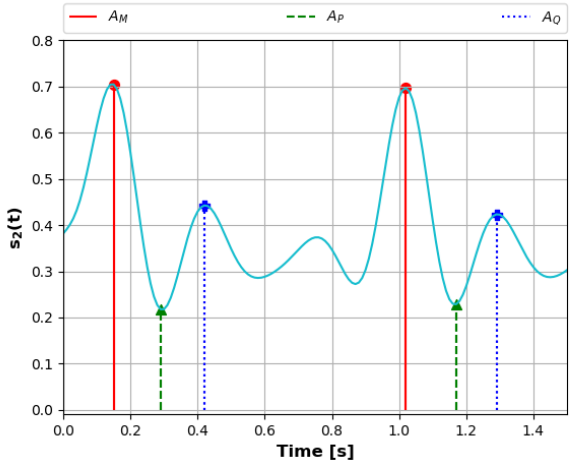

Fig. 4. Detected points and corresponding amplitudes for HR estimation.

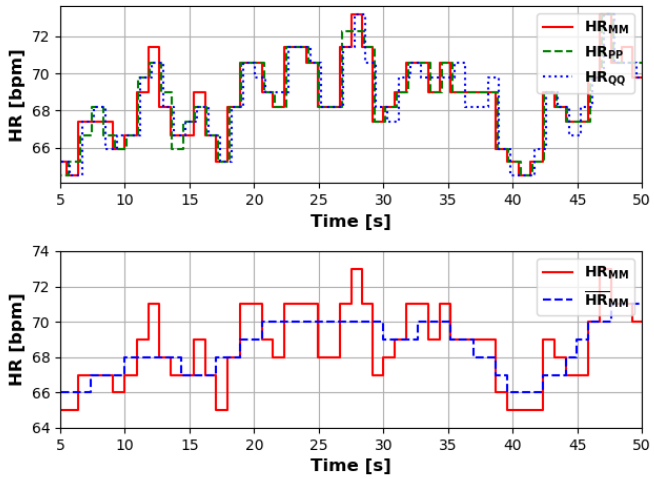

Fig. 5. Calculated HR values based on MM, PP and QQ intervals, as well as a comparative view of the original and the averaged HR based on the MM interval.

B. GUI developed for PPG analysis

In Fig. 6 developed graphical user interface for PPG signal acquisition is presented. The panel for data acquisition shows the main buttons.

Button CONNECT enables connection to Arduino microcontroller over serial port on PC. Besides the automatic serial port search, activation of this button finds the communication speed. After successful connection, the label of the used serial port is displayed in the appropriate panel. Command TEST starts the signal acquisition for 5s and the signal is afterwards shown in the graphical panel. If the signal is of adequate quality, by pressing RECORD button a user can record the signal. It also enables the user to enter the date of acquisition. User chooses the location where the record is saved. Several file extensions for records are provided: *Python* file (.npz), *Matlab* file (.mat), textual file (.txt). Command LOAD loads saved files into the program interface and displays the signal in the graphical interface. Button QUIT is for exiting the program.

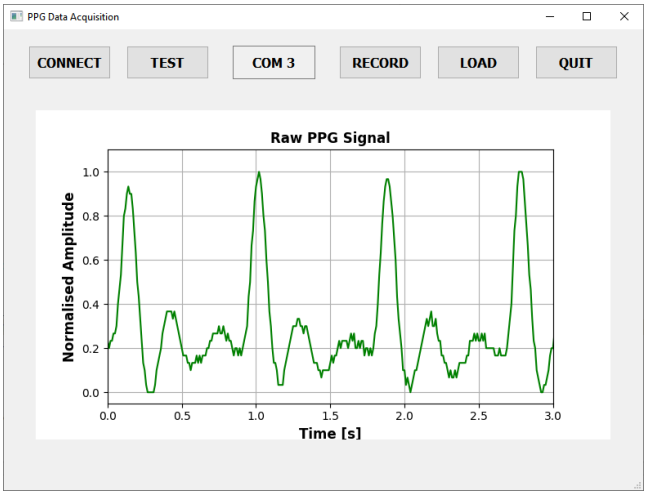

Fig. 6. Panel for acquisition of the PPG signal.

C. Cognitive influence results

The scattering in Fig. 7 presents the feature values before the cognitive experiment (blue dots in Fig. 7). The same procedure is repeated in the case of a mental exercise (red crosses in Fig. 7). A change in two phases is obvious. In the cognitive load there is a significant level of dispersion in the characteristics. The relative amplitude ratio values are greater during the mental exercise.

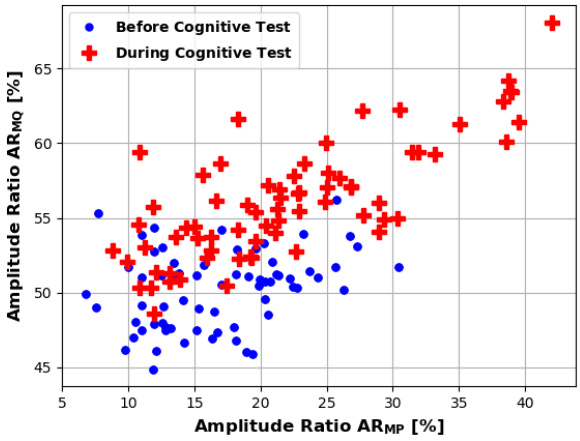

Fig. 7. Diagram of amplitude based scattering corresponding to the PPG signal before and during the cognitive load.

VII. Conclusion

This paper presents IoT system, based on the open source platforms, for telemedical (e-health) applications. The system uses PPG sensor. Graphical user interface for BAN acquisition has been developed, which can be supplemented with new features such as a PPG signal analysis block. The price of this implemented system is very low, and represents a good starting point for the use of PPG in IoT systems.

Despite the low price of realized device, the acquired signal is of good quality, and it is possible to evaluate the set of parameters that represent the condition of patients and

people who are engaged in physical activity. Amplitude features are clearly distinguished and used for calculating the adequate amplitude-based ratio at characteristic locations. The influence of cognitive load on the amplitude based values is also illustrated.

In further work, we plan to record a larger set of signals under different stress conditions, as well as to define new features in different domains that could be helpful in the healthcare systems.

DASH video user interface based on GPU background subtraction and OpenCL C++ framework

Katarina Popović, Ana Gavrovska, *Member, IEEE,* Irini Reljin, *Senior Member, IEEE*

***Abstract*—The media delivery over the Hypertext Transfer Protocol (HTTP) got extremely popular over the years. Dynamic Adaptive Streaming over HTTP (DASH) provided the adaptive multimedia delivery utilizing a chunk based approach. In this paper vision based user interface has been developed enabling the analysis of media presentation description files, as well as the implementation of fundamental steps for video processing such as background subtraction. This is enabled by OpenCL C++ framework. The obtained experimental results show advantages of GPU computing over CPU where 30% less processing time is needed for high resolution video.**

***Index Terms*—Video, MPEG-DASH, parallel processing, background subtraction, GPU, OpenCL.**

I. Introduction

Content delivery networks (CDNs) are oriented toward delivering video services for communication and entertainment purposes. They are changing under the internet pressure due to video consumption [1]. Broadband video delivery has experienced exponential growth over traditional broadcasting systems, where video represent a huge part of communication and IP (Internet Protocol) based traffic. VoD (Video- On-Demand) services, OTT (Over-The-Top) services, popular platforms (Netflix, Youtube, Vimeo, etc.), real-time video conferencing (Skype, Viber, etc.) contribute to the changes. Information-centric networking (ICN) has been proposed to support high quality video services and streaming [1], where a multimedia standard such as MPEG-DASH is being helpful [2]. Dynamic Adaptive Streaming over HTTP (DASH) provides the adaptive multimedia delivery utilizing a chunk based approach, standardized by MPEG (Motion Picture Experts Group) [2, 3]. Namely, the packets are sent over HTTP (HyperText Transfer Protocol) in adaptive manner according to network's conditions, where HTTP traffic has reliable transfer infrastructure [4]. DASH enables interoperability between servers and clients from different vendors and high quality multimedia streaming over the Internet delivered from conventional HTTP web servers. The MPEG-DASH Media Presentation Description (MPD) is an XML document containing information about media segments [2]. It provides information needed for decoding and streaming [4-7]. One the most relevant technologies is Software Defined Networking (SDN) making the application-centric intelligent routing strategies, providing high quality services to DASH clients [4].

With growing popularity of video content, need for real-time video processing appeared. Since video processing is very demanding, parallel programming became inevitable. The need for high speed computing popularized parallel approaches [8-10]. Parallel programming uses heterogeneous hardware, processing on CPU (*central processing unit*), GPU (*graphic processing unit*) and other processing units.

Modern GPUs have wide use not only in image processing and computer vision, but also in machine learning and big data analysis, because of their ability to execute tasks in parallel (much faster than CPU) [3, 8-12]. They are inevitable part of smart devices and are used for mobile and video services. Today we have plenty of different kinds of servers and user devices (clients) with need to effectively communicate with each other. In video processing generally, video surveillance and object tracking, the first task is usually performing background subtraction or to extract foreground from background [9-14]. Thus, the background subtraction methods are applied in this paper for experimental analysis using OpenCV and OpenCL [15-16].

In this paper graphical user interface (GUI) has been developed for streaming and processing video using DASH data. Here, two methods for background subtraction are compared (Gaussian mixture model and k-nearest neighbors) [13-15], based on computing time (clock time) and selected processing unit (CPU/GPU). The analysis is performed to test the advantages of GPU approach. For coordination of processing units OpenCL C++ framework is used.

The paper is organized as follows. After the introduction, a brief explanation regarding MPEG-DASH standard and DASH data is given in Section II. Video processing using OpenCV and OpenCL is described in Section III. The details regarding the simulation performed in this paper are explained in Section IV. The obtained experimental results followed by discussion are presented in Section V. Finally, the conclusion is given in Section VI.

II. MPEG-DASH STANDARD AND DASH DATA

DASH, known also as MPEG-DASH, represents an adaptive bitrate streaming technique over the Internet delivered from conventional HTTP web servers [2-3, 5]. It is based on breaking the content into a sequence of HTTP-based file segments (chunks). Moreover, the content is made at different bitrates enabling the adaptive approach depending on the network conditions.

Content distribution architecture based on MPEG-DASH standard consists of four main parts: media capture and encoding, media origin servers, HTTP cache server and user devices. Content is stored on servers in form of media presentation, which can be related to video or audiovisual content and/or other data described by appropriate description (metadata). Thus, besides the media segments, there is a Media Presentation Description (MPD) [2, 4-7]. After TCP connection with server is established, a client first downloads MPD file. Based on information given in MPD, network state and users requests (or device characteristics), a client selects appropriate segments. Static MPD is used when the content is stored like in VoD applications, whereas dynamic MPD is used for live streaming or PVR (Personal Video Recorder) applications.

MPD is XML document that provides information about available segments. Hierarchical structure of DASH data, i.e. MPD file, is shown in Fig.1.

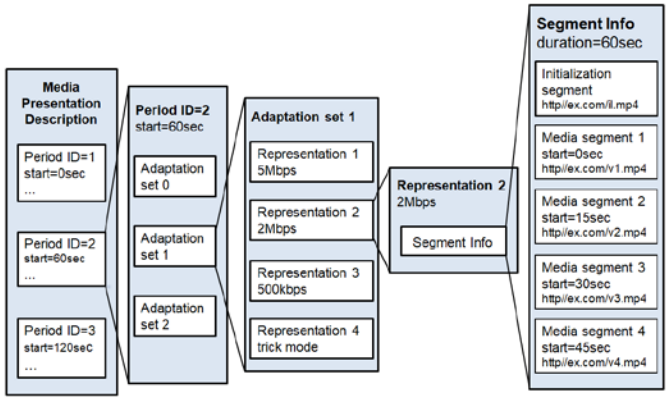

Fig. 1. Hierarchical structure of MPEG-DASH data.

MPD is divided according to time periods. One time period has multiple adaptation sets. Adaptation sets define different content (e.g. audio, video, text). One adaptation set has multiple representations. They represent the same content with different encoding or bitrates. Representation gives information about segments, their ID, location, beginning time and duration (that could be given implicitly or explicitly). First segment is usually initialization segment, and gives to the client information necessary for decoding.

For generating MPD (manifest) file in this paper MP4Box [17] is used. MP4Box is a multimedia packager that enables preparation of HTTP adaptive streaming content, and can be used for many manipulations on multimedia and ISO (International Organization for Standardization) files, like MP4.

DASH represents both media and delivery information. By parsing the manifest a DASH client should be able to reproduce the content. MPEG-DASH implementation is presented in Fig.2, where communication between Content Server and DASH Client is illustrated.

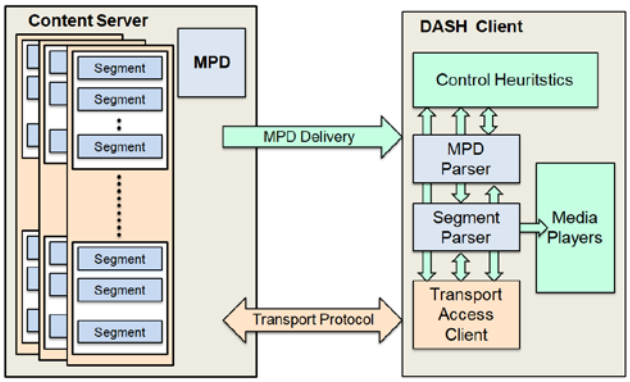

Fig.2. MPEG-DASH implementation in communication between Content Server and DASH Client.

III. VIDEO PROCESSING BASED ON OPENCV AND OPENCL

During video content analysis, motion analysis and object tracking are mostly performed. The popular cross-platform open source library for computer vision and machine learning OpenCV (Open Source Computer Vision Library) [15] contains modules providing common infrastructure for video application and service development.

One of the common tasks during video content or frame based analysis represents the background subtraction [9-12]. It represents a way to extract the moving foreground from the relatively static background and analyze motion within video sequence. Foreground modeling is usually more computationally demanding and more challenging due to the change of relevant pixel locations [11].

In this paper, for the purpose of testing two background-subtraction algorithms are used. Both of them combine statistical background image estimation and pixel-level Bayesian segmentation. One algorithm is based on GMM (Gaussian mixture model), whereas the second one represents knn (k-nearest neighbors) background subtraction [13-15]. If a pixel is adequately described by the predefined probability, the pixel can be considered as a part of background. GMM based method uses the assumption of initial state for probability description in comparison to knn based on the fixed number of frames [3, 13]. The mixture weights represent the time proportions of the colours that are more probable and stay longer within the scene. This is suitable for real time processing. Here, the methods are implemented using the default parameters [15], where their setting was not a part of this study.

A. OpenCL C++ framework

OpenCV [15] is used for image and video processing, while OpenCL (*Open Computing Language*) [16] is open source framework for hardware code accelerations. OpenCL C++ framework is used in this paper. OpenCL provides API (*application programming interface*) for coordination of code execution on heterogeneous processors [16].

OpenCV has a module dedicated to OpenCL [15-16]. In previous versions this was separate module, but from version 3.0 it is a part of core module. *Umat* (Unified matrix) class/type is introduced enabling rewriting data from one memory to another. It tells OpenCV functions to process data with OpenCL which may use OpenCL-enabled GPU or CPU otherwise. Algorithms that were implemented in *ocl* module are retained. This relatively new type enabled writing unique code that could run on both CPU and GPU or any other OpenCL device. Device/hardware selection for code executing is done by using instruction *ocl::setUseOpenCL(bool).* If it is set to false, the code will be executed on CPU, otherwise it will be executed on GPU or other OpenCL device, using parallel processing.

IV. Simulation

In the first step test video sequence is converted into several formats (five different spatial resolutions), encoded with H.264 with different bitrate. This is performed using ffmpeg [18], as in case of 160x90 video (the example of code line is shown below).

```
ffmpeg –i input.mp4 –s 160x90 –c:v libx264 –b:v 250k
–g 90 –an input_video_160x90_250k.mp4
```

In the second step MPD (manifest) file is made by MP4Box based on video sequences generated in the first step. Code line example is shown below.

```
MP4Box –dash 5000 –rap –profile
dashavc264:onDemand –mpd-title BBB –out
manifest.mpd –frag 2000 input_audio_128k.mp4
input_video_160x90_250k.mp4
input_video_320x180_500k.mp4
input_video_640x360_750k.mp4
input_video_640x360_1000k.mp4
input_video_1280x720_1500k.mp4
```

Command *-dash* represents duration of segment in milliseconds, command *-profile* sets profile to “on demand” or “live” streaming and *–out* represents the name of the MPD file. At the end of line all the sequences are listed.

User interface is prepared using Qt Creator [19] and C++ programming language. The interface allows downloading and parsing MPD file, selecting preferred video sequence for analysis, choosing processing units (CPU or GPU) and methods for background subtraction.

For MPD parsing *QdomDocument* and *QxmlReader* classes are used. After parsing, one of the video sequences is selected for testing the method (here background subtraction). Original frame of the test sequence “Big Buck Bunny” [20] is shown in Fig.3. Also, for the testing processing unit is selected (CPU or GPU). The number of tacts (clock time) is measured and used to compare the performance between CPU and GPU usage during testing. The time required for getting segments through network is taken into account. Function *clock()* from *ctime* class is used for measuring tact number per video sequence. The video sequence tact number is measured five times. This is followed by calculating mean tact number for each sequence. Absolute relative difference is calculated as:

$$D = \left| \frac{tact\_number(On) - tact\_number(Off)}{tact\_number(Off)} \right| \quad (1)$$

where On stands for computing on GPU, and Off for CPU.

Intel OpenCL platform is used for the analysis. The simulation is performed on laptop with Windows 10 (Intel Core i3-4005U CPU-1.70GHz, 4GB RAM). For the task of GPU based processing Intel HD Graphics 4400 is used.

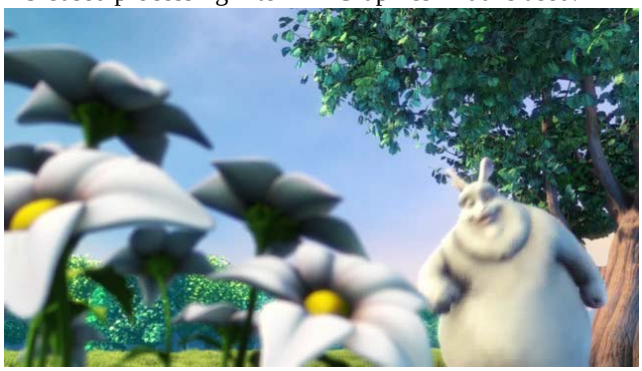

Fig. 3. “Big Buck Bunny” test video sequence (frame/scene example).

V. Experimental results

A. Manifest creating and type setting for MPD files

Results of a test sequence conversion are shown in Table I. After generating the MPD file with MP4Box and obtained results, user can get access to the manifest by using server’s public IP address (*http://[public_ip_address]/manifest.mpd*).

TABLE I
TEST VIDEO SEQUENCES

Test seq.	Resolution	Encoding	Bitrate	GOP *key frame* interval
1	160x90	H.264	250k	90
2	320x180	H.264	500k	90
3	640x360	H.264	750k	90
4	640x360	H.264	1000k	90
5	1280x720	H.264	1500k	90

In order to recognize manifest file (.mpd extension), it is necessary to set Internet Media Type (content type). This is also called MIME type (Multipurpose Internet Mail Extensions), originally created for emails helping to extend their limited capabilities. It indicates nature and format of a document. According to MPEG-DASH standard, type should be application with subtype dash+mpd [21], Fig.4.

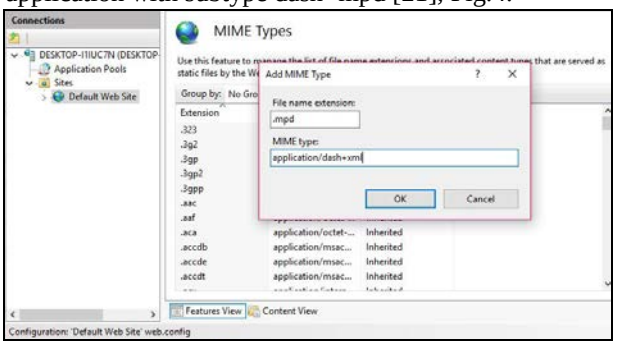

Fig. 4. Internet media type settings and MPD extension.

B. GUI for video processing

Realization of GUI using [19] is shown in Fig.5. Button MPD enables downloading and parsing MPD file. After parsing, in the right corner appears a list of all available video sequences. Streaming and processing starts by pressing Start/Refresh button. Processing unit is chosen by selecting on/off (On for GPU, Off for CPU). User can choose between GMM and knn by selecting mog2 or knn option, respectively. Also, user can set the frame number from which streaming starts.

For downloading a manifest, *QNetworkAccessManager* object is required, because *QDomDocument* cannot load xml document directly from network. *QNetworkAccessManager* object allows control over downloading content from network/internet. In this case, new class *mymanager* is written, for defining required signals and slots. For the purpose of defining and using a *QNetworkAccessManager* object, classes *QNetworkAccessManager* and *QNetworkReply* are used. In *mymanager* class, function *makeRequest* is defined. This function sends request for manifest downloading. If downloading is successful, signal *finished(QNetworkReply*)* is emitted and response is being forwarded to slot *readRead(QNetworkReply*)*. Response is written in variable *QbyteArray* type and signal *dataReadyRead(QByteArray)* is loaded. Then, within *collectData(QByteArray)* slot parsing of MPD file is done, and the first step is writing information on from variable *QByteArray* type to the variable with *QDomDocument* type.

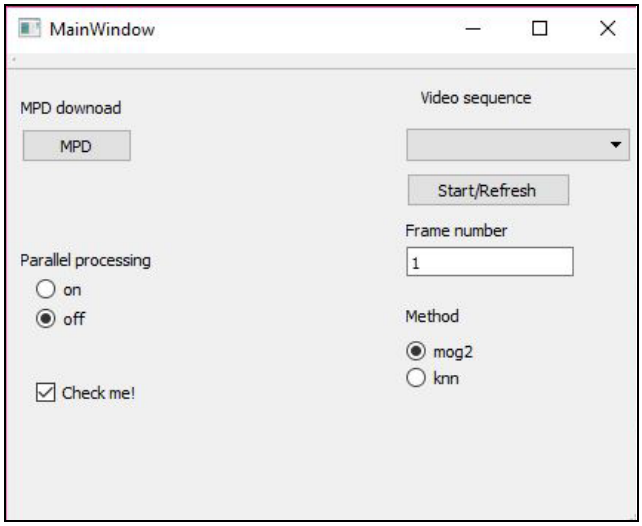

Fig. 5. MPD/DASH based graphical user interface.

C. GPU based background subtraction results

Video processing has been performed using two methods, where GMM showed better visual results in background subtraction compared to knn. GMM based video background subtraction result is presented in Fig. 6.

Five independent tests has been performed for each test sequence with different resolution and bitrate, and without or with GPU, meaning processing using CPU or processing on GPU.

Fig. 6. GMM based video background subtraction result.

Obtained results and mean values of the clock time (tact numbers) for processing using GMM are presented in Table II. In Table III CPU or GPU based background subtraction using GMM is compared to knn method.

TABLE II
VIDEO PROCESSING RESULTS USING GMM METHOD

Test sequences					
resolution, bitrate	160x90, 250k	320x180, 500k	640x360, 750k	640x360, 1000k	1280x720, 1500k

Clock time without or with GPU (Off/On) - mean values for knn				
42743/ 43022	47157/ 47073	73846/ 74807	73622/ 74012	180761/ 179075
Absolute relative difference in percents (compared to CPU)				
0.7%	1.8%	1.3%	0.5%	0.9%

The result of background subtraction and/or measured clock time can be shared with another user, by opening new TCP connection. Based on the results given in Table II and Table III, GMM based computing on GPU is above 30% faster compared to CPU computing for high resolution. Also, GMM based computing was 30-50% faster compared to knn for higher resolutions. Computing knn on GPU did not show much difference compared to knn computing on CPU. Around 1-2% difference was obtained.

VI. Conclusion

In this paper we performed experimental analysis based on OpenCL C++ framework platform and MPEG-DASH standard. Graphical user interface has been developed for DASH (MPD) data. It enables adaptive streaming of video content on demand and its processing. Two methods for background subtraction are compared, which are based on Gaussian mixture model and k-nearest neighbors. GMM method showed better results from the computational time aspect compared to knn regardless the processor unit. GMM method computing on GPU for higher resolutions gave good results. The results gave above 30% difference in clock time compared to CPU, and above 30% difference compared to knn regardless the processor unit.

Efficient processing is important for real-time applications. Providing new options for the user interface are expected as next steps. The future work should be oriented towards the analysis of different parallel processing and GPU based possibilities, machine and deep learning optimizations, providing efficient solutions for video processing and multimedia systems.

Group delay equalization of discrete Butterworth tan filters in the continuous domain

Negovan Stamenković, Nikola Stojanović and Milan Savić

***Abstract*— We present new techniques to approximate the magnitude response of discrete Butterworth tan filters with the delay characteristic which is constant in a maximally flat sense. The algorithm is used to obtain stable allpass filter, which acts as a group delay equalizer, with the aim to equalize group delay of the discrete tan filter in a maximal flat sense. The proposed method relies on a set of nonlinear equations, derived directly from the flatness conditions of the group delay response of the equalized filter at the origin in the analog domain, in order to obtain the unknown coefficient values of the discrete allpass filter. The algorithm implemented in the symbolic Matlab platform returns the coefficients of allpass filter. In the given example, firstly we design an discrete tan filter with a maximally flat magnitude at origin, and secondly, we augment the system with cascade connection of non-minimum phase allpass discrete filter, in order for the group delay response of the whole filter to equalize in a maximally flat sense.**

***Keywords*— Modified-Jacobi polynomials, return loss, stepped impedance filter**

I. Introduction

In recently published papers [1] and [2], the group delay equalization of analog and discrete Butterworth sine (all-pole) filters in a maximally flat sense, respectively, is presented. The conditions for the maximally flat group delay response of a lowpass filter require that the first $2m+1$ derivatives of the group delay function in the discrete frequency variable z, evaluated at $z=1$ to be all zeros [3], where m is the equalizer degree. The proposed method derives a set of nonlinear equations that satisfy the conditions for the group delay response to be flat with certain degrees of flatness at origin. In that method the system of nonlinear equation is expressed in terms of the first $2m$ derivatives of the numerator and the first $2m$ derivatives of the denominator of group delay response.

Let us denote the constant group delay equalization of the continuous and discrete filters can be in an equal ripple or in a maximally flat sense. In point of fact, there are several techniques for designing group delay equalizers primarily for continuous filters [4], [5], [6]. Unfortunately, these techniques cannot be applied to the discrete filters design through a s-to-z transformation, such as the bilinear transformation, because the group delay characteristic is not preserved under such a transformation [7].

N. Stamenković and M. Savić, University in Pristina-Kosovska Mitrovica, Faculty of Science, L. Ribara 29, 28220 K. Mitrovica, Serbia; e-mail: (negovan.stamenkovic@pr.ac.rs).

N. Stojanović, Faculty of Electronic Engineering, A. Medvedeva 14, 18000 Niš, Serbia; e-mail: (nikola.stojanovic@elfak.ni.ac.rs).

The design the group delay equalizer, on the other hand, can be accomplished by using an iterative technique direct in the z-domain that searches the constant group delay solution in an equal ripple sense by using Fletcher's optimization algorithm [8] or in the quasi equal ripple sense by using neural networks [9]. The evolutionary algorithm, the Differential Evolution Algorithm in particular is used to obtain an equal ripple group delay frequency response in the passband of lowpass filter [10]. The mentioned procedures are for designing optimum group delay equalizers that whole filter has the group delay response in an equal ripple sense.

In this paper, a novel approach to equalization of the discrete low-pass tan filter group delay response is presented. The proposed method relies on a set of nonlinear equations, derived from the flatness conditions of the equalized group delay response at the origin in continuous plane [1], to obtain the unknown coefficient values of the discrete allpass filters. There is a trade off between creating a system of nonlinear equations without a differentiation operation and standard bilinear transformation.

II. Digital Butterworth tan filters transfer function

The magnitude squared function of the nth degree lowpass discrete Butterworth tan filter [11], [12], which is a logical equivalent of an analog Butterworth filter, is given by:

$$|H_B(e^{j\omega T})|^2 = \frac{1}{1+\varepsilon^2\left[\dfrac{\tan^2\frac{\omega}{2}}{\tan^2\frac{\omega_p}{2}}\right]^n} \tag{1}$$

where ω_p is cutoff edge passband angular frequency, ε can be calculated from the specified passband edge attenuation a_{max}, $\varepsilon^2 = 10^{a_{max}} - 1$, and $2n-1$ is the degree of the flatness of the amplitude characteristic at the origin (the first $2n-1$ derivatives with respect to ω are equal to zero).

Appealing to analytic continuation by substituting ω by $-j\log(z)$, we obtain

$$|H_B(e^{j\omega T})|^2 = \frac{\tan^{2n}\dfrac{\omega_p}{2}}{\tan^{2n}\dfrac{\omega_p}{2} + \varepsilon^2(-1)^n\left(\dfrac{z-1}{z+1}\right)^{2n}} \tag{2}$$

The poles of Butterworth tan transfer function are found by substituting

$$q = \frac{z-1}{z+1} \tag{3}$$

in (2), from which we can find that the $2n$ poles of $q = x + jy$ are uniformly spaced around a circle of radius $\rho = \tan(\omega_p/2)/\sqrt[n]{\varepsilon}$. The poles of $z = u + jv$ are then readily found by using the inverse function to (3), namely

$$z = \frac{1+q}{1-q} \tag{4}$$

From (3) and (4) the corresponding poles in the z plane are computed to be in closed form [13]. For odd values of n, the $2n$ poles of z have the u_m and jv_m coordinates

$$\begin{aligned} u_m =& \frac{1-\rho^2}{1-2\rho\cos\dfrac{m\pi}{n}+\rho^2} \\ v_m =& \frac{2\rho\sin\dfrac{m\pi}{n}}{1-2\rho\cos\dfrac{m\pi}{n}+\rho^2} \end{aligned} \tag{5}$$

for $m = 0, 1, 2, \ldots, 2n-1$. For even values of n the coordinates are

$$\begin{aligned} u_m =& \frac{1-\rho^2}{1-2\rho\cos\dfrac{(2m+1)\pi}{2n}+\rho^2} \\ v_m =& \frac{2\rho\sin\dfrac{(2m+1)\pi}{2n}}{1-2\rho\cos\dfrac{(2m+1)\pi}{2n}+\rho^2} \end{aligned} \tag{6}$$

Consider the nth degree real-coefficient discrete tan filter transfer function, where only the poles inside the unit circle are to be included in the transfer function, having the form

$$H_F(z^{-1}) = \frac{h(1+z^{-1})^n}{\sum_{i=0}^{n} \mathsf{a}_i z^{-i}}, \tag{7}$$

with $\mathsf{a}_0 = 1$, whose gain is adjusted to unity at dc. Since the numerator of the transfer function can always be chosen as a mirror-image polynomial [7, p. 534] which does not affect to the linearity of phase, this group delay equalization will be performed like as by the discrete sine transfer function.

The group delay function $\tau_F(z)$ of a discrete tan low-pass transfer function (7) is a rational function in z. In the Appendix it is shown' that the group delay function is given by

$$\begin{aligned} \tau_B(z) = -\frac{1}{2}\Bigg[& \frac{z}{H_B(z)}\frac{\mathrm{d}H_B(z)}{\mathrm{d}z} \\ & - \frac{z}{H_B(z^{-1})}\frac{\mathrm{d}H_B(z^{-1})}{\mathrm{d}z}\Bigg]_{z=e^{j\omega}} \end{aligned} \tag{8}$$

After the addition, the denominator and the numerator of the group delay function (8) are mirror-image polynomials of degree $2n$, where n is the filter degree. In other words, the group delay is a *mirror-image rational function*.

Using (8), it can be derived an expression for the group delay value of this transfer function (7) at the origin ($z = 1$) as $\tau_B(1) = -(n/2 - \sum_{i=1}^{n} i\mathsf{a}_i / \sum_{i=0}^{n} \mathsf{a}_i)$. This formula is valid for arbitrary discrete tan filters with image-mirror polynomial in the numerator, because it does not affect to the phase linearity.

III. Group delay equaliser design

The group delay of the original filter can be equalized by connecting an allpass filter (delay equalizer) in cascade with the original filter. The magnitude response of an allpass filter is unity over its entire frequency range. Let $H_E(\mathbf{c}, z)$ denote an mth degree causal real-coefficients discrete transfer function of an allpass filter, i.e.,

$$H_E(\mathbf{c}, z) = \frac{c_m z^m + c_{m-1} z^{m-1} + \cdots + c_1 z + c_0}{c_0 z^m + c_1 z^{m-1} + \cdots + c_{m-1} z + c_m}, \tag{9}$$

where $c_0 = 1$ and $\mathbf{c} = [c_1, c_2, \ldots, c_m]$ is the real vector coefficient. The numerator of the allpass filters (9) is the reciprocal polynomial of the denominator polynomial, that implies that the poles and zeros of a real coefficient allpass filter exhibit mirror image symmetry with respect to the unit circle. To guarantee the stability of allpass filter (9), the poles of its transfer function have to be inside of the unit circle.

Applying (8) to an allpass function (9), an expression for the group delay of the allpass filter can be derived as

$$\tau_E(\mathbf{c}, z) = \frac{\beta_1(\mathbf{c}) z^{2m-1} + \cdots + \beta_m(\mathbf{c}) z^m + \cdots + \beta_1(\mathbf{c}) z}{\alpha_0(\mathbf{c}) z^{2m} + \cdots + \alpha_m(\mathbf{c}) z^m + \cdots + \alpha_0(\mathbf{c})} \tag{10}$$

As expected, the numerator and denominator polynomial form a mirror-image rational function. For example, the coefficients of the corresponding mirror-image rational function of the third degree group delay allpass filter can be calculated as

$$\begin{aligned} \beta_1(\mathbf{c}) =& c_2 - c_1\, c_3 & \alpha_0(\mathbf{c}) =& c_3 \\ \beta_2(\mathbf{c}) =& 2\, c_1 - 2\, c_2\, c_3 & \alpha_1(\mathbf{c}) =& c_2 + c_1\, c_3 \\ \beta_3(\mathbf{c}) =& c_1^2 - c_2^2 - 3\, c_3^2 + 3 & \alpha_2(\mathbf{c}) =& c_1 + c_1\, c_2 + c_2\, c_3 \\ & & \alpha_3(\mathbf{c}) =& c_1^2 + c_2^2 + c_3^2 + 1 \end{aligned} \tag{11}$$

The total group delay of the cascade connection of the original filter and the equalizer is defined as a sum of the group delays on each of them, so that:

$$\tau_{BE}(\mathbf{c}, z) = \tau_B(z) + \tau_E(\mathbf{c}, z) \tag{12}$$

Let $\tau_{BE}(z) = B(z)/A(z)$. The first $2m+1$ derivatives of $\tau_{BE}(z)$ will be zero at origin, if $\tau_{BE}(z)|_{z=1} = \lambda$ and the first m even-order derivatives of $B(z)$ at $z = 1$, are equal to the first m even-order derivatives of $A(z)$ at $z = 1$ multiplied by λ, i.e.

$$\frac{\mathrm{d}^k \tau_{BE}(z)}{\mathrm{d}z^k}\Big|_{z=1} = 0, \quad \text{for } k = 1, 2, \ldots, 2m+1 \tag{13}$$

if

$$\frac{\mathrm{d}^k B(z)}{\mathrm{d}z^k}\Big|_{z=1} - \lambda \frac{\mathrm{d}^k A(z)}{\mathrm{d}z^k}\Big|_{z=1} = 0, \quad \text{for } k = 2, 4, \ldots, 2m \tag{14}$$

where m is a degree of allpass filter that controls the degree of flatness at origin. Hence, the group delay response of the tan filters can be equalised in the maximally flat sense. It should be noticed the equalization to be carried out directly in the discrete domain.

On the other hand, the mirror-image rational function in

the discrete domain is the counterpart of the even rational function in the continuous domain [14]. The well known inverse bilinear transformation

$$z = \frac{1+s}{1-s} \tag{15}$$

is used to transform both discrete group delay functions, (8) and (10), into a continuous domain. The group delay response of the Butterworth tan filter/equalizer combination in the continuous s-domain can be expressed as

$$\tilde{\tau}_{BE}(\mathbf{c},\omega) = \tilde{\tau}_B(s)|_{s=j\omega} + \tilde{\tau}_E(\mathbf{c},s)|_{s=j\omega} \tag{16}$$

In this paper, we will focus only on designing a discrete allpass filter (9) which will act as an equalizer of the discrete tan filter. If a vector coefficient c is known, then the poles and zeros of the allpass filter prototype can also be calculated. Thus, the resulting group delay function $\tau_{BE}(\mathbf{c},z)$ approximates constant group delay response in the maximally flat sense over the passband interval.

The group delay of the equalized filter $\tilde{\tau}_{BE}(\mathbf{c},\omega)$ is an even rational function in ω as

$$\tilde{\tau}_{BE}(\mathbf{c},\omega) = \frac{b_0 + \cdots + b_{2m}\omega^{2m} + \cdots + b_{2(n+m)}\omega^{2(n+m)}}{a_0 + \cdots + a_{2m}\omega^{2m} + \cdots + a_{2(n+m)}\omega^{2(n+m)}} \tag{17}$$

with the coefficients being dependent on m allpass filter coefficients $\mathbf{c}$. Since, there are only m unknown parameters of the allpass network design, only $2m+1$ derivatives of the group delay response given by (17) can be equal to zero, including all odd order derivatives which are identically zero. This results in simpler m nonlinear equations [1] and this simplifies the vector coefficient $\mathbf{c}$ calculation

$$f_k(\mathbf{c}) = \frac{b_k}{a_k} - \frac{b_0}{a_0} = 0, \text{ for } k = 2,4,\ldots,2m \tag{18}$$

The m unknown coefficients for the discrete group delay equalizer design to be solved by iterative techniques. The Matlab Symbolic Toolbox can be used to solve the system of m nonlinear equations (18) for the arbitrary degree of both the lowpass tan filter and the group delay equalizer (i.e. allpass network $H_E(\mathbf{c},z)$), by using command `[x,fval]=fsolve(f,x_o)`, whereas $\mathbf{x} = \mathbf{c}$ and $\mathbf{f}(\mathbf{c}) = [f_2(c), f_4(c), \ldots, f_{2m}(c)]^T$. The exponent T stands for matrix operation transpose.

The denominator coefficients of the mth degree Butterworth tan transfer function (7), whose group delay will be corrected, can be used as initial solution values for the coefficient vector $\mathbf{x\_o} = [c_2, c_4, \cdots, c_{2m}]$.

As is mentioned Matlab rutine, which is used to solve system of nonlinear equations $\mathbf{f}(\mathbf{c}) = 0$, employs a number of least squares algorithms that find the solution to the problem

$$\Big[\min_{c_2,\ldots,c_{2m}} \sum_{k=1}^{m} f_k^2(\mathbf{c})\Big]^{\frac{1}{2}} \le \delta \tag{19}$$

where δ is an arbitrarily small number. Since the minimum of (19) is $\delta = 0$ and this occurs when all $f_i(\mathbf{c}) = 0$, a solution $\delta > 0$ to (19) will also be a solution to the equation system (18).

Finally, the group delay of the filter/equalizer combination is constant in the maximally flat sense since it has the first $2m+1$ derivatives that are approximately equal to zero at the origin, because the zero value of derivatives cannot be achieved.

The quality of an equalizer is inversely related to the maximum variation of τ_{BE} over the frequency band of interest. A measure that can be used to assess the quality of a group delay equalizer design can, therefore, be defined as

$$Q_\tau = \frac{\max\limits_{0\le\omega\le\omega_c} \tau_{BE}(\omega) - \min\limits_{0\le\omega\le\omega_c} \tau_{BE}(\omega)}{\max\limits_{0\le\omega\le\omega_c} \tau_{BE}(\omega) + \min\limits_{0\le\omega\le\omega_c} \tau_{BE}(\omega)} 100 \tag{20}$$

We are used that the minimum value of group delay value is expected at the origin, $\min\limits_{0\le\omega\le\omega_c} \tau_{BE}(\omega) = \tau_{BE}(0)$, then the quality of group delay equalization does not depend on the passband edge attenuation. Hence,Q_τ will be referred to as the maximum group delay deviation, hereafter.

IV. Design example

In order to demonstrate the effectiveness of the present method for the group delay equalisation for discrete Butterworth tan filter a practical example has been worked out. The fifth-degree group delay equalizer for the seventh-degree discrete Butterworth tan filter with the normalized $a_{max} = 3.0103$ dB ($\varepsilon = 1$) at the cutoff point of $\omega_c = 0.30\pi$ radians is considered as a design example. The transfer function of the 7th degree Butterworth tan filter is calculated by using equations (5) and (7)

$$H_B(z^{-1}) = \frac{0.000962894(1+z^{-1})^7}{\begin{array}{r}1 - 2.78251z^{-1} + 3.96681z^{-2} - 3.40515z^{-3} \\ +1.87586z^{-4} - 0.65094z^{-5} + 0.13085z^{-6} \\ -0.01166z^{-7}\end{array}}$$

The general form of the 5th degree allpass filter transfer function is given by Eq. (10). The system of nonlinear equations (18) is solved with an initial solution `x_o= [-2.1830 2.2787 -1.3028 0.3969 -0.0508]`, calculated as the denominator coefficients of the 5th degree Butterworth tan filter. Matlab to return the values of allpass filter coefficients as follows

Listing 1. Allpass discrete filter coefficients

```
ans =

[ c1,    -2.209203171366232]
[ c2,     2.082326315189515]
[ c3,    -1.037836012889430]
[ c4,     0.271589008818471]
[ c5,    -0.029678379559256]
```

with `c0=1`.

The pole-zero locations of the 7th-degre discrete Butterworth tan lowpass filter with cutoff frequency $\omega_p = 0.3\pi$ and for the 5th-degree group delay equalizer in the maximally flat sense are shown in Fig. 1. In other word, this is pole-zero plot of the whole filter. Therefore, equalized filter is a nonminimum phase system, because allpass network introduces the zeros outside unit circle.

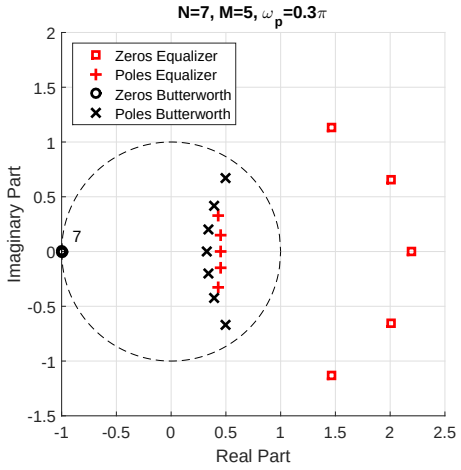

Fig. 1. The pole-zero locations of the 7th-degre discrete Butterworth tan lowpass filter with cutoff frequency $\omega_p = 0.3\pi$ and of the group delay equalizer for the maximally flat sense.

The value of the function $\mathbf{f}(\mathbf{c})$ at the solution $\mathbf{x}$ Matlab is returned in the vector `fval`, as in Listing 2 is given:

Listing 2. The accuracy of the solution of a nonlinear equation system

```
fval =

Fig. 2 presents the comparison of a group delay response of the Butterworth tan filter with yhe group delay of the equalized system. The maxumally flat attenuation response of the Butterworth tan filter, at the same time for the whole filter, is also given in this figure. As one can notice, the compensation of constant group delay characteristics in a maximally flat sense brings that the difference between maximum and minimum values of the group delay characteristic in the passband has been lowered. The maximum group delay deviation (20) of the equalized Butterworth tan filter is $Q_{\tau_{BE}} = 0.055192597270427$, and it is about seven times smaller in comparison with the maximum group delay deviation of the Butterworth tan filter without equalizatin $Q_{\tau_B} = 0.370319660189653$.

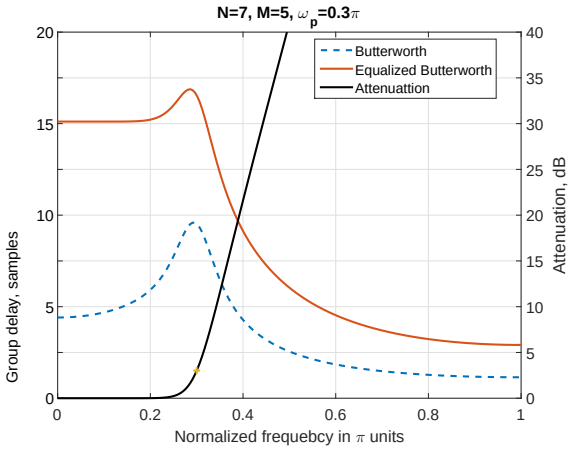

Fig. 2. Group delay equalization of a 7th-degree Butterworth tan filter with the bandwidth value of 0.30π radians; the frequency responses of the original Butterworth filter and group delay frequency responses of Butterwworth filter/equaliser with $m = 5$ combination.

On the other hand, the group delay value of group delay equalized filter (15.112039 samples) is obviously greater than in the Butterworth tan filter (4.409946 samples), however this value does not play an important role in many applications. From the engineering point of view, the important feature is constancy of the group delay in the filter pass-band.

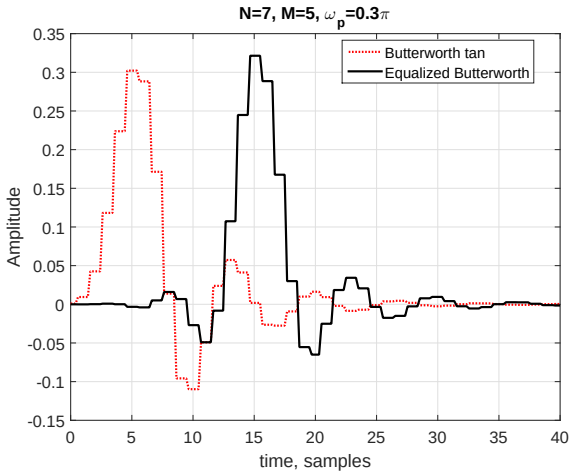

Fig. 3. Impulse response of a 7th-degree Butterworth tan filter with the bandwidth value of $\omega_p = 0.30\pi$ radians, and the impulse responses of the Butterworth tan filter/equaliser with $m = 5$ combination.

Improvement of the transient (dynamic) properties of the group delay equalized Butterworth tan filter is given in Fig. 3 which shows the impulse response of the Butterworth tan and equalized filter. It can be seen, that the introduction of a non-minimum-phase transfer function

obviously introduces ripples (or echoes) before the rise of the impulse response output from such a system. Number of pre-transition oscillation is equal to the degree of allpass equaliser.

It can be seen that side lobes of the impulse response are suppressed and man lobe is more symmetric.

V. Conclusion

A novel optimization algorithm has been applied to the design of the allpass filters for group delay equalized for a discrete Butterworth tan filters in a maximally flat sense. The proposed method relies on a set of nonlinear algebraic equations, derived directly from the flatness conditions of the group delay response at the origin in the analog domain, which is much simpler than that derived in the discrete domain, whose solution gives the unknown values of the allpass filter coefficients. Since $2m+1$ derivatives of group delay exist and they are zero at the origin, where m is the allpass filter degree, the equalized group delay response is called maximally flat.

The Matlab routine `fsolve` is used to solve this set of nonlinear equations using a quasi-Newton method. The proposed technique is illustrated by designing the 5th degree group delay equalizer for a 7th degree Butterworth tan filter with a normalized cutoff frequency of $\omega_p = 0.30\pi$ rad. The proposed method can be used for an arbitrary type discrete tan approximation, for an arbitrary filter degree, and with arbitrary filter bandwidth.

Since the numerator of the recursive rational transfer function can always be chosen as a mirror-image polynomial, which does not affect the linearity of phase, the proposed method can be extended towards the design of group delay equalizers for other types of filters with rational transfer function, for example, Elliptic and Inverse Chebyshev filters.

Appendix

To derive (8), let

$$H_F(e^{j\omega}) = |H_F(e^{j\omega})|e^{j\phi_F(e^{j\omega})}$$

Then

$$H_F(e^{-j\omega}) = |H_F(e^{j\omega})|e^{-j\phi_F(e^{j\omega})}$$

Therefore

$$\frac{H_F(e^{j\omega})}{H_F(e^{-j\omega})} = e^{2j\phi_F(e^{j\omega})}$$

Then

$$\log H_F(e^{j\omega}) - \log H_F(e^{-j\omega}) = 2j\phi_F(e^{j\omega})$$

Therefore, if we let $z = \exp(j\omega)$, we can write $\mathrm{d}z/\mathrm{d}\omega = jz$ and

$$\log H_F(z) - \log H_F(z^{-1}) = 2j\phi_F(z)$$

or

$$\phi_F(z) = \frac{1}{2j}\Big[\log H_F(z) - \log H_F(z^{-1})\Big]$$

Th group delays function of the above phase function can be derived as given below

$$\begin{aligned}\tau_F(z) &= -\frac{\mathrm{d}\phi_Z(z)}{\mathrm{d}z}\frac{\mathrm{d}z}{\mathrm{d}\omega} \\ &= -\frac{1}{2j}\Big[\frac{1}{H_F(z)}\frac{\mathrm{d}H_F(z)}{\mathrm{d}z} - \frac{1}{H_F(z^{-1})}\frac{\mathrm{d}H_F(z^{-1})}{\mathrm{d}z}\Big]jz\end{aligned}$$

The equation (8) is derived.

Analiza značaja DCT koeficijenata u objektivnoj proceni kvaliteta slike zasnovanoj na promeni kontrasta

Nenad Stojanović, Boban Bondžulić i Ivana Stojanović

***Apstrakt*—U radu je dat predlog metode za procenu kvaliteta slike koji se zasniva na poređenju originalne i test slike. Prilikom određivanja vrednosti kvaliteta slike koristi se diskretna kosinusna transformacija, pri čemu se na lokalnom nivou određuje kontrast koji daljim usrednjavanjem daje krajnju vrednost kvaliteta. U radu je pokazano da prilikom proračuna, na krajnju procenu kvaliteta utiče broj korišćenih koeficijenata diskretne kosinusne transformacije. Performanse predložene mere date su kroz linearnu korelaciju i korelaciju rangova sa subjektivnim ocenama kvaliteta nakon testiranja na četiri javno dostupne baze slika, pri čemu su tri baze slika sa višestrukim degradacijama.**

***Ključne reči*—Procena kvaliteta slike, očuvanje kontrasta, diskretna kosinusna transformacija, višestruke degradacije.**

I. Uvod

PROCENA kvaliteta različitih tipova digitalnih signala je postala sve značajnija u sistemima prenosa gde se kvalitet pružene usluge korisniku može prilagoditi korišćenjem složenijih, ali efikasnijih algoritama u odnosu na najčešće korišćenu verovatnoću bitske greške (*Bit Error Rate*, BER). Sa povećanjem kapaciteta telekomunikacionih kanala, kako u stacionarnim, tako i u mobilnim telekomunikacionim sistemima, povećane su i mogućnosti da se korisnicima pruže servisi većeg kapaciteta kao što su mirne slike i video zapisi visokih rezolucija ili video striming.

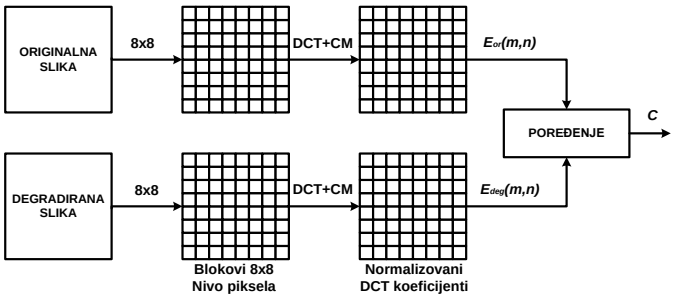
Mere za procenu kvaliteta slike sa potpunim referenciranjem (*Full-Reference*, FR), gde se prilikom procene kvaliteta slike vrši poređenje originalne (referentne, izvorne) slike i testirane (degradirane) slike, se često koriste prilikom projektovanja, testiranja i optimizacije različitih sistema. Mere bez referenciranja (*No-Reference*, NR), s obzirom da ne koriste nikakvu referencu tokom procene, već je za procenu kvaliteta slike neophodna samo degradirana slika, mogu se koristiti u sistemima koji zahtevaju rad u realnom vremenu. Tako se sistem prenosa može optimizovati odmah po detekciji određenog stepena degradacije u prenošenom sadržaju.

U radu je predstavljena mera za procenu kvaliteta slike sa potpunim referenciranjem. Prilikom procene kvaliteta, korišćena je diskretna kosinusna transformacija (*Discrete Cosine Transform*, DCT) i analiziran je značaj njenih koeficijenata prilikom određivanja kontrasta. Algoritam procene kvaliteta slike na osnovu analize promene kontrasta proizašao je iz metoda za sjedinjavanje multisenzorskih slika [1] i metoda za poboljšanje kvaliteta slike [2], kod kojih je kontrast računat u DCT domenu.

U drugom delu rada opisana je predložena mera procene kvaliteta slike. Značaj DCT koeficijenata analiziran je u trećem delu rada testiranjem mere na jednoj javno dostupnoj bazi slika. Analiza mere sa parametrima koji su pokazali najbolje performanse izvršena je u četvrtom delu rada na tri javno dostupne baze slika sa višestrukim degradacijama. Na kraju su dati osnovni zaključci i budući pravci istraživanja.

II. Procena kvaliteta slike metodom očuvanja kontrasta

Koncept procene kvaliteta slike kroz analizu očuvanja kontrasta prikazan je blok šemom na Sl. 1. Izvorna slika i slika sa degradacijom se najpre podele na blokove dimenzija 8x8 piksela. Nakon toga se odredi DCT za svaki blok posebno. DCT razlaže blok u nizove talasnih oblika, svaki sa određenom prostornom frekvencijom. Blok 8x8 piksela je izabran kao standardan i za druge primene DCT transformacije, kao što je kompresija slike.



Sl. 1. Blok šema mere očuvanja kontrasta.

DCT koeficijenti sa uporedivom prostornom frekvencijom se grupišu i koriste za definisanje kontrasta. Radi definisanja nivoa kontrasta, potrebno je podeliti blokove u 15 različitih

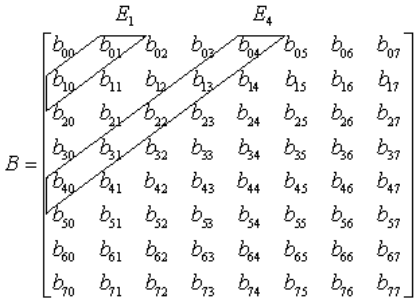
frekvencijskih opsega. Opsezi su ilustrovani na Sl. 2 (prvi i četvrti opseg su naglašeni) i njih čine koeficijenti duž dijagonala matrice.



Sl. 2. Blok DCT koeficijenata.

Matrica *B* predstavlja DCT koeficijente *n*-tog bloka slike, obeležene sa $b_{i,j}$, $0 \le i,j \le 7$. Za svaki od blokova određuje se srednja vrednost amplitude *k*-tog opsega kao [1, 2]:

$$E_k = \frac{\sum_{i+j=k} |b_{i,j}|}{N}, \tag{1}$$

pri čemu *N* predstavlja broj članova unutar svakog od opsega i on se može napisati kao:

$$N = \begin{cases} k+1, k < 8 \\ 14-k+1, k \ge 8 \end{cases}. \tag{2}$$

Iz relacije (1) se vidi da *k*-ti opseg čine koeficijenti bloka DCT koeficijenata čiji je zbir jednak *k* ($i+j=k$).

Kontrast se definiše na svakoj poziciji (i,j) unutar matrice *B* kao:

$$C_{i,j} = \frac{b_{i,j}}{\sum_{k=0}^{m-1} E_k}, \tag{3}$$

gde je *m* ukupan broj opsega (za podelu na blokove 8x8 piksela $m=15$). Na ovaj način je izvršena normalizacija DCT koeficijenata i normalizovani koeficijenti $C_{i,j}$ imaju vrednosti između -1 i 1.

Ako normalizovane DCT koeficijente svih blokova izvorne slike obeležimo sa E_{or}, normalizovane koeficijente slike sa degradacijom obeležimo sa E_{deg}, sličnost dve slike na globalnom nivou (nivou slika) može se odrediti pomoću izraza:

$$C = \frac{1}{MN} \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} \left(\frac{2E_{or}(m,n) E_{deg}(m,n) + g}{E_{or}^2(m.n) + E_{deg}^2(m,n) + g} \right), \tag{4}$$

gde je *g* konstanta ($g=10^{-16}$), a dimenzije slika su *M*x*N* piksela.

Nakon poređenja (4) dobija se vrednost *C* koja predstavlja kvalitet slike sa degradacijom i ona može biti između -1 i 1. Slika sa većom vrednošću *C* je boljeg kvaliteta (sličnija izvornoj slici). Ako je $C=1$ slike koje se porede su identične. Konstanta *g* služi za stabilizaciju mere *C* kada su normalizovani koeficijenti jednaki nuli.

Izrazom:

$$C(m,n) = \frac{2E_{or}(m,n) E_{deg}(m,n) + g}{E_{or}^2(m.n) + E_{deg}^2(m,n) + g}, \tag{5}$$

koji predstavlja deo izraza (4), dobijaju se vrednosti očuvanja kontrasta na poziciji (m,n) – nivo piksela. Mera *C* se dobija usrednjavanjem vrednosti očuvanja kontrasta na svim pozicijama [3].

III. Analiza značaja DCT koeficijenata kod mere očuvanja kontrasta

Osobina DCT da se velika količina energije koncentriše u malom broju koeficijenata niske frekvencije koristi se u mnogim primenama, a najčešće u kompresiji podataka sa gubicima, gde se na osnovu malog broja koeficijenata može izvršiti rekonstrukcija slike zadovoljavajućeg kvaliteta [4]. Shodno tome, prilikom kvantizacije i kodovanja DCT koeficijenata vrši se skeniranje istih prema značaju, takozvano cik-cak skeniranje na način prikazan u Tabeli I. Pored najčešće korišćenog cik-cak skeniranja, postoje alternativni načini skeniranja DCT koeficijenata prema njihovom značaju, a u cilju postizanja što boljih rezultata u obradi signala. Jedan od primera alternativnog načina skeniranja je prikazan u Tabeli II [4]. Brojevi u tabelama predstavljaju redne brojeve DCT koeficijenata prilikom korišćenja (skeniranja).

Dimenzije bloka za izračunavanje DCT koeficijenata, mogu značajno da utiču na krajnje procene kvaliteta mere očuvanja kontrasta [3]. Kako su u [3] najbolji rezultati dobijeni za blokove dimenzija 5x5 i 7x7 piksela, ove dve dimenzije bloka su izabrane i za dalju analizu, gde se analiza promene kontrasta vrši na osnovu određenog broja DCT koeficijenata prema jednom od dva navedena pravila skeniranja. Broj i značaj DCT koeficijenata koji je korišćen u proračunima, za blok dimenzije 7x7 piksela je prikazan u Tabelama III i IV, a za blok dimenzija 5x5 piksela u Tabelama V i VI.

TABELA III
Cik-cak način skeniranja DCT koeficijenata za blok 7x7 piksela

Analiza performansi mere za tri različite dimenzije bloka i dva načina skeniranja DCT koeficijenata izvršena je testiranjem na LIVE bazi slika [5]. LIVE baza slika (*Laboratory for Image and Video Engineering*) Teksas Univerziteta (*University of Texas at Austin*) se sastoji od 982 kolor slike. Baza slika je izvedena od 29 izvornih kolor slika rezolucije uglavnom 768x512 piksela. Slike u bazi su dobijene tako što su izvorne slike degradirane korišćenjem pet tipova distorzije. Svaka od izvornih slika je degradirana sa svim tipovima distorzije i to tako da kvalitet dobijenih slika pokriva potpuni opseg kvaliteta, tj. od slika lošeg do slika dobrog kvaliteta. Kvalitet izvornih slika je narušen korišćenjem JPEG2000 kodovanja, JPEG kodovanja, dodavanjem belog šuma, Gausovim zamrljanjem – filtriranjem (*Blurring*) i simulacijom grešaka u prenosu JPEG2000 povorke bita korišćenjem Rejlijevog (*Rayleigh*) modela kanala sa brzim fedingom. Pored izvornih slika i slika sa degradacijama, dostupne su i subjektivne ocene kvaliteta koje su date u formi diferencijalnih MOS skorova (*Differential Mean Opinion Score*, DMOS), gde niže vrednosti predstavljaju bolji subjektivni kvalitet. Performanse mere su prikazane na Sl. 3 kroz stepen slaganja sa subjektivnim ocenama pomoću korelacije rangova (*Spearman Rank Order Correlation Coefficient*, SROCC).

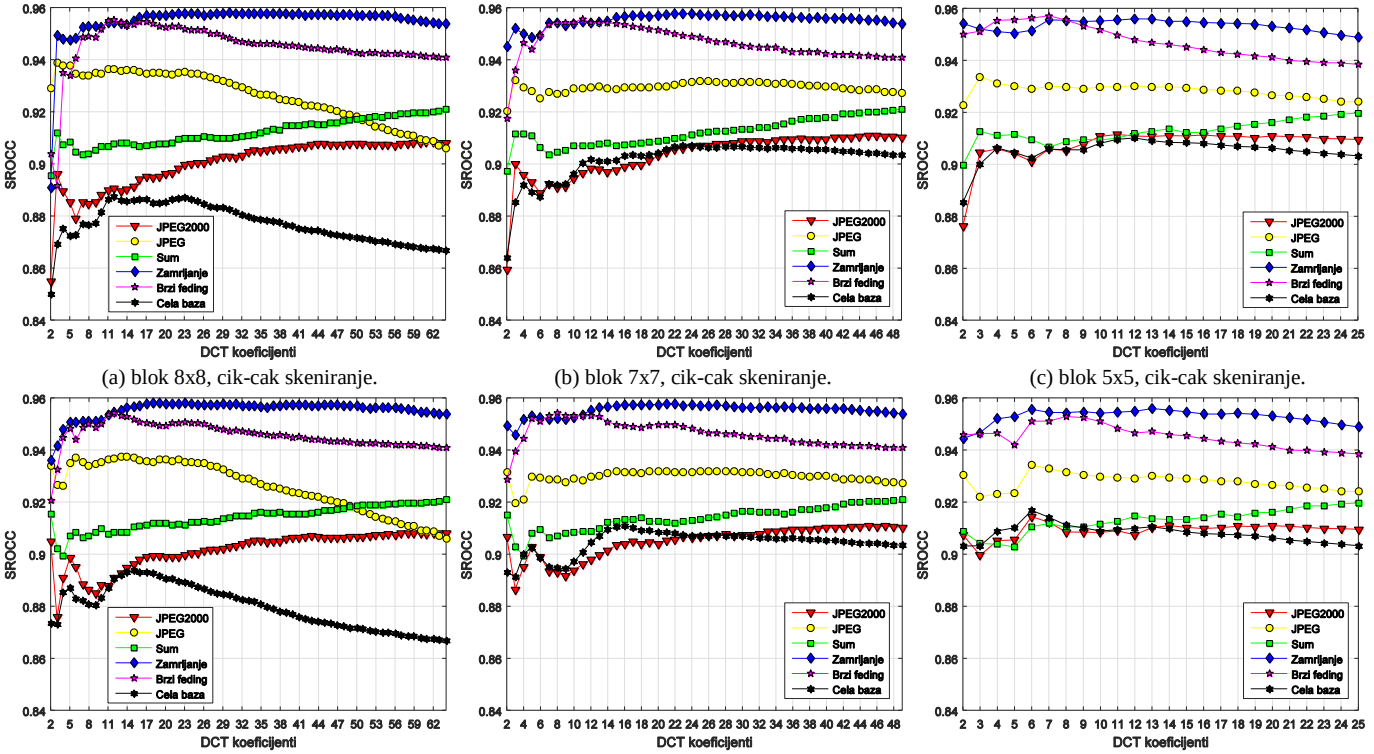
Najviši stepen slaganja sa subjektivnim ocenama mera postiže za slike sa zamrljanjem, dok se za skup slika degradiranih brzim fedingom dobijaju za nijansu lošiji rezultati. Najlošije performanse, mera pokazuje za skup slika degradiranih JPEG2000 kompresijom i na nivou kompletne baze. U zavisnosti od tipa degradacije, broj DCT koeficijenata korišćen prilikom proračuna kontrasta na lokalnom nivou različito utiče na krajnje performanse mere u korelaciji sa subjektivnim ocenama.

Kod JPEG kompresije, bolji rezultati se postižu sa malim brojem DCT koeficijenata bez obzira na dimenzije bloka i način skeniranja. Takođe, kod JPEG2000 kompresije i aditivnog belog Gausovog šuma veći broj DCT koeficijenata doprinosi boljim performansama. Kod slika sa zamrljanjem i brzim fedingom broj korišćenih DCT koeficijenata pri čemu se postiže najviši stepen slaganja sa subjektivnim ocenama je približno sličan i relativno se poklapa sa brojem DCT koeficijenata gde se postižu najbolji rezultati na kompletnoj bazi.

Korišćenjem različitog broja DCT koeficijenata prilikom određivanja vrednosti kvaliteta slike merom *C*, kod dimenzije bloka 8x8 piksela dobijeno je poboljšanje slaganja sa subjektivnim procenama od oko 2% na nivou cele baze, kod bloka 7x7 piksela oko 3-4% i za dimenziju bloka 5x5 piksela maksimalnih 5%. Na taj način je korelacija sa subjektivnim procenama sa 87% podignuta na oko 92%.

Dobijeni rezultati upoređeni su sa najčešće korišćenim merama kao što su PSNR (*Peak Signal to Noise Ratio*), SSIM_index (*Structural Similarity Index Metric*) i SSIM (vrši predobradu slike za razliku od prvobitnog SSIM_index) [6], kao i sa merama koje su postigle izuzetno visok stepen slaganja sa subjektivnim ocenama kod LIVE baze slika i to IW-SSIM (*Information Content Weighted* SSIM) [7], VIF (*Visual Information Fidelity*) [8] i MAD (*Most Apparent Distortion*) [9]. Poređenje je vršeno pomoću linearne korelacije (*Pearson Linear Correlation Coefficient*, PLCC) - Tabela VII i korelacije rangova - Tabela VIII. Pored početne verzije mere *C* (opisana u poglavlju II), za dalje poređenje je izabrana ista mera gde je prilikom proračuna korišćena

dimenzija bloka 5x5 piksela i šest DCT koeficijenata po alternativnom načinu skeniranja, što je i naznačeno u Tabeli VI. Navedeni parametri su izabrani, jer je njima postignut najveći stepen korelacije sa subjektivnim procenama na nivou cele baze, a pritom je taj broj DCT koeficijenata doprineo maksimalnim vrednostima korelacije na skoro svim skupovima slika po tipovima distorzije. Mera *C* sa navedenim parametrima u daljem radu je označena sa *C_5x5_a6*. U odnosu na mere PSNR i SSIM_index, mera *C_5x5_a6* postigla je bolje rezultate, za razliku od mere *C* sa početnim parametrima koja je bila u rangu sa merom PSNR i nešto lošija u odnosu na SSIM_index na nivou kompletne baze.



(a) blok 8x8, cik-cak skeniranje. (b) blok 7x7, cik-cak skeniranje. (c) blok 5x5, cik-cak skeniranje.

(d) blok 8x8, alternativno skeniranje. (e) blok 7x7, alternativno skeniranje. (f) blok 5x5, alternativno skeniranje.

Sl. 3. Korelacija rangova subjektivnih i objektivnih procena kvaliteta mere očuvanja kontrasta na LIVE bazi slika za različit broj DCT koeficijenata.

TABELA VII
Koeficijenti linearne korelacije na LIVE bazi slika

PLCC	JPEG2000	JPEG	Gausov šum	Zamrljanje	Brzi feding	Cela baza

TABELA VIII
Koeficijenti korelacije rangova na LIVE bazi slika

SROCC	JPEG2000	JPEG	Gausov šum	Zamrljanje	Brzi feding	Cela baza
PSNR	0.895	0.881	0.985	0.782	0.891	0.876
SSIM_index	0.935	0.945	0.963	0.894	0.941	0.910
SSIM	0.961	0.976	0.969	0.952	0.956	0.948
IW-SSIM	0.965	0.981	0.967	0.972	0.944	0.957
VIF	**0.969**	**0.985**	**0.986**	**0.973**	**0.965**	0.964
MAD	0.968	0.976	0.984	0.946	0.957	**0.967**
C	0.908	0.906	0.921	0.954	0.941	0.867
C_5x5_a6	0.914	0.934	0.910	0.956	0.951	0.917

U odnosu na ostale testirane mere, mera *C_5x5_a6* postiže nešto slabije rezultate. Na nivou cele baze taj zaostatak je od 3-4%, s obzirom da mere MAD i VIF dostižu korelaciju sa subjektivnim ocenama blizu 97%. Slična, pa i nešto veća, je razlika između ovih mera kada se posmatraju pojedinačni tipovi degradacije, osim u slučaju brzog fedinga gde je za linearnu korelaciju mera *C_5x5_a6* postigla najbolji rezultat.

IV. TESTIRANJE MERE OČUVANJA KONTRASTA NA BAZAMA SLIKA SA VIŠESTRUKIM DEGRADACIJAMA

Dalje testiranje performansi mere označene sa *C_5x5_a6* izvršeno je na bazama slika sa višestrukim degradacijama. U tu svrhu korišćene su LIVE MD (LIVE *Multiply Distorted*) [10], IVL (*Imaging and Vision Laboratory, University of Milan-Bicocca*) [11, 12] i MDID (*Multiply Distorted Image*

Database) [13] baze slika.

LIVE MD baza slika je kreirana od 15 izvornih slika rezolucije 1280x720 piksela. Baza je organizovana kroz dva scenarija. Prvi scenario je predstavljen sa 225 slika (90 sa jednom i 135 slika sa dve degradacije) degradiranih sa zamrljanjem i JPEG kompresijom, a drugi scenario je takođe predstavljen sa 225 slika (90 sa jednom i 135 slika sa dve degradacije) degradiranih zamrljanjem i Gausovim šumom. Korišćeno je tri nivoa degradacija.

IVL baza slika se sastoji od ukupno 1130 degradiranih slika od čega je 380 slika sa jednostrukom degradacijom (200 slika sa Gausovim šumom i 180 slika sa JPEG kompresijom) i 750 slika sa dvostrukom degradacijom (350 slika sa zamrljaniem + JPEG kompresijom i 400 slika sa Gausovim šumom + JPEG kompresijom). Degradirane slike su dobijene od 20 izvornih slika, rezolucije 886x591 piksel, pri čemu je 10 od tih slika korišćeno za generisanje dela slika sa dve distorzije. Korišćeno je do 10 različitih nivoa degradacija prilikom kreiranja test slika.

Baza slika MDID se sastoji od 1600 degradiranih slika kreiranih od 20 izvornih slika. Sa jednom degradacijom ima 275 slika, sa dve 415 slika, sa tri 444 slike i 466 slika sa četiri degradacije. Slike su dimenzija 512x384 piksela. Za generisanje test slika u bazi korišćeno je pet različitih tipova distorzija i to Gausov šum, zamrljanje, promena kontrasta, JPEG kompresija i JPEG2000 kompresija. Na slikama se javljaju od jedne do četiri različite distorzije tako da se dva tipa kompresije nikad ne pojavljuju zajedno. Korišćeno je pet različitih nivoa distorzija.

U Tabeli IX su prikazani rezultati linearne korelacije na tri opisane baze koje sadrže slike sa višestrukim degradacijama. Generalno, sve mere imaju lošije performanse nego što je to slučaj kod LIVE baze slika sa jednostrukim degradacijama. Mera *C_5x5_a6* je pokazala značajno poboljšanje performansi u odnosu na početnu meru očuvanja kontrasta iz [3]. Kod LIVE MD baze slika to poboljšanje iznosi 8% na nivou cele baze, a za slike sa jednostrukom degradacijom čak 18%.

Poboljšanje stepena slaganja sa subjektivnim ocenama je postignuto i kod IVL baze za oko 10% na svim podskupovima slika. Kod baze MDID, rezultati su slični kao i kod prvobitne verzije mere *C*, osim kod slika sa jednostrukom degradacijom gde je evidentiran značajniji pad performansi, za oko 7%. U odnosu na ostale testirane mere, mera *C_5x5_a6* je pokazala bolje performanse u odnosu na PSNR i SSIM_index gotovo na svim podskupovima slika na sve tri testirane baze, dok je koeficijent korelacije sa subjektivnim ocenama kvaliteta značajno približen merama SSIM, IW-SSIM, VIF i MAD.

Rezultati dobijeni kroz korelaciju rangova su prikazani u Tabeli X i neznatno se razlikuju u odnosu na rezultate dobijene kod PLCC. Osobina koju je pokazala mera *C* [14], kada se posmatra SROCC, da su bolji rezultati dobijeni na slikama sa višestrukim degradacijama, mera *C_5x5_a6* nije uspela da pokaže. Poboljšanja koje je mera *C_5x5_a6* donela su značajno veća kada se posmatraju slike sa jednostrukim degradacijama i kompletne baze, dok su poboljšanja kod podskupova slika sa višestrukim degradacijama, iako postoje, znatno manja i to je praktično dovelo do toga da kao i sve ostale testirane mere, mera *C_5x5_a6* ima bolje performanse kod slika sa jednom u odnosu na slike sa više degradacija.

V. ZAKLJUČAK

U radu je predložena objektivna mera za procenu kvaliteta slike sa potpunim referenciranjem koja se zasniva na primeni diskretne kosinusne transformacije. Pored osnovne mere, predložene su i njene modifikacije u smislu korišćenja određenog broja DCT koeficijenata na tri različite dimenzije bloka prilikom proračuna krajnje vrednosti kvaliteta. Pokazano je na jednoj javno dostupnoj bazi slika da broj korišćenih DCT koeficijenata u krajnjem proračunu kvaliteta može značajno da poboljša performanse mere i da je dodatno približi rezultatima mera koje se često koriste i već imaju široku primenu.

Parametri mere očuvanja kontrasta koji su pokazali najbolji rezultat na bazi slika sa jednostrukom degradacijom, iskorišćeni su za dalje testiranje na tri javno dostupne baze slika sa višestrukim degradacijama. Na dve od tri baze slika postignuta su značajna poboljšanja u korelaciji sa subjektivnim ocenama, bilo posmatrajući kompletne baze, bilo posmatrajući određene podskupove slika u okviru baza na kojima je mera testirana.

U daljem radu, planira se unapređenje mere očuvanja kontrasta, kako kombinovanjem koeficijenata diskretne kosinusne transformacije na različite načine, tako i uvođenjem predfiltracije i skaliranja slika čiji se kvalitet procenjuje. Dalje testiranje objektivne mere procene kvaliteta slike vršiće se na većem broju baza slika sa što više različitih tipova degradacija.

ABSTRACT

The paper proposes a method for image quality assessment, which is based on original and test image comparison. During determination of image quality, the measure use discrete cosine transform, whereby local values of contrast is determined which with further averaging is obtaining final qualiy value. In the paper is shown that during calculation, number of used discrete cosine transform's coefficients has impact in final quality assessment. The performance of the proposed measure is given through linear correlation and rank correlation with subjective quality scores after its testing on four public available image datasets, whereby three of four datasets are with multiply degradation.

DCT Coefficients Significance Analysis in Contrast-Based Objective Image Quality Assessment

Poredjenje zavisnosti verovatnoće lažnog alarma i faktora skaliranja CA-CFAR i OS-CFAR detektora za različite tipove klatera

Dušan Ristić, Slobodan Simić

***Apstrakt*—U ovom radu je napravljena komparativna analiza CA-CFAR i OS-CFAR detektora. Uporedjivali smo odzive CA-CFAR i OS-CFAR detektora pod identičnim uslovima u različitim tipovima klatera. Pokazali smo koji detektor ima manju verovatnoću lažnog alarma u zavisnosti od vrednosti faktora skaliranja. Poredjenje detektora je prikazano na graficima. Za potrebe ovog rada kreirana je GUI aplikacija u programskom paketu MATLAB.**

***Ključne reči*—CA-CFAR, OS-CFAR, klater, verovatnoća lažnog alarma, faktor skaliranja.**

I. Uvod

Zahvaljujući novim generacijama računara, danas je moguće potvrditi mnoge statističke teorije koje ranije nismo mogli. U radarstvu, radarska okruženja, radarski ciljevi i ostale pojave se mogu opisati različitim statističkim raspodelama. Uz pomoć softverskih paketa koje imamo danas, moguće je opisati različita radarska okruženja. Statističke raspodele koje su razmatrane u ovom radu za opisivanje radarskih okruženja su Rejlijeva, Rajsova, lognormalna i eksponencijalna raspodela. Cilj ovog rada je da u laboratorijskim uslovima i bez eksperimentalnog merenja, pokažemo kako bi se OS-CFAR i CA-CFAR približno ponašali u realnim uslovima i da pored toga utvrdimo zavisnost verovatnoće lažnog alarma i faktora skaliranja za oba detektora. U tu svrhu je kreirana GUI aplikacija u softverskom paketu MATLAB.

II. Teorijski modeli klatera

Klater je neželjeni eho signal koji potiče od svih objekata koji nisu predmet osmatranja radara. Najčešće je to prirodno okruženje koje ometa radar i smanjuje verovatnoću ispravne detekcije cilja. Pod klaterom se podrazumevaju eho signali zemlje, mora, atmosferskih pojava i životinja. Klater je prostorno rasporedjen i veći je u fizičkom smilsu od rezolucione ćelije radara. Objekti koje su napravili ljudi (npr. zgrade) su „tačke“, ili diskretni klaterski odrazi. Veliki klaterski odrazi mogu da maskiraju eho signale ciljeva. Klater može biti površinski i zapreminski. Eho signali zemlje ili mora su primeri površinskog klatera. Eho signal kiše je primer zapreminskog klatera. Amplituda površinski raspodeljenog klatera je proporcionalna površini osvetljenoj radarskim snopom [1]. Za modelovanje radarskog okruženja, koristili smo Rejlijevu, Rajsovu, lognormalnu i eksponencijalnu raspodelu.

Rejlijeva raspodela je bazirana na pretpostavci da se u rezolucionoj ćeliji radara nalazi veliki broj slučajno raspodeljenih uniformnih reflektora koji su medjusobno nezavisni. Funkcija gustine verovatnoće naponske anvelope za Rejlijevu raspodelu klatera je

$$p(v) = 2 * \frac{v}{m_2} * e^{\left[-\frac{v^2}{m_2}\right]} \qquad (1.)$$

gde je m_2 srednja kvadratna vrednost (drugi momenat raspodele) anvelopoe v, a m_1 je srednja vrednost (prvi momenat raspodele). Srednja vrednost Rejlijeve raspodele je proporcionalna standardnoj devijaciji [1]

$$StDev = \sqrt{\frac{4}{\pi} - 1} * \mu = 0.523 * \mu \qquad (2.)$$

gde je μ srednja vrednost Rejlijeve raspodele.

Rejlijev model klatera se primenjuje kada je rezoluciona ćelija velika i sadrži mnogo reflektora, medju kojima nema dominantnih reflektora. Koristi se za opisivanje relativno uniformnog klatera. Medjutim, ova raspodela ne predstavlja dobro klater kada su rezoluciona ćelija i upadni ugao zraka mali. Pod ovim uslovima, postoji veća verovatnoća dostizanja velikih vrednosti klatera nego što je to opisano Rejlijevom raspodelom. Jedna od prvih raspodela koja treba bolje da opiše klater od Rejlijeve raspodele je lognormalna raspodela. Lognormalna raspodela ima veću verovatnoću dostizanja velikih vrednosti od Rejlijeve raspodele (raspodela sa dugim repom, „long tail distribution“). Funkcija gustine verovatnoće lognormalne raspodele je

$$p(P) = \frac{1}{\sqrt{2\pi} s P} e^{\left[-\frac{1}{2s^2}(\ln(\frac{P}{P_m}))^2\right]}, P \geq 0 \qquad (3.)$$

Dušan Ristić – Vojna akademija, Univerzitet odbrane, Veljka Lukića Kurijaka 33, 11000 Beograd, Srbija (e-mail: dusanristic152@gmail.com).

Slobodan Simić – Vojna akademija, Univerzitet odbrane, Veljka Lukića Kurijaka 33, 11000 Beograd, Srbija (e-mail: simasimic01@gmail.com).

gde je s standarda devijacija od ln(P), i Pm medijana vrednosti P. Odnos srednje vrednosti i medijane je $e^{\frac{s^2}{2}}$.

Lognormalnu raspodelu karakterišu dva parametra (standardna devijacija i srednja vrednost), dok Rejlijevu raspodelu karakteriše samo jedan parametar (srednja kvadratna vrednost). Klater lognormalne raspodele je često opisan preko odnosa njegove srednje vrednosti i medijane. Treba očekivati da, zbog dva parametra, funkcija gustine verovatnoće lognormalne raspodele može da da bolje eksperimentalne rezultate od Rejlijeve raspodele [1].

Eksponencijalna funkcija gustine verovatnoće data je formulom

$$f(x) = \begin{cases} \lambda * e^{-\lambda x}, x \geq 0 \\ 0, drugde \end{cases} \quad (4.)$$

gde je λ konstanta [2].

III. Modelovanje CFAR detektora

CFAR (Consat False Alarm Rate) detektor se sastoji od 2*n ćelija koje okružuju ćeliju koja se testira. Svaka ćelija sadrži vrednosti signala iz odgovarajuće rezolucione ćelije i ove vrednosti se pomeraju u desno kada dodju vrednosti signala iz nove rezolucione ćelije. Oko ćelije koja se testira se nalazi 2*m ćelija čuvara koje služe da se izbegnu problemi sa interferencijom prilikom procene šuma. Rastojanje izmedju ćelija odgovara rezolucionoj ćeliji radara [3]. CA-CFAR i OS-CFAR su adaptivni detektori koji, na dva različita načina, prilagodjavaju vrednost praga detekcije u zavisnosti od nivoa klatera u rezolucionoj ćeliji. CA-CFAR (Cell-Averaging Consat False Alarm Rate) to radi usrednjavanjem rezolucionih ćelija pre i posle ćelije koja se testira, dok OS-CFAR (Order Statistic Consat False Alarm Rate) odredjuje vrednost praga sortiranjem vrednosti iz CFAR prozora. Detekcija CA-CFAR detektora je optimalna u slučajevima kada imamo homogeno okruženje i kada referentne ćelije sadrže medjusobno nezavisne i slučajno rasporedjene reflektore. Verzije CA-CFAR detektora (kao što su CAGO-CFAR i CASO-CFAR) su napravljene u ciljlu poboljšanja orginalnog CA-CFAR detektora za prelaze u regionima osmatranja i za situacije u kojima imamo više ciljeva. Ove verzije računaju odvojeno srednje vrednosti ćelija levo i desno od ćelije koja se testira, pa onda od ova dva rezultata biraju manji ili veći za nivo okruženja.

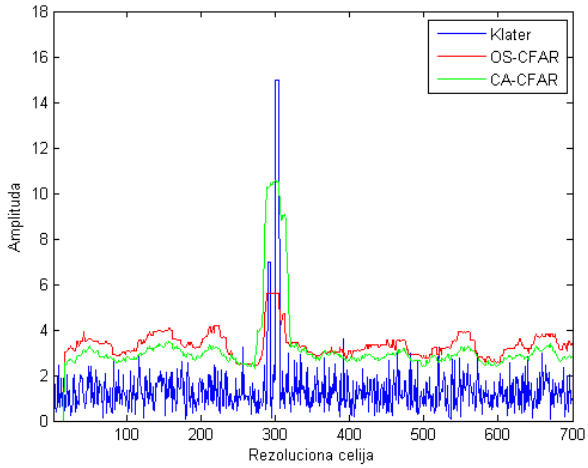
Da bi se unapredila detekcija u ovakvim situacijama, osmišljeni su OS-CFAR detektori. Detektori zasnovani na statistici, OS-CFAR detektori, imaju dobre karakteristike za nehomogena okruženja. Kod ovih detektora se sortiraju svi odbirci u rastućem redosledu, pa se potom bira referentni odbirak na osnovu kojeg se odredjuje nivo interferencije u ćeliji koja se testira. Kao rezultat, OS-CFAR pokazuje mnogo bolje rezultate u okruženju sa više ciljeva i u heterogenom klaterskom okruženju [4].

IV. Eksperimentalni rezultati

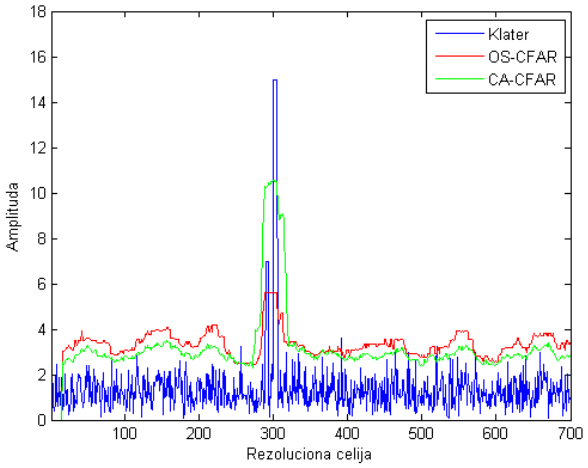
U eksperimentu su generisani odzivi CA-CFAR i OS-CFAR detektora za radarska okruženja modelovana različitim statističkim raspodelama. Odzivi su generisani pod identičnim uslovima. Na osnovu generisanih signala klatera i odziva CFAR detektora, proračunat je broj lažnih alarma za svaki detektor u svim radarskim okruženjima zasebno.

A. Poredjenje zavisnosti verovatnoće lažnog alarma i faktora skaliranja za Rejlijevu i Rajsovu raspodelu

Na graficima koje generiše GUI aplikacija, možemo videti odzive CA-CFAR i OS-CFAR detektora. Već na osnovu samih odziva detektora možemo uočiti da OS-CFAR detektor ima manje detektovanih lažnih alarma od CA-CFAR detektora, pod istim zadatim uslovima. Na slikama 1. i 2. su prikazani odzivi CFAR detektora u okruženjima modelovanim Rejlijevom i Rajsovom raspodelom.



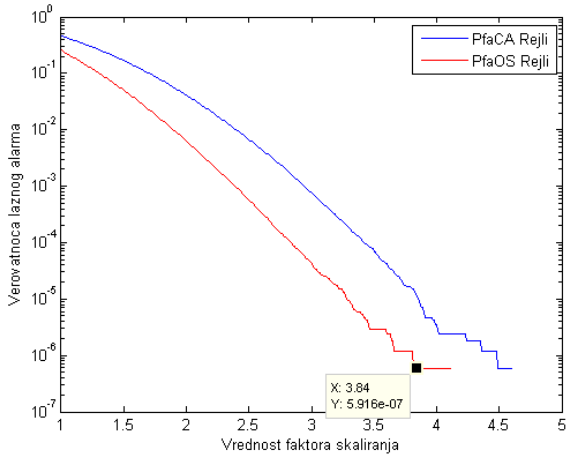
Sl. 1. Odzivi CA-CFAR i OS-CFAR detektora u okruženju modelovanom Rejlijevom raspodelom.



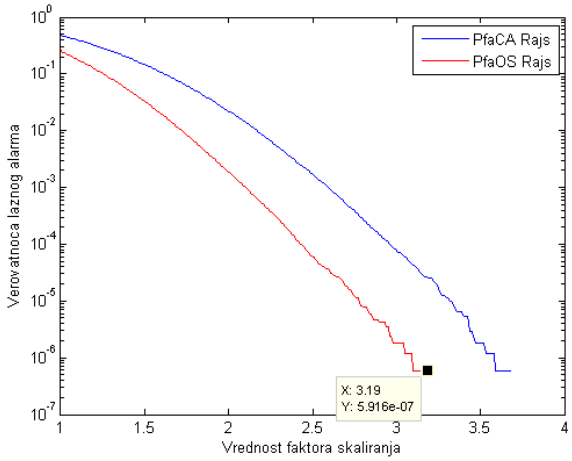
Sl. 2. Odzivi CA-CFAR i OS-CFAR detektora u okruženju modelovanom Rajsovom raspodelom.

Ovu pojavu, smo na osnovu rezultata generisanih u aplikaciji, prikazali na grafiku gde je iscrtana zavisnost

verovatnoće lažnog alarma od faktora skaliranja. Na slikama 3. i 4. su prikazane ove zavisnosti.



Sl. 3. Zavisnost verovatnoće lažnog alarma i faktora skaliranja za Rejlijevu raspodelu.

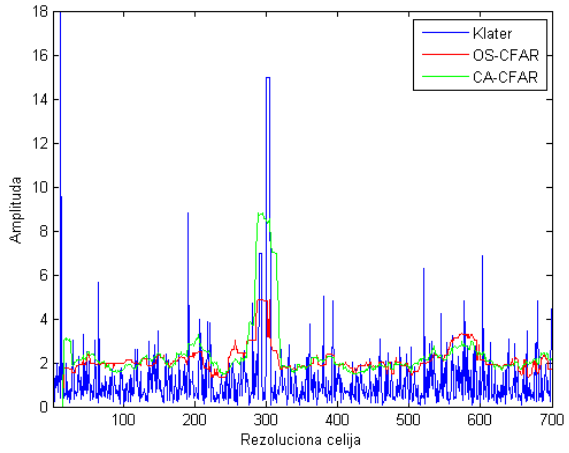


Sl. 4. Zavisnost verovatnoće lažnog alarma i faktora skaliranja za Rajsovu raspodelu.

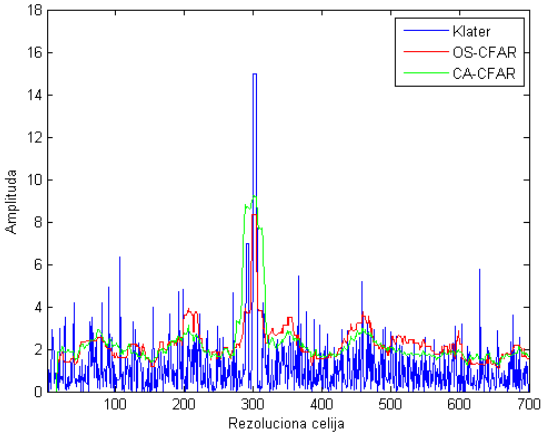
Sa grafika možemo uočiti da OS-CFAR ima mnogo manju verovatnoću lažnog alarma za istu vrednost faktora skaliranja u odnosu na CA-CFAR. Rejlijeva i Rajsova raspodela su zajedno poredjene zato što imaju zajedničku karakteristiku da imaju malo vrednosti klatera koje su približno jednake vrednostima cilja.

B. Poredjenje zavisnosti verovatnoće lažnog alarma i faktora skaliranja za lognormalnu i eksponencijalnu raspodelu

Za razliku od Rejlijeve i Rajsove raspodele, u kojima skoro da nema većih skokova signala klatera, eksponencijalna i lognormalna raspodela generišu veliki broj skokova koji po svojoj amplitudi mogu čak biti i veći od eho signala cilja. Ove raspodele se nazivaju raspodelama sa dugačkim repovima („long tail distributions“) zbog velike verovatnoće pojavljivanja vrednosti koje su znatno veće od srednje vrednosti signala. Posledica ovih raspodela je veliki broj lažnih alarma u odzivima CFAR detektora, koje možemo videti na graficima generisanim u GUI aplikaciji. Odzivi CFAR detektora za lognormalnu i eksponencijalnu raspodelu su prikazani na slikama 5. i 6.

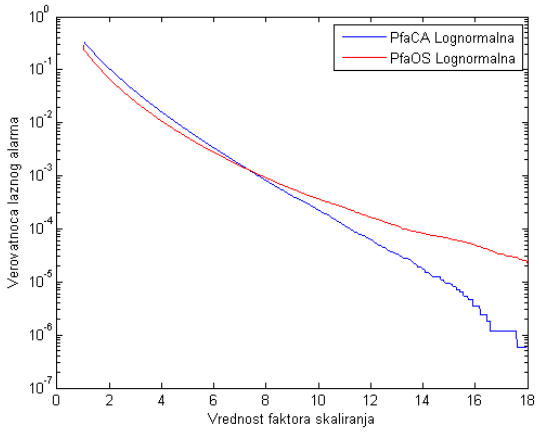


Sl. 5. Odzivi CA-CFAR i OS-CFAR detektora u okruženju modelovanom Lognormalnom raspodelom.

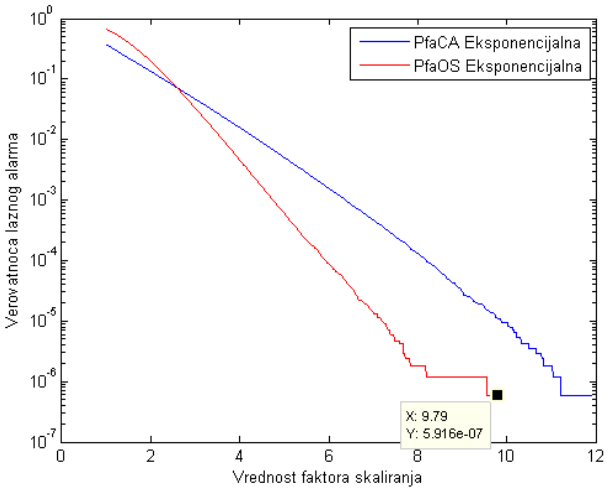


Sl. 6. Odzivi CA-CFAR i OS-CFAR detektora u okruženju modelovanom Eksponencijalnom raspodelom.

Ovu pojavu smo prikazali i na graficima zavisnosti verovatnoće lažnog alarma i faktora skaliranja. Zavisnosti su prikazane na slikama 7. i 8.



Sl. 7. Zavisnost verovatnoće lažnog alarma i faktora skaliranja za Lognormalnu raspodelu.

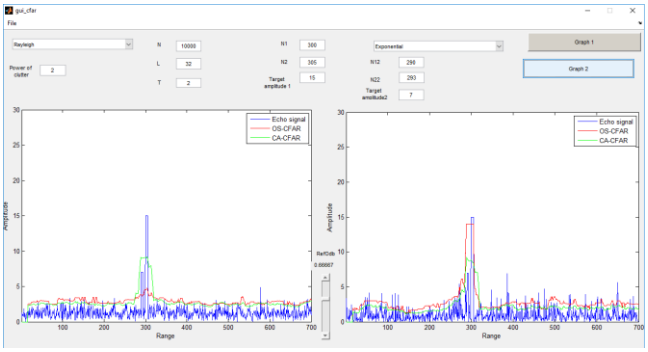


Sl. 8. Zavisnost verovatnoće lažnog alarma i faktora skaliranja za Eksponencijalnu raspodelu.

U Rohlingovom radu [5], data je tabela zavisnosti faktora skaliranja i rednog broja odbirka u odnosu na koji se radi sortiranje. Tabela je napravljena za verovatnoću lažnog alarma od 10^{-6} u okruženju modelovanom eksponencijalnom raspodelom. U skladu sa tom tabelom, možemo zaključiti da je simulacija u ovom radu dala približno isti rezultat za verovatnoću lažnog alarma 10^{-6}.

V. Realizacija eksperimenta

Za potrebe komparativne analize CFAR detektora kreirana je GUI aplikacija u softverskom paketu MATLAB. U aplikaciiji su uporedjivana oba detektora pod identičnim uslovima. Kao ulazne podatke unosili smo snagu klatera (drugi moment raspodele), broj odbiraka sa kojima će aplikacija raditi, dužinu CFAR prozora, faktor skaliranja, redni broj rezolucionih ćelija u kojima se javljaju ciljevi i amplitude eho signala. U padajućim menijima smo birali tip raspodele po kojoj će biti generisano radarsko okruženje. Kao ulazni parametar se unosi i referentni odbirak u odnosu na koji se radi procena nivoa interferncije kod OS-CFAR detektora. Kao izlazne rezultate smo dobili odzive CFAR detektora za odredjeni tip klatera i zavisnost verovatnoće lažnog alarma u odnosu na vrednost faktora skaliranja. Prikaz okruženja GUI aplikacije nalazi se na slici 9.



Sl. 8. Prikaz okruženja u GUI aplikaciji.

Za svaku statističku raspodelu kreirana je zasebna funkcija za generisanje klatera i odziva CFAR detektora. Sve funkcije su na kraju uvezene u glavnu funkciju koja pokreće aplikaciju i generiše grafike. Kodovi ovih funkcija su takodje iskorišćeni za iscrtavanje grafika zavisnosti verovatnoće lažnog alarma i faktora skaliranja.

VI. Pravci daljeg rada

Ovaj rad može poslužiti za dalje ispitivanje uticaja klatera na odzive CFAR detektora. Kao predlog za neka dalja istraživanja može biti ispitivanje uticaja referentnog odbirka i faktora skaliranja na željenu vrednost verovatnoće lažnog alarma. Ovakav rad bi bio sličan poput rada [], s tim što bi u našem slučaju, zbog savremenih softverskih paketa, bilo moguće raditi ispitivanja za sve tipove raspodela. Predlog za dalje unapredjenje rada može biti i dodavanje neke od raspodela koje nisu pomenute u ovom radu.

Abstract

In this paper comparative analysis of CA-CFAR and OS-CFAR has been made. The responses of the detectors CA-CFAR and OS-CFAR with the same parameters were compared in different clutter types. It was shown which detector has less probability of false alarm in the dependence of value of scaling factor. Comparison of detectors was shown on figures. For this paper, the GUI application in the software package MATLAB was created.

Comparison of dependence of probability of false alarm on scaling factor for CA-CFAR and OS-CFAR in differnet types of clutter

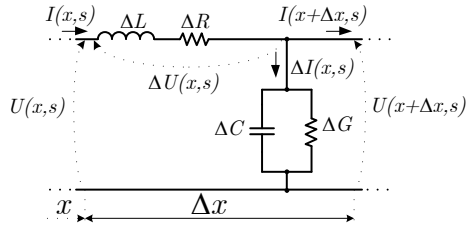
Фреквенцијске карактеристике два тополошка уопштења фракционе једначине телеграфичара

Стеван М. Цветићанин, Душан Зорица, Милан Р. Рапаић

Сажетак—Једначина телеграфичара уопштена је модификацијом Хевисајдовог елементарног кола тако да се узму у обзир мемориски ефекти феномена поларизације и магнетизације медијума, што је постигнуто фракционим калемом и фракционим кондензатором у елеменентарном колу, уместо класичних. Такође, разматрана су и два тополошка уопштења једначине телеграфичара, која су последица додавања кондензатора у редну грану елементарног кола, а чиме је узет у обзир ефекат нагомилавања наелектрисања дуж вода. Урађена је фреквенцијска анализа модула и аргумента функције преноса, добијене из уопштених фракционих једначина телеграфичара које су последица поменутог тополошког уопштења, укључивањем паралелно и редно додатног кондензатора у редну грану елементарног кола вода.

I. Увод

Класична једначина телеграфичара се изводи тако што се електрични вод издели на једнаке секције, а затим се свака секција вода моделира Хевисајдовим елементарним електричним колом приказаним на сл. 1. Овај класичан приступ моделрања вода занемарује



Слика 1. Класична топологија елементарног кола.

одређене физичке феномене, као што су: утицај струја у оточним гранама на стварање магнетског поља, као и акумулацију наелектрисања дуж вода. Такође, класичан модел претпоставља да промене електричног поља тренутно изазову промене у поларизацији диелектрика и да промене магнетског поља тренутно изазову промене у магнетизацији материјала.

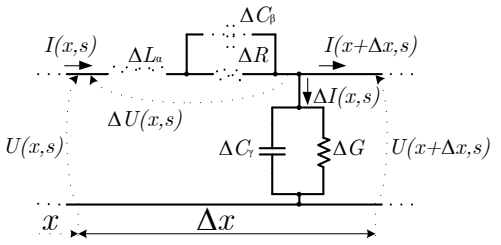
Наведена занемарења су потуно оправдана у великој већини практичних случајева, а поготово када се разматрају веома ниске учесталости, као што је случај код електроенергетских водова. Међутим, у пракси постоје случајеви када класичан модел није адекватан, нпр. THz-line (водови за пренос сигнала учесталости реда терахерца), као и CRLHT-line (composite right/left-handed transmission line) где су се фракциони модели показали много погоднији од класичних модела, види [1]. Наравно, фракциони модели нису једини начин да се опишу фреквенцијске карактеристике феномена на електричним водовима. Нпр. у раду [2] нису коришћени фракциони изводи, а постигнута је веома добра фреквенцијска зависност величина од интереса, и то на учесталостима до неколико GHz.

Моделирање операторима нецелог реда веома је практично за моделирање различитих физичких феномена, па и процеса поларизације и магнетизације материјала, када се жели узети у обзир меморијски ефекат. На пример, конеднзатори и калемови моделирани изводима нецелог реда су разматрани у [3]–[8].

У претходном раду [9] аутори су извели и анализирали уопштену фракциону једначину телеграфичара (1) засновану на паралелном елементарном колу са сл. 2, које представља уопштење класичног елементарног кола, сл. 1.

$$K^2\left(\tau_\alpha\tau_\beta\tau_\gamma\,{}_0\mathrm{D}_t^{\alpha+\beta+\gamma}+\tau_\alpha\tau_\beta\,{}_0\mathrm{D}_t^{\alpha+\beta}+\tau_\alpha\tau_\gamma\,{}_0\mathrm{D}_t^{\alpha+\gamma}+\tau_\alpha\,{}_0\mathrm{D}_t^{\alpha}+\tau_\gamma\,{}_0\mathrm{D}_t^{\gamma}+1\right)u(x,t)=\left(\tau_\beta\,{}_0\mathrm{D}_t^{\beta}+1\right)\frac{\partial^2}{\partial x^2}u(x,t)\,. \quad (1)$$

Уопштење се огледа у томе што је у редну грану

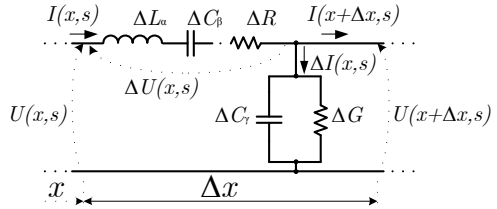


Слика 2. Паралелна топологија елементарног кола.

С. М. Цветићанин (stevan.cveticanin@uns.ac.rs), М. Р. Рапаић (rapaja@uns.ac.rs) – Универзитет у Новом Саду, Факултет техничких наука, Трг Доситеја Обрадовића 6, 21000 Нови Сад, Србија

Д. Зорица (dusan_zorica@mi.sanu.ac.rs) – Математички институт Српске академије наука и уметности, Кнеза Михаила 36, 11001 Београд, Србија – Универзитет у Новом Саду, Природно-математички факултет, Департман за физику, Трг Доситеја Обрадовића 3, 21000 Нови Сад, Србија

додат кондензатор, паралелно отпорнику, чиме је узет у обзир ефекат нагомилавања наелектрисања дуж вода. У (1) оператор ${}_0\mathrm{D}_t^{\xi}$, $\xi \in \mathbb{R}_+$, представља Риман-Лиувилов фракциони извод, за $\alpha, \beta, \gamma \in [0,1]$, где је $K > 0$ статички коефицијент слабљења, а $\tau_\alpha, \tau_\beta, \tau_\gamma > 0$ фракционе временске константе. Фреквенцијском анализом (1), приказаном у [10] и [11], показано је да (1) описује дифузне процесе за $\alpha + \gamma \in (0,1)$, а за $\alpha + \gamma \in (1,2)$, узима у обзир и таласне процесе.



Слика 3. Редна топологија елементарног кола.

$$K^2\left(\tau_\alpha\tau_\beta\tau_\gamma\,{}_0\mathrm{D}_t^{\alpha+\beta+\gamma} + \tau_\alpha\tau_\beta\,{}_0\mathrm{D}_t^{\alpha+\beta} + \tau_\beta\tau_\gamma\,{}_0\mathrm{D}_t^{\beta+\gamma} + \tau_\beta\,{}_0\mathrm{D}_t^{\beta} + \tau_\gamma\,{}_0\mathrm{D}_t^{\gamma} + 1\right)u(x,t) = \tau_\beta\,{}_0\mathrm{D}_t^{\beta}\frac{\partial^2}{\partial x^2}u(x,t)\,. \quad (2)$$

У наставку је разматрана уопштена фракциона једначина телеграфичара (2) заснована на елементарном колу са сл. 3, које је такође добијено додавањем кондензатора у редну грану класичног елементарног кола, сл. 1, али сада редно са калемом и отпорником. Слична тополошка уопштења елементарног кола коришћена су у [12] за моделирање водова за пренос сигнала веома високих учесталости.

Фракциона и тополошка уопштења модела електроенергетског вода у практичним случајевима углавном нису од интереса. Међутим, у неким другим примерима електроенергетике тополошка уопштавања елементарног кола, како би се добио општији и бољи модел, односно уважио већи скуп физичких феномена, и те како се користе, види нпр. [13].

Овај рад је проширење раније објављених радова [9]–[11] у којима је разматран фракциони модел вода (1), док је у овом раду извршена и анализа модела (2), као и поређење модела у фреквенцијском домену.

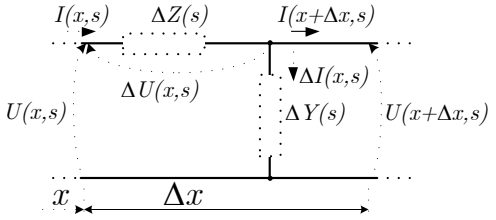
II. Формулација модела

Импедансе фракционог калема и фракционог кондензатора дефинисане су следећим изразима

$$Z_{L_\xi} = s^\xi L_\xi \quad \text{и} \quad Z_{C_\xi} = \frac{1}{s^\xi C_\xi}, \quad (3)$$

који су добијене применом Лапласове трансформације $F(s) = \mathcal{L}[f(t)](s) = \int_0^\infty f(t)\mathrm{e}^{-st}\,\mathrm{d}t$ на њихове конститутивне релације (за нулте почетне услове), користећи Лапласову трансформацију Риман-Лиувиловог фракционог извода $\mathcal{L}\left[{}_0\mathrm{D}_t^{\xi} f(t)\right](s) = s^\xi F(s)$.

Математички модели, односно уопштене фракционе једначине телеграфичара (1) и (2), који одговарају елементарним колима са сл. 2 и 3, могу се извести у комплексном домену (Лапласова трансформација) разматрајући еквивалентну импедансу редне гране ΔZ и еквивалентну адмитансу оточне гране ΔY елементарног кола, види сл. 4.



Слика 4. Елементарно коло у комплексном домену.

Применом Кирхофових закона на елементарно коло са сл. 4 добија се систем једначина

$$U(x+\Delta x,s) - U(x,s) = -\Delta Z(s) I(x,s), \quad (4)$$

$$I(x+\Delta x,s) - I(x,s) = -\Delta Y(s) U(x+\Delta x,s). \quad (5)$$

Преласком на континуум, $\Delta x \to 0$, једначине (4) и (5) прелазе у

$$\frac{\partial U(x,s)}{\partial x} = -Z(s) I(x,s) \text{ и } \frac{\partial I(x,s)}{\partial x} = -Y(s) U(x,s), \quad (6)$$

где је $Z(s) = \lim\limits_{\Delta x \to 0} \frac{\Delta Z(s)}{\Delta x}$ подужна редна импеданса, а $Y(s) = \lim\limits_{\Delta x \to 0} \frac{\Delta Y(s)}{\Delta x}$ подужна оточна адмитанса.

Једначина телеграфичара у комплексном домену

$$\frac{\partial^2 U(x,s)}{\partial x^2} - k^2(s)\, U(x,s) = 0, \quad (7)$$

где је $k(s) = \sqrt{\psi(s)} = \sqrt{Z(s)Y(s)}$ тзв. коефицијент простирања, добија се увршавањем $(6)_1$, претходно диференциране по x, у $(6)_2$.

Када је у питању класична топологија, сл. 1, редна подужна импеданса и оточна подужна адмитанса дефинишу се као

$$Z_k(s) = \lim_{\Delta x \to 0} \frac{\Delta Z_L(s) + \Delta R}{\Delta x} = sL + R \text{ и}$$

$$Y_k(s) = \lim_{\Delta x \to 0} \frac{\Delta Y_C(s) + \Delta G}{\Delta x} = sC + G,$$

где су L, R, C, и G подужни параметри вода: индуктивност, отпорност, капацитивност и проводност. Редна подужна импеданса, у случају паралелне и редне топлогије елементарног кола са сл. 2 и 3, јесу

$$Z_p(s) = \frac{RL_\alpha C_\beta s^{\alpha+\beta} + L_\alpha s^\alpha + R}{RC_\beta s^\beta + 1} \text{ и}$$

$$Z_r(s) = \frac{L_\alpha C_\beta s^{\alpha+\beta} + RC_\beta s^\beta + 1}{C_\beta s^\beta},$$

док је оточна подужна адмитанса иста за обе топологије $Y(s) = C_\gamma s^\gamma + G$. Коефицијенти простирања у случају класичне, паралелне и редне топологије су

$$k_k(s) = K\sqrt{(\tau_L\, s+1)(\tau_C\, s+1)},$$
$$k_p(s) = K\sqrt{\frac{(\tau_\alpha\tau_\beta\, s^{\alpha+\beta} + \tau_\alpha\, s^\alpha + 1)(\tau_\gamma\, s^\gamma + 1)}{\tau_\beta\, s^\beta + 1}}, \quad (8)$$
$$k_r(s) = K\sqrt{\frac{(\tau_\alpha\tau_\beta\, s^{\alpha+\beta} + \tau_\beta\, s^\beta + 1)(\tau_\gamma\, s^\gamma + 1)}{\tau_\beta\, s^\beta}}. \quad (9)$$

Уопштене једначине телеграфичара (1) и (2), које одговарају паралелној и редној топологији, добијене су применом инверзне Лапласове трансформације на (7) користећи одговарајуће коефицијенте простирања k_p и k_r, (8) и (9). Константе које фигуришу у једначинама и коефицијентима простирања дефинисане су као: $K = \sqrt{RG}\,\left[m^{-1}\right]$, $\tau_L = L/R\,[s]$, $\tau_C = C/G\,[s]$, $\tau_\alpha = L_\alpha/R\,[s^\alpha]$, $\tau_\beta = RC_\beta\,\left[s^\beta\right]$ и $\tau_\gamma = C_\gamma/G\,[s^\gamma]$.

Једначине (1) и (2) могу се извести и директно у временском домену, као што је урађено у [9] и [14].

III. Функција преноса и фреквенцијска анализа

Једначинама (1) и (2) моделираће се полубесконачан вод, $x \geq 0$, из чега произлазе одговарајући гранични услови $u\,(0,t) = u_0\,(t)$ и $\lim_{x\to\infty} u\,(x,t) = 0$, односно њихови комплексни ликови $U(0,s) = U_0(s)$ и $\lim_{x\to\infty} U(x,s) \to 0$, где $u_0\,(t)$ представља напон извора на који је вод прикључен.

A. Функција преноса

Опште решење једначине (7) је облика $U(x,s) = A(s)\mathrm{e}^{xk(s)} + B(s)\mathrm{e}^{-xk(s)}$, где се константе A и B одређују из наведених граничних услова. Према томе, израз за функцију преноса (импулсни одзив), која је дефинисана као количник комплексних ликова напона вода на произвољној позицији x и напона извора, јесте

$$W(x,s) = \frac{U(x,s)}{U_0(s)} = \mathrm{e}^{-xk(s)}, \quad (10)$$

где је $k\,(s)$ коефицијент простирања одговарајуће топологије, (8) и (9). Због квадратног корена и поткорених израза у $k\,(s)$, функција преноса, осим $s = 0$, може да има и додатне тачке гранања које одређују тип прелазних процеса на воду. У зависности од вредности параметара модела (α, β, τ_α и τ_β), могућа су три случаја: да нема додатних тачака гранања, тада је одзив апериодичан; да постоји једна реална негативна тачка гранања, тада је одзив критично апериодичан; и да постоји пар конјуговано комплексних тачака гранања са негативним реалним делом, тада је одзив пригушено осцилаторан. За детаље видети [9] и [14].

B. Фреквенцијска анализа

Изрази за фреквенцијске зависности модула и аргумента функције преноса (10)

$$|W\,(x,\omega)|_{\mathrm{dB}} = -20\,x\,\mathrm{Re}\,k\,(\omega)\log\mathrm{e} \quad \text{и} \quad (11)$$
$$\arg W\,(x,\omega) = -x\,\mathrm{Im}\,k\,(\omega)\,, \quad (12)$$

добијени су након смене $s = \mathrm{i}\omega$ у израз за $k\,(s)$, затим раздвајањем његовог реалног и имагинарног дела $k\,(\omega)$, па уврштавањем у (10). Зависност модула и аргумента (11) и (12) функције преноса од позиције дуж вода је линеарна, док је фреквенцијска зависност одређена топологијом елементарног кола преко фреквенцијске зависности реалног и имагинарног дела одговарајућег коефицијената простирања k_p и k_r, односно (8) и (9).

За одређивање реалног и имагинарног дела коефицијента простирања коришћене су следеће математичке релације

$$\mathrm{Re}\,k\,(\omega) = \sqrt{\frac{|k^2(\omega)| + \mathrm{Re}\,k^2\,(\omega)}{2}} \quad \text{и} \quad (13)$$
$$\mathrm{Im}\,k\,(\omega) = \mathrm{sgn}\left(\mathrm{Im}\,k^2(\omega)\right)\sqrt{\frac{|k^2(\omega)| - \mathrm{Re}\,k^2\,(\omega)}{2}}. \quad (14)$$

Фреквенцијске зависности реалног и имагинарног дела коефицијента простирања, према (13) и (14), у случају паралелне топологије су

$$\begin{matrix}\mathrm{Re}\,k_p^2(\omega)\\ \mathrm{Im}\,k_p^2(\omega)\end{matrix} = \frac{K^2}{|\tau_\beta(\mathrm{i}\omega)^\beta + 1|^2}\Big(\tau_\alpha\tau_\beta^2\tau_\gamma\,\omega^{\alpha+2\beta+\gamma}\begin{matrix}\cos\\ \sin\end{matrix}\frac{(\alpha+\gamma)\pi}{2}$$
$$+ \tau_\alpha\tau_\beta^2\,\omega^{\alpha+2\beta}\begin{matrix}\cos\\ \sin\end{matrix}\frac{\alpha\pi}{2}$$
$$+ 2\tau_\alpha\tau_\beta\tau_\gamma\,\omega^{\alpha+\beta+\gamma}\cos\frac{\beta\pi}{2}\begin{matrix}\cos\\ \sin\end{matrix}\frac{(\alpha+\gamma)\pi}{2}$$
$$+ 2\tau_\alpha\tau_\beta\,\omega^{\alpha+\beta}\begin{matrix}\cos\\ \sin\end{matrix}\frac{\alpha\pi}{2}\cos\frac{\beta\pi}{2}$$
$$+ \tau_\alpha\tau_\gamma\,\omega^{\alpha+\gamma}\begin{matrix}\cos\\ \sin\end{matrix}\frac{(\alpha+\gamma)\pi}{2}$$
$$\begin{matrix}+\\ -\end{matrix}\tau_\beta\tau_\gamma\,\omega^{\beta+\gamma}\begin{matrix}\cos\\ \sin\end{matrix}\frac{(\beta-\gamma)\pi}{2} + \tau_\alpha\,\omega^\alpha\begin{matrix}\cos\\ \sin\end{matrix}\frac{\alpha\pi}{2}$$
$$\begin{matrix}+\\ -\end{matrix}\tau_\beta\,\omega^\beta\begin{matrix}\cos\\ \sin\end{matrix}\frac{\beta\pi}{2} + \tau_\gamma\,\omega^\gamma\begin{matrix}\cos\\ \sin\end{matrix}\frac{\gamma\pi}{2} + \begin{matrix}1\\ 0\end{matrix}\Big),$$

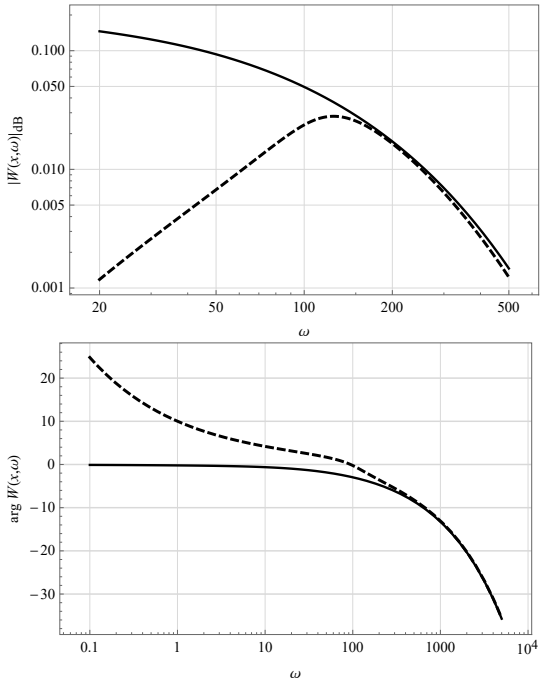
док су у случају редне топологије

$$\begin{matrix}\mathrm{Re}\,k_r^2(\omega)\\ \mathrm{Im}\,k_r^2(\omega)\end{matrix} = K^2\Big(\tau_\alpha\tau_\gamma\,\omega^{\alpha+\gamma}\begin{matrix}\cos\\ \sin\end{matrix}\frac{(\alpha+\gamma)\pi}{2}$$
$$+ \tau_\alpha\,\omega^\alpha\begin{matrix}\cos\\ \sin\end{matrix}\frac{\alpha\pi}{2} + \tau_\gamma\,\omega^\gamma\begin{matrix}\cos\\ \sin\end{matrix}\frac{\gamma\pi}{2} + \begin{matrix}1\\ 0\end{matrix}$$
$$+ \frac{\tau_\gamma}{\tau_\beta}\,\omega^{\gamma-\beta}\begin{matrix}\cos\\ \sin\end{matrix}\frac{(\gamma-\beta)\pi}{2} + \begin{matrix}+\\ -\end{matrix}\frac{1}{\tau_\beta\omega^\beta}\begin{matrix}\cos\\ \sin\end{matrix}\frac{\beta\pi}{2}\Big).$$

За детаљније извођење израза фреквенцијске анализе, два разматрана тополошка уопштења фарккционе једначине телеграфичара, погледати [14], а начелно за фреквенцијску анализу електричних кола [15].

IV. Нумерички примери

Приказане су фреквенцијске карактеристике модула и аргумента функције преноса полубесконачног вода, која произлази из редног и паралелног елементарног кола и њима одговарајућих коефицијената простирања, тј. произлази из једначина (1) и (2) и



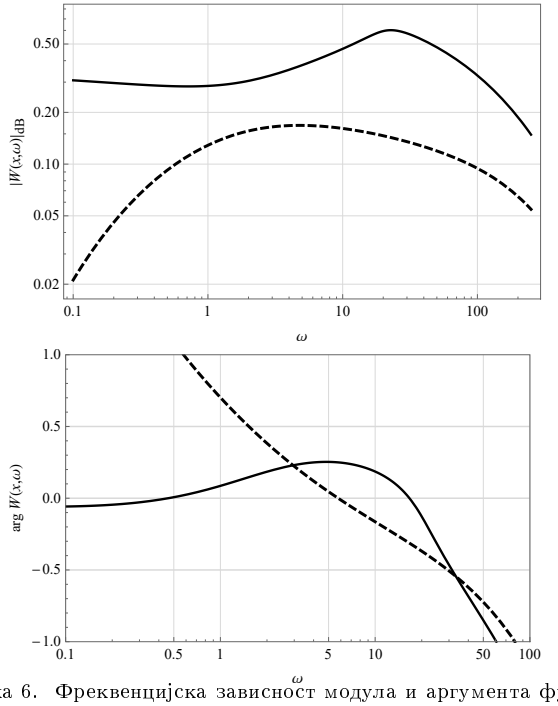
Слика 5. Фреквенцијска зависност модула и аргумента функције преноса, према паралелној (пуна линија) и редној (испрекидана линија) топологији, на позицији $x = 1$, за $K = 1$, $\alpha = 0.9$, $\beta = 0.85$, $\gamma = \frac{1}{3}$, $\tau_\alpha = 0.05$, $\tau_\beta = 0.005$ и $\tau_\gamma = 1$.

граничних услова. Урађено је поређење фреквенцијских карактеристика двеју топологија за идентичне параметре, али различите случајеве броја и позиције тачака гранања коефицијента простирања, сл. 5 - 7.

На сл. 5 приказане су карактеристике када коефицијент простирања паралелне топологије k_p нема тачака гранања, док коефицијент простирања редне топлогије k_r има пар конјуговано комплексних тачака гранања. Сл.6 резервисана је за случај када k_p има пар конјуговано комплексних тачака гранања, док их k_r нема уопште; а на сл. 7 приказане су фреквенцијске карактеристике када коефицијенти простирања обе топологије имају пар конјуговано комплексних тачака гранања.

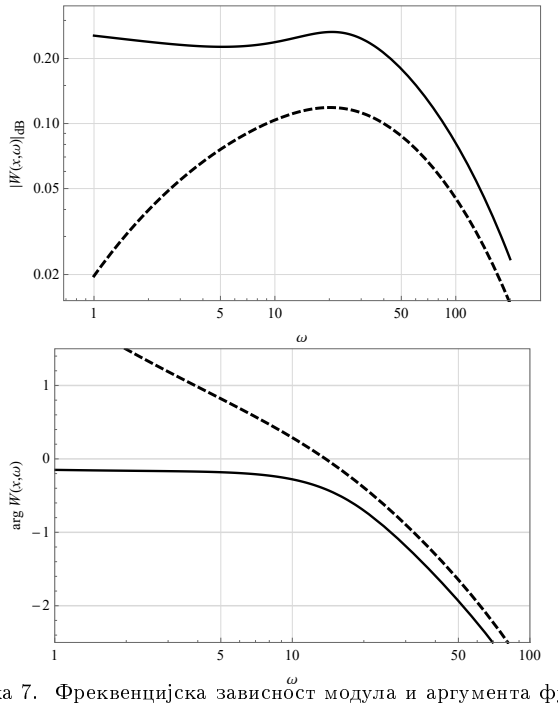
Са сл. 5 - 7 може се уочити да је код паралелне топологије фреквенцијска карактеристика модула монотоно опадајућа (нископропусник) када не постоје тачке гранања, а немонотона са израженим минимумом и максимумом када постоји пар конјуговано комплексних тачака гранања, док се код редне топологије увек јавља само један максимум (пропусник опсега) без обзира на број и природу тачака гранања.

Што се тиче фреквенцијских карактеристика аргумента функције преноса, у случају паралелне топологије она не мора бити немонотона и када постоји пар



Слика 6. Фреквенцијска зависност модула и аргумента функције преноса, према паралелној (пуна линија) и редној (испрекидана линија) топологији, на позицији $x = 1$, за $K = 1$, $\alpha = 0.9$, $\beta = 0.85$, $\gamma = \frac{1}{3}$, $\tau_\alpha = 0.01$, $\tau_\beta = 0.5$ и $\tau_\gamma = 1$.

конјуговано комплексних тачака гранања (упоредити графике са сл. 6 и 7), док је у случају редне топологије фреквенцијска карактеристика аргумента функције преноса мнотоно опадајућа, без обзира на број и позицију тачака гранања коефицијента простирања.



Слика 7. Фреквенцијска зависност модула и аргумента функције преноса, према паралелној (пуна линија) и редној (испрекидана линија) топологији, на позицији $x = 1$, за $K = 1$, $\alpha = 0.9$, $\beta = 0.85$, $\gamma = \frac{1}{3}$, $\tau_\alpha = 0.05$, $\tau_\beta = 0.1$ и $\tau_\gamma = 1$.

V. Закључак

При извођењу уопштених фракционих једначина телеграфичара, као модела електричног вода, коришћен је исти приступ као и при извођењу класичне једначине телеграфичара. Наиме, вод је издељен на сесегменте, а затим је сваки сегмент моделиран паралелним или редним елементарним колом, приказаним на сл. 2 и 3, респективно. Применом Кирхофових закона и преласком на континуум добијене су једначине (1) и (2), као уопштени фракциони модели електричног вода.

Класичне конститутивне релације, односно импедансе, калема и кондензатора замењене су фракционим, чиме је узет у обзир меморијски ефекат при процесу поларизације и магнетизације медијума. Додатним кондензатором у редној грани уважен је и ефекат нагомилавања наелектрисања дуж вода, а како је и тај додатни кондензатор фракциони узета је у обзир и историја ефекта нагомилавања наелектрисања.

Дата је функција преноса за полубесконачан вод (10), која се за паралелну и редну топологију разликује избором одговарајућег коефицијента простирања, (8) и (9), респективно. Урађена је фреквенцијска анализа и дат упоредни приказ модула и аргумента функције преноса за паралелну и редну топологију, као и класификација према броју и природи тачака гранања коефицијената простирања (8) и (9).

Поменути резултат може имати практичну примену при избору одговарајућег модела електричног вода (топологије елементарног кола и/или једначине) за који су познате фреквенцијске карактеристике модула и аргумента.

Abstract

The classical telegrapher's equation is generalized by modification of the Heaviside's elementary circuit such that the memory effects of polarization and magnetization phenomena of the medium are taken into account, which is achieved by using the fractional inductor and the fractional capacitor in the elementary circuit, instead of the classical ones. Also, two topological generalizations of the telegrapher's equation were considered, which are the consequence of the addition fractional capacitor in the serial branch of the elementary circuit, which takes into account the effect and history of charge accumulation along the line. The frequency analysis of the transfer function modulus and the transfer function argument, which is derived from the general telegrapher's equations, i.e. consequences of the above-mentioned topological generalizations of elementary circuit, has been performed.

Frequency Characteristics of two Topological Generalization of the Fractional Telegrapher's Equation

Design Space Exploration in Advanced CMOS Process: IIR filter case study

Dejan Mirkovic, *Member, IEEE* and Milena Stanojlovic Mirkovic

***Abstract*—This paper deals with ever increasing complexity of digital integrated circuits design in advanced CMOS process. Concretely, hardware synthesis of IIR filter in 45nm CMOS process is considered. Filter synthesis procedure, starting form specs all the way to the generation of HDL code, is exemplified though the design of simple, third order, all-pole, selective IIR filter. Two options for standard cells under worst case conditions are examined with the help of custom written tcl scrip for early design space exploration. Obtained results gives valuable information crucial for searching of optimal synthesis solution in target CMOS process.**

***Index Terms*—Integrated circuit; Digital Synthesis; IIR Filters; CMOS process.**

I. Introduction

THERE is no doubt that CMOS technology prevails as the main implementation technology for electronics circuitry. Supersonic progress of CMOS technology in past several decades certainly ensured significant improvement in circuits performance and power consumption meaning more functionality can be implemented in the same area [1]. This inevitably led to increased complexity of the implemented systems especially when digital sub-systems are concerned. SoC (System on Chip) become main-stream concept in the world of integrated circuits (IC) design. Techniques like multiple frequency and supply/threshold voltage are common practice in today's ICs. All this is made possible with introduction of the advanced sub-hundred-micron process nodes. Besides complexity, initial (fixed) costs for the design in advanced process nodes also increases due to more masks per chip and more sophisticated photolithography techniques and testing equipment employed in the manufacturing process. This means that finding the optimal solution early in the design process is crucial. This paper tries to give insight in such process at the hardware synthesis level. Practically, this is the first stage in the digital design flow where, if appropriate models are available, designer can try to search for optimal solution in target CMOS process.

Fortunately, leading CAD/EDA tools vendors, like Cadence, Mentor Graphics and Synopsis, recognized this need and implemented routines for design space exploration (DSE) in their products. This means that digital designer needs to add another skill into his/her toolbox. Unfortunately, even those new routines are available in CAD/EDA tools, they are usually buried in piled documentation. Therefore, authors of this paper tried to do their best to highlighting and explain some of these options available in CAD/EDA tools.

Since tcl is widely adopted as the EDA language in CAD/EDA tools, DSE options are invoked by appropriate commands in conjunction with standard tcl branching statements [2]. For this purpose, custom tcl script is written. Before coping with DSE, synthesizable HDL description of the designed system has to be available. Simple third order, selective, high-pass filter will serve as a case study.

Following section of the paper is dedicated to the brief overview of the IIR filter design. In the third section process of digital synthesis and DSE are explained. Summarized simulation results are presented in the fourth section. Finally, paper concludes with suggestions and thoughts regarding presented DSE mythology.

II. IIR Filter Design

Generally, there are two approaches when synthesizing IIR filters. First approach is the traditional one where filter function is synthesized in analog domain (s domain) and digital filter is obtained by proper transform into discrete domain (z domain) [3]. Second approach is based on direct synthesis in z domain [4]. Here, first approach is adopted.

For analog prototype Least-Square Monotonic (LSM) low-pass filter function is utilized. LSM filter function belongs to the class of the filter functions with Critical Monotonic Amplitude Characteristics (CMAC) developed by Rakovic and Litovski [5]. This class of the filters offers good tradeoff between selectivity, step response and group delay characteristics. Since detailed discussion about CMAC class of filters is beyond the scope of this paper interested reader is advised to dive into [6].

For a sake of example simple high-pass, third order selective filter with f_c=5MHz cutoff frequency is designed. Sampling frequency of f_s=61.44MHz is used targeting Multi-Standard Radio (MSR) application.

Design of the filter is done with the help of the toolbox developed by the author [7]. Toolbox covers filter design flow from specs to the VHDL code generation at Register Transfer Level (RTL) and simulation.

For concrete example, poles of the analog LSM low-pass prototype filter are $s_{p1,2}= -0.4076505822 \pm j0.8728824407$ and

Dejan Mirkovic is with the University of Nis, Faculty of Electronic Engineering, 14 Aleksandra Medvedeva, 18106 Niš, Serbia (e-mail: dejan.d.mirkovic@elfak.ni.ac.rs).

Milena Stanojlovic Mirkovic is with the Innovation Centre of Advanced Technologies Ltd. Niš-Crveni krst, Bulevar Nikole Tesle 61, loc. 5, 18000 Nis, Serbia (e-mail: milena.stanojlovic@icnt.rs).

s_{p3}= −0.7958988354. Poles of the real, translated, high-pass analog filter are easily obtained by scaling with cutoff, angular frequency, ω_c=2π(5MHz). Since high-pass filter is designed, three zeros at zero are present in the *s* domain transfer function of the resulting filter.

Applying the bilinear transform to the *s* domain transfer function, digital counterpart is obtained [4]. To minimize degradation of the filter characteristics due to final world length, transfer function needs to be decomposed as the sum or product of first and/or second order transfer functions. These sub-systems described with first and/or second transfer functions are often called sections (or cells). Decomposing filter function as a product of the sections results with the cascade (serial) realization. For cascode (parallel) realization filter function is decomposed as a sum of sections. Both of them has its own strengths and weaknesses [7]. Here, cascade realization is adopted since it is the most popular one. Final transfer function of the digital filter is given in (1) and corresponding architecture is shown in Fig. 1.

$$H(z)=\frac{c_{0,I}+c_{1,I}z^{-1}}{1+d_{1,I}z^{-1}}\cdot\frac{c_{0,II}+c_{1,II}z^{-1}+c_{2,II}z^{-2}}{1+d_{1,II}z^{-1}+d_{2,II}z^{-2}} \qquad (1)$$

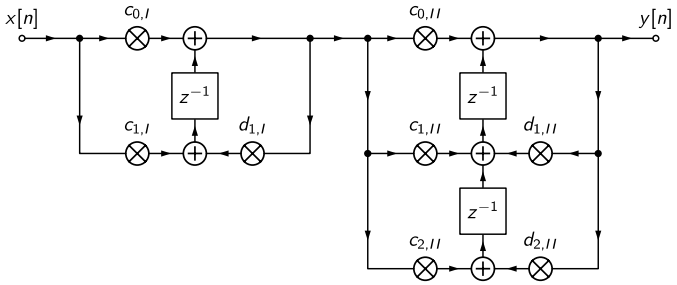

Fig. 1 Architecture of the designed IIR filter.

One can note that Transpose Direct Form II (TDF-II) form is used. Since this form is canonical it is always desirable when hardware realization is intended [3, 4]. Being the third order, filter transfer function is decomposed into cascade of the first and second order sections. Sixteen-bit word length proved to be safe enough in order to preserve good filter characteristics in discrete domain. Filter coefficients are quantized in format Q[16 14], where *W*=16 is the word length and *F*=14 is the number of bits reserved for fractional part. Hexa-decimal representation of the filter coefficients is given in Table I.

TABLE I.A
QUANTIZED NUMERATOR COEFFICIENTS OF THE THIRD-ORDER LSM HIGH-PASS IIR FILTER SECTIONS

Section	Numerator coefficients			Denominator coefficients	
	c_0	c_1	c_2	d_1	d_2
I	33C9	CC37	0000	2A5C	0000
II	33C9	986E	33C9	5EBD	D506

III. DIGITAL SYNTHESIS

After HDL description of the design filter is available, next stage in the design flow is hardware synthesis. Generally, hardware synthesis represents sophisticated optimization process. Therefore, industry standard CAD/EDA tools supported with appropriate technology vendor database must be exploited for this task. These tools provide reliable way of mapping behavioral HDL description of the digital system into gate-level netlist for target CMOS process node. Since this process is similar to the compilation of the software source code, these tools are usually called RTL compilers. There are three main-stream tools for digital synthesis namely Design Compiler (DC), Genus Synthesis Solution (GSS), and Oasys-RTL by Synopsis, Cadence, and Mentor Graphics, respectively. All of them support powerful environment with GUI and tcl script-based design flows. In this work Oasys-RTL tool is used.

A. The Flow

Although from different CAD/EDA tools vendors, RTL compilers share some common stages in the digital synthesis which are illustrated in Fig. 2.

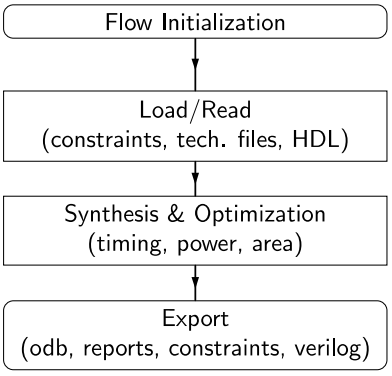

Fig. 2 Simplified flow of digital hardware synthesis process.

In flow initialization stage user's and tool specific variables are defined (e.g. paths to constraints/technology/HDL files). Technology specific information is captured in Liberty Timing (LIB) and Library Exchange Format (LEF) files. These files are prepared and delivered by the technology vendor and digital designer takes them as is. Technology vendor often provides several versions of these files covering important Process Voltage Temperature (PVT) corners of the process as well as various options for standard cells. Traditionally, at least timing constraints in a form of Synopsys Delay Constraints (SDC) file must be assigned [7].

Keeping track of the rate in the development of CMOS technology, RTL compilers now offer early estimate of the power and/or area consumption. This is done by defining desired power consumption intent (power domains) and rough floorplan through files in Common/Unified Power Format (C/UPF) and Design Exchange Format (DEF), respectively. Practically, flow initialization phase is the phase where the

most designer-flow interaction happens. The rest of the flow is almost grossly automated.

Second stage is where the tool specific tcl commands for loading/reading/compiling and/or elaborating previously assigned files.

Digital synthesis & optimization takes place in the third phase of the flow. Generally, synthesis is two stage process. First tool translate (compiles) the behavioral HDL description into structural, gate-level, netlist. Next, gate-level netlist is mapped (linked) to the concrete standard cells available in the target CMOS process. Further, tool automatically invokes a set of analyses with the goal of finding optimal synthesis solution for given timing/power/area constraints. At the end of the synthesis process tool generates new constraints (new SDC, UPF, DEF files) which contain more realistic prediction of circuit performance.

Finally, in the fourth stage synthesized design is exported in one of the standard formats (Verilog, DEF, etc.).

Technology Verilog netlist and constraints obtained in digital synthesis stage further drives the process of digital implementation. In digital implementation stage final, physical, abstraction of the design is generated (GDSII files).

B. Design Space Exploration

Bearing in mind that chip fabrication is very expensive, it is crucial to explore various options for standard cells for target design. In this example Nangate OpneCell 45nm technology with nominal power supply voltage of 1.25V is used [8]. LIB files for three standard cells options are available:

- High Threshold Voltage (HVT), slow but low-power;
- Low Threshold Voltage (LVT), fast but high-power;
- Standard Threshold Voltage (SVT), typical.

All three options are characterized under the wort case conditions i.e. at −40°C with two 0.85V and 0.95V power supply voltages.

Today's CAD/EDA tools support DSE early in the design flow i.e. at the synthesis level. The way of how DSE analysis can be performed is exemplified through the custom written tcl script for Oasys-RTL compiler.

Code of the DSE tcl script is shown in Fig. 3. Design variables are defined from line one to sixteen. It is important to note that default time scale is in ns. Accordingly, each numerical variable related to time units has to be converted into ns (lines two and three).

For the sweep of clock period three options are created namely, *Tclk_m20per*, *Tclk*, *Tclk_p20per* denoting 0%, +20% and −20% variation (lines eight to ten).

Two worst case process options, HVT and LVT, are to be examined. These options are defined as *hvt* an *lvt* (lines eleven to thirteen).

For the voltage variations two cases are considered. These options are defined as *VDD_0p95v* and *VDD_0p85v* representing 0.95V and 0.85V power supply voltage (lines fourteen to sixteen).

Fig. 3 Example of the tcl script used for early design space exploration.

Altogether, tool is setup to perform twelve design synthesis/analysis & optimization runs (three for clock × two for process × two for supply voltages runs).

After initialization of the design (line nineteen), appropriate LIB and LEF files are read into work memory (lines twenty-two to thirty-three). In lines thirty-six to fifty tool is setup to perform multiple optimizations combining low and high threshold/supply voltages. One should note that for each supply voltage option appropriate UPF file has to be prepared (upf95.tcl and upf85.tcl). Design compilation and gate-level synthesis is performed in lines fifty-three and fifty-six after which clock driver is created (line fifty-nine) and tool is setup for exploring defined options for clock period (lines sixty-two to sixty-five).

Optimization process is issued in line sixty-eight. Here, command switch *virtual* is used to relax optimization process. Specifying this option ensures that the optimization process converges by ignoring potential physical level problems that can lead to unsuccessful timing closure. With *virtual* switch tool performs only coarse (virtual) placement of the cells. Ones all timing problems can be fixed with *virtual* option, full optimization can be invoked. In early DSE, where multiple analyses are to be performed, using *virtual* option offers significant time savings. Finally, obtained results of DSE flow are reported (lines sixty-nine to seventy-one). More in-depth explanation of the Oasys-RTL commands can be found in [9].

IV. Simulation Results

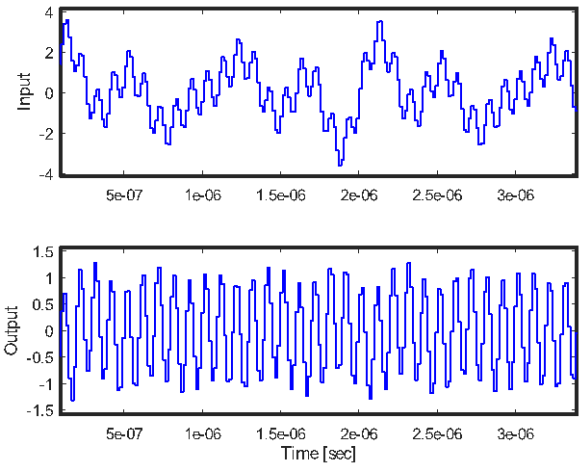
In order to verify HDL description of the designed IIR filter, logic simulation is performed. Filter is excited with composite signal given in (2).

$$x[n] = \sum_{k=0}^{3} \sin\left(2\pi \frac{f_k}{f_s} n\right), \qquad (2)$$

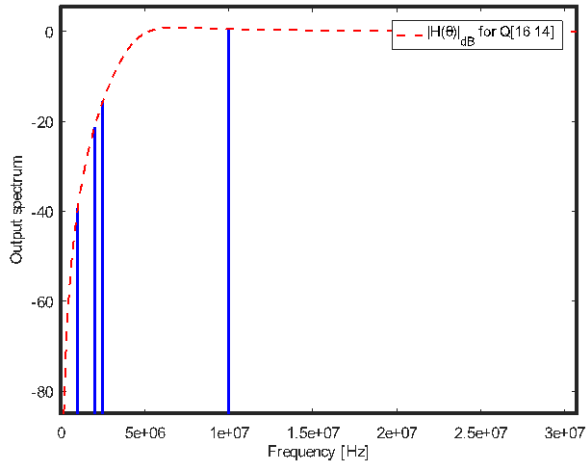
where $f_k \in \{1\text{MHz}, 2\text{MHz}, 2.5\text{MHz}, 10\text{MHz}\}$ and f_s=61.44MHz. These test frequencies are chosen in such a way to easy check filter selectivity. Time response and output spectrum of the filter are shown in Fig. 4. Output spectrum is estimated with 2^{18}-point FFT.

Based on the time response given in Fig. 4a one can clearly see that the high frequency (10MHz) component prevails. Comparing values of the magnitude of the frequency response, output spectrum shown in Fig. 4b, at 1MHz and 2MHz 18dB/oct slope is observed. Similar can be concluded when looking output spectrum at 2.5MHz and 5MHz. This response clearly corresponds to the third-order transfer function which is plotted with dashed line in the output spectrum.

Summarized DSE results are given in Table III. When looking last two columns of the table it can be seen that there is no significant variation in area or number of gates. On the other hand, Worst Negative Slack (WSN) and total power consumption experience significant changes over examined cases. Generally, optimization of WNS parameter is the prime goal in the digital design. This parameter is the most important results of Static Timing Analysis (STA) [10].



a) Time response



b) Output spectrum

Fig. 4 Time response (a) and output spectrum (b) of the RTL model of the third-order, selective, LSM IIR filter.

Practically, its value determines whether design is feasible in target CMOS process under given constraints. WNS is defined as difference between arrival time (AT) and required time (RT).

AT is calculated for each standard cell based on timing information available in LIB files and it represents time needed for the signal to arrive at certain point. RT is the least time delay allowed for the signal which guarantees that clock period will not need to be increased (or equivalently clock frequency lowed).

Therefore, for positive value of the WNS there is enough margin in timing constraints. This means that, not only that the designed circuitry meets timing requirements, but that it can even run at higher clock rate then it was intended. On the other hand, negative value of the WNS indicates that timing requirements are not met and re-design or/and relaxation of the timing constraints is needed.

When the time closure of the design is achieved, one can try to optimize power consumption.

TABLE III
SUMMARIZED DSE RESULTS

Supply voltage [V]	V_t library	Clock period variation [%]	Clock frequency [MHz]	WSN [ns]	Total power [µW]	Area [µm^2]	Number of gates
0.95	hvt	0	62.500	7.6671000	264.531769	3030	1305
		+20	52.083	10.867100	220.446198	3030	1305
		−20	78.125	4.467100	330.659851	3030	1305
	lvt	0	62.500	15.436200	320.37915	3032	1307
		+20	52.083	18.636200	269.296906	3032	1307
		−20	78.125	12.236200	397.002777	3032	1307
0.85	hvt	0	62.500	2.688800	218.100967	3030	1305
		+20	52.0833	5.888800	175.045609	3030	1305
		−20	78.125	0.796200	282.736511	3061	1382
	lvt	0	62.500	12.806600	266.098267	3032	1307
		+20	52.083	16.006599	225.735413	3032	1307
		−20	78.125	9.606600	326.642456	3032	1307

Changes in WNS and total power are illustrated in Fig. 5. Both parameters of interest are scaled with its maximum values in order to produce comparable representation.

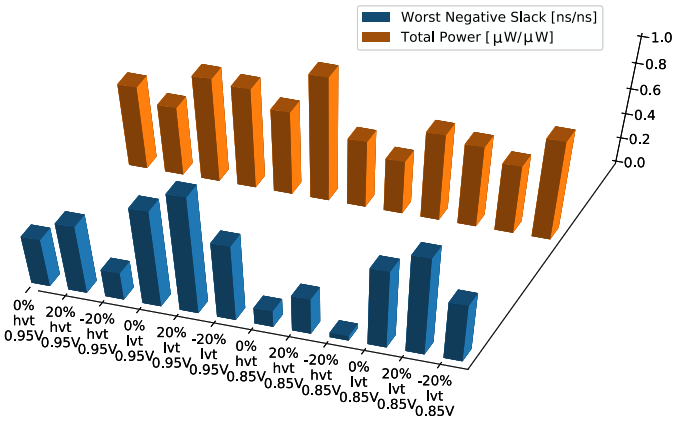


Fig. 5 Comparative graphical representation of DSE results for Worst Negative Slack (WNS) and Total power consumption.

Graphical representation given in Fig. 5 can be used as a guide for tradeoff between WNS and total power consumption. For example, if main goal is WNS maximization regardless of the power consumed case with 20% increase in clock period, 0.95V supply voltage and cells with low threshold voltage should be used. By contrast, if the power consumption is the prime goal then option with −20% reduction of clock period, 0.85V power supply voltage and cells with high threshold voltage can be used.

If the optimal design is sought it can be found with the help of Fig. 6. Since WNS needs to be maximized and total power minimized, ratio of the two will unveil the optimal synthesis solution.

According to Fig. 6, case with 20% increase in clock period, 0.85V power supply voltage and cells with low voltage threshold gives optimal synthesis solution. Of course, here equal weight is assumed for both parameters of interest.

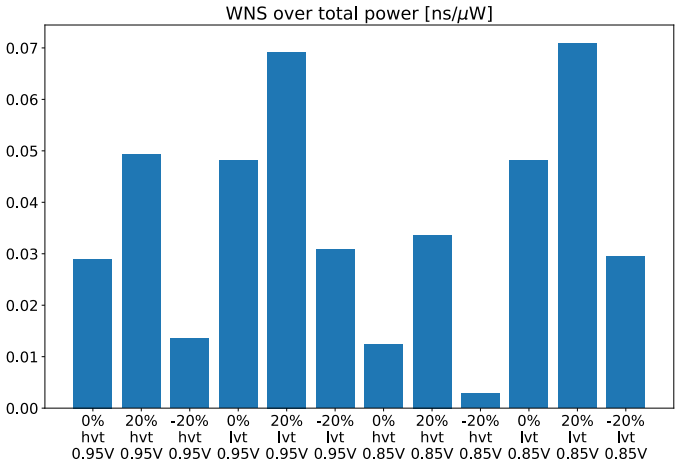

Fig. 6 WNS over total power estimation

Depending on the target application one can favor one parameter over the other. This can be easily done by assigning desired weights to the WSN and total power and recreating plots shown in Fig. 5 and 6 with the data given in Table III.

V. CONCLUSION

The main reasons for early design space exploration in the design of digital ICs targeting advanced CMOS process is explained and elaborated.

Brief overview of the IIR filter synthesis and hardware realization is given.

One example of the design space exploration in advanced 45nm CMOS process is presented. DSE flow is applied to the design of the simple, third-order, selective LSM IIR filter. For performing this task custom tcl script is written. Execution of the script is discussed in detail.

Twelve cases covering two values for power supply voltages, three for the clock period and two options for standard cells are examined.

HDL description of the RTL model of the filter is verified in time and frequency domain.

Based on DSE results important conclusions are drawn regarding optimal synthesis solution.

Obtained results proved that early DSE can give valuable information before coping with more complex implementation stages of the digital ICs design flow. This way, design time can be significantly reduced.

Important feature of this work is that it can be easily extended and modified to suite similar CAD/EDA tools for digital synthesis.

Classification of Nonlinear Loads using Current Spectrum

Marko Dimitrijević, *Member, IEEE*, Miona Andrejević Stošović *Member, IEEE* and Dejan Stevanović

***Abstract*—One of the most prominent characteristics of nonlinear loads is existence of the higher harmonics in current spectrum. They cause losses and disturbance in power grid; thus, the power factor must be generalized to a total or true power factor where the apparent power, involved in its calculations, includes all harmonic components. Nevertheless, harmonic components of the current spectrum can be regarded as specific "signature" of some nonlinear load, therefore providing the means for identifying classes of nonlinear loads connected to the power grid. In this paper, we will present the method for identifying and classification of nonlinear loads using harmonics' amplitudes as inputs for the artificial neural network.**

***Index Terms*— artificial neural network; harmonics; nonlinear loads.**

I. Introduction

Transition to the new millennium also marked transition in our use of electric energy. The significant growth in electronic industry had immense impact on world economy and led to significant changes in our lifestyle. The electronic devices and appliances which contain electronics are everywhere. In addition, growing awareness of global warming influenced automotive industry to change from fossil fuel engines to electric motors. As a consequence, electronic devices take a significantly bigger share in overall power consumption.

Electronic devices are nonlinear loads by nature. They are usually very complex circuits, consisting active semiconductor components that require direct current (DC) for polarisation. However, electricity is delivered to end-users using an alternating current (AC), suitable for the transmission of electricity, which cannot be directly applied to electronic circuits. The means of conversion, AC/DC (power) converters, can be analyzed as two-port networks with reactive and nonlinear impedance seen from the power grid. The characterization of the power converter, and hence the electronic device that contains it, can be performed by determining the current spectrum, i.e. calculating current harmonics.

Marko Dimitrijević is with Faculty of Electronic Engineering, University of Niš, Aleksandra Medvedeva 14, 18000 Niš, Serbia (e-mail: marko.dimitrijevic@elfak.ni.ac.rs).

Dejan Stevanović is with ICNT, Bulevar Nikole Tesle 61, 18000 Niš, Serbia (e-mail: dejan.stevanovic@icnt.rs).

There are many approaches that are used in identifying and monitoring electronic devices (nonlinear loads) connected to the power grid. They are divided into two categories, depending on the means of collecting data: Intrusive Load Monitoring (ILM) and Non-Intrusive Load Monitoring (NILM). ILM methods are implemented with a number of voltage and current probes placed on each monitored device. NILM methods require only one measuring device for the group of devices, for instance entire household. Although ILM methods are more accurate for obvious reasons, NILM methods are commonly used, due to the implementation costs.

In our previous proceedings, we have presented a method for classification of nonlinear loads using artificial neural networks (ANNs), based on active, reactive and distortion power [1,2].

In this paper, we will use amplitudes of current harmonics as inputs for classification of nonlinear loads. The presented method fits into NILM category – we have used one measuring apparatus for various combinations of devices. The method consists of three phases: signal acquisition, current harmonic extraction and device identification/classification using ANNs. The acquisition and harmonic extraction are performed using system for nonlinear load analysis [3,4]. The extracted parameters, i.e. amplitudes of current harmonics are used for ANN training. Finally, the trained ANN is employed for identification of similar nonlinear loads and unknown combinations of loads connected to the power grid.

The paper is organized as follows: in the second section we will present signal acquisition system and algorithms for harmonic analysis, third sections describes ANN topology, training process and obtained results. Fourth section concludes the paper.

II. Data acquisition and harmonic analysis

The signal acquisition is performed using acquisition system consisting of acquisition modules for A/D conversion [5], and computer interface. A/D resolution is 16-bit, with 100 kSa/s sampling rate and ±50 A dynamic range. This system is described in great detail in [4]. Although this system is capable for real-time operation, due to the offline nature of ANN training, this capability is not used. However, the authors are aware that when the ANN training is finished, the trained ANN can be integrated into the system, enabling identification of nonlinear loads in real time.

In the presence of nonlinear loads, the circuit no longer operates in sinusoidal condition and use of circuit's fundamental frequency analysis could not be applied any
